Many species of atomic nuclei (nuclides) also possess magnetic dipole moments. When such nuclides are the nuclei of paramagnetic ions (or even the nuclei of neighboring atoms or ions), the magnetic dipole–dipole interaction between nucleus and electron moments affects the energies of both. This effect is given the name *hyperfine interaction.* The small magnitude of the nuclear moment in comparison to that of the electron ($\sim 10^3$ smaller) means that the electron experiences very weak magnetic fields, on the order of 1 mT, in addition to the applied field H_0. In contrast, the nucleus experiences a strong field (the hyperfine field) due to the strong electron moment, frequently much stronger than any H_0 used in NMR experiments.

In the simplest cases, the hyperfine interaction is isotropic, and perturbation theory shows that the interaction energy is represented by a term aMm_I, where m_I is the z-component angular momentum quantum number of the nuclear spin I, and a is proportional to the product of the nuclear and electron moments and to the electronic spin density at the nucleus. Since there can be a total of $2I+1$ values of m_I, corresponding to the allowed orientations of the spin I in the field H_0, each electronic level characterized by M splits into $2I+1$ closely spaced levels. In the EPR spectrum resulting from transitions in which $\Delta M = \pm 1$, the nuclear orientation, i.e., m_I, remains fixed, so that each line in the spectrum splits into $2I$ components which are referred to as *hyperfine structure* (hfs). The hyperfine interaction often provides direct identification of the atom or locale of the paramagnetic entity. Figures 3, 5, 7, and 11 provide examples of hyperfine structure in EPR spectra.

More generally, the hyperfine interaction contains contributions from both the electron's orbital motion (*dipolar* contribution) with respect to the nucleus while in p or d orbitals, and its direct (*contact*) interaction with the nucleus while in an s orbital. The dipolar part, A, contributes anisotropically whereas the contact interaction, a, contributes only isotropically.

2.5 Resonance Line Shapes and Intensity

In bulk matter (solid or liquid), the magnetic moments interact with the static field $\mathbf{H}_0$, with one another, and also with the random thermal motions of the lattice (all other atoms). Except at very low temperatures, the lattice serves effectively as an infinite thermal reservoir at temperature T since the thermal energy $k_BT \gg \gamma\hbar H_0$ even in moderately strong magnetic fields, where k_B is the Boltzmann constant. In thermal equilibrium, assuming interactions between the moments are also weak, the equilibrium magnetization is proportional to $\mathbf{H}_0$ and is given by the Curie formula for the magnetic susceptibility χ_0,

$$\mathbf{M}_0 = \chi_0 \mathbf{H}_0 = \frac{N\gamma^2\hbar^2 J(J+1)}{3k_B\mathrm{T}} \mathbf{H}_0 \qquad (11)$$

where N is the density of magnetic moments per unit volume.

In the resonance experiment the total applied field is the sum of $\mathbf{H}_0$ and the field $\mathbf{H}_1$ perpendicular to $\mathbf{H}_0$ and oscillating at frequency ω. To describe the behavior of the macroscopic magnetization vector $\mathbf{M}$ in such a field, where $\mathbf{M}$ is the sum of all the individual moments, i.e., $\mathbf{M} = \Sigma_i \boldsymbol{\mu}_i$, the basic torque equation

$$\frac{d\mathbf{M}}{dt} = \gamma \mathbf{M} \times \mathbf{H}, \qquad (12)$$

which describes the precessional and nutational motions of the magnetization $\mathbf{M}$, is added to equations describing the transient damping out of nonequilibrium components of $\mathbf{M}$. Taking $\mathbf{H}_0$ in the z direction,

$$\frac{dM_z}{dt} = -\frac{(M_z - M_0)}{T_1} \qquad (13)$$

defines the longitudinal, or spin–lattice, relaxation time T_1 with which M_z approaches its equilibrium value $M_0 = \chi_0 H_0$. Similarly,

$$\frac{dM_{x,y}}{dt} = -\frac{M_{x,y}}{T_2} \qquad (14)$$

defines the transverse relaxation time T_2 with which M_x and M_y are reduced to their equilibrium value of zero.

Under these assumptions the motion of $\mathbf{M}$ is described by the equations [the *Bloch equations* (Bloch *et al.*, 1946)]

$$\frac{d\mathbf{M}}{dt} = \gamma \mathbf{M} \times \mathbf{H} - \frac{M_x \mathbf{i} + M_y \mathbf{j}}{T_2} + \frac{M_z - M_0}{T_1} \mathbf{k}, \qquad (15)$$

where $\mathbf{H} = \mathbf{H}_0 + \mathbf{H}_1$, and $\mathbf{i}, \mathbf{j}, \mathbf{k}$ are unit vectors in the x, y, z directions in the laboratory coordinate frame.

The steady-state solution of these equations has a component of $\mathbf{M}$ in phase with the applied oscillating field $\mathbf{H}_1$ and a component out of phase with $\mathbf{H}_1$. Conventionally, that part of $\mathbf{M}$ parallel to $\mathbf{H}_1$ is written as a complex quantity $\mathbf{M}_1 = (\chi' - i\chi'')\mathbf{H}_1$. The components of the rf susceptibility $\chi' - i\chi''$ are

$$\chi'=\frac{1}{2}\chi_0\omega_0\frac{\Delta\omega T_2^2}{1+(\Delta\omega)^2T_2^2+(\gamma H_1)^2T_1T_2}, \qquad (16)$$

$$\chi''=\frac{1}{2}\chi_0\omega_0\frac{T_2}{1+(\Delta\omega)^2T_2^2+(\gamma H_1)^2T_1T_2}, \qquad (17)$$

where $\Delta\omega=(\omega_0-\omega)$. These susceptibilities exhibit a resonance character similar to those of the complex impedance of a tuned circuit. When the third term in the denominators becomes significant, both χ' and χ'' decrease in magnitude. This *saturation* term $\gamma^2H_1^2T_1T_2$ is usually made smaller than the other terms in cw experiments by reducing H_1 sufficiently.

For a sample in a resonant microwave cavity, the changes in the cavity quality factor Q and resonance frequency ω in passing from off resonance to on resonance (e.g., by varying the applied field H_0) depend on χ' and χ''. Resonance can be detected by the change in Q or by the shift in the resonant frequency of the circuit. These signals are referred to as the *absorption* and *dispersion modes,* respectively, and it is the absorption-mode (χ'') signal that is ordinarily observed. For this,

$$\Delta Q/Q_0=4\pi f\chi''Q_0, \qquad (18)$$

where Q_0 is the Q of the empty cavity and f (filling factor) represents the ratio of magnetic energy within the sample volume to the total magnetic energy stored in the resonant cavity.

Without saturation, the shape of $\chi''(\omega)$ is *Lorentzian* [after the function $f(x)=a/(1+x^2)$]. The half width at half-maximum intensity (HWHM) is $\Delta\omega_{1/2}=1/T_2$, so that measurement of the linewidth determines T_2. If T_1 is very short, the linewidth is dominated by lifetime broadening (Sec. 1.2), and $T_2=T_1$, so that in such cases measurement of the linewidth determines T_1.

The other commonly encountered line shape is the *Gaussian* function, for which $\chi''(\omega)\propto\exp[-(\Delta\omega T_2)^2/2]$. Such a line shape, which is an envelope of contributions from spins in slightly different magnetic field environments, is *inhomogeneously* broadened. It is frequently possible to *burn a hole* in such a resonance by subjecting a portion of it to strong microwave radiation whose frequency spread is less than the total linewidth, as then only those spins within a narrow range of local fields experience saturation. EPR spectra of color centers provide examples of such resonances (see Sec. 3.3.1.2 and Fig. 11). In contrast, *homogeneous* broadening occurs when the resonance results from a transition between energy levels that are not sharply defined, but are broadened somewhat by the dipolar interaction between moments, or by a short T_1, or by diffusive motion, for example.

3. SOURCES OF EPR SPECTRA: THEIR INTERPRETATION AND APPLICATIONS

EPR signals may arise whenever unpaired electron spins are present. This may happen in solids, liquids, and gases, and may be a natural consequence of the electronic structure of the material or may be induced by a variety of changes and external influences. The following sections illustrate EPR spectra in several categories of materials. The application and utilization of these spectra are described.

3.1 Free Radicals and Triplet States

The analysis and interpretation of the hyperfine structure (hfs) in the spectra of free radicals in solution have yielded some of the most important EPR results. First, the electrons in covalent bonds are strongly constrained to the molecular framework, so that there is a large energy splitting of the orbital levels. The isotropic g factor is always close to g_e, and the g tensor is close to isotropic. Put simply, the hfs reflects directly the unpaired-electron distribution in the radical. The fast random tumbling of a radical in solution averages the dipolar (anisotropic) hyperfine contribution to zero, so that the observed hfs results from the contact interaction with electrons in s orbitals. The isotropic interaction parameter a is directly related to the spin-density distribution of the unpaired electron at nuclei in the radical.

The organic salt $(C_6H_5)_2N{-}NC_6H_2(NO_2)_3$, diphenyl picryl hydrazine, usually known as DPPH, was among the first free radicals studied by EPR. Because of its narrow resonance, $g=2.0036$, close to g_e, and strong signal (<10 μg yields a readily detected signal at 9 GHz), it has been extensively used to provide magnetic field calibration by including a minute crystal in the resonance cavity adjacent to the material under investigation. When DPPH is dissolved in benzene, a well-defined hyperfine pattern appears having a central peak flanked by two subsidiary lines on each side. Since $I=1$ for ^{14}N, the total nuclear spin of the two central N atoms is 2, so that $2\times2+1=5$ orientations of the total nuclear spin can occur. This shows that the unpaired electron wave function is distributed equally over the two *N* atoms.

Free radicals have been extensively used in the form of *spin labels* to study bimolecular structure. In many cases the free radical is the relatively unreactive nitroxide (N–O) group containing an unpaired electron localized on the N, so that the EPR signal shows the characteristic three-line hyperfine pattern due to the spin-1 ^{14}N nucleus. A reactive functional group on the other end of the molecule containing the N–O group enables the spin label to be attached to the molecules or systems under study. Information about the host is derived from the effects of motion and *chemical exchange* (see Sec. 4.3) on the spectrum. The effects of motion are illustrated in Fig. 7 which shows the spectrum of the nitroxide radical $[(CH_3)_3C]_2N–O$ dissolved in ethylene glycol at temperatures ranging from 25 °C in (a) down to −150 °C in (d). At 25 °C the fast random tumbling motion in the nonviscous solvent averages the anisotropic hyperfine contribution to zero, leaving a sharp, symmetric spectrum. With decreasing temperature, the increasing viscosity of the solvent slows down the tumbling motion of the radical, and the spectrum becomes increasingly asymmetric as the anisotropy of the hyperfine interaction begins to contribute. In (d) the solvent has essentially become a glass, so that all orientations of N–O groups contribute to the hyperfine *powder pattern* spectrum.

Both spin labels and naturally occurring free radicals have been extensively used in studies of natural organic matter, including applications to metabolic activity, enzymes, photosynthesis, protein structure, etc. Other applications have included the study of coal and coal derivatives and many other forms of charred materials—even cigarette tar and roasted coffee.

The triplet state of an organic molecule arises from two electrons, $S_1=S_2=1/2$, separated by a distance *r*, which yield a total spin $S=1$. This may occur when one electron from an electron-pair bonding orbital is excited to a higher energy level with its spin aligned parallel to that of the remaining electron. The magnetic dipole–dipole interaction between them is responsible for the fine structure energy parameters *D* and *E* of Eq. (11). Although the interaction is not generally isotropic, both *D* and *E* are proportional to $g^2\beta^2/r^3$. For $S=1$, the zero-field splitting ($H_0=0$) is just *D* in the isotropic case ($E=0$), and the EPR spectrum consists of two lines symmetrically displaced on either side of the nominal resonance position. Their spacing depends on sample orientation *via* Eq. (10).

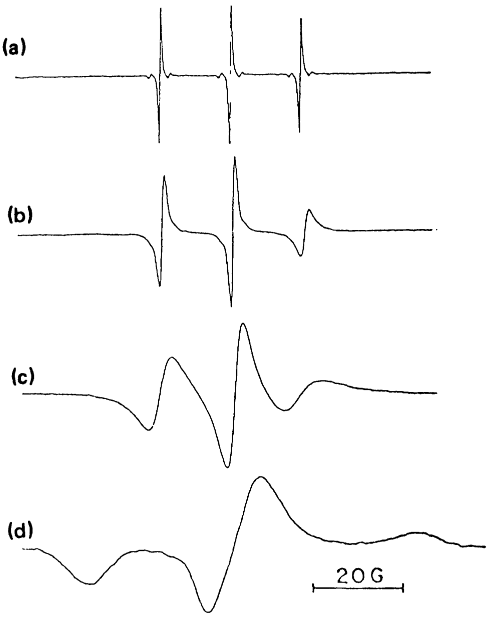

FIG. 7. EPR spectra of the nitroxide free radical $[(CH_3)_3C]_2N–O$ dissolved in ethylene glycol at (a) 25 °C, (b) −25 °C, (c) −80 °C, and (d) −150 °C, showing the progression of the three-line ^{14}N hyperfine pattern from fast fluid motion to a random rigid solid (Griffith and Waggoner, 1969).

As an example, Fig. 8 shows the angular variation of the triplet state spectrum of the naphthalene molecule, $C_{10}H_8$, diluted in a crystal of durene, 1,2,4,5-$(CH_3)_4C_6H_2$ (Hutchison and Mangum, 1961). The triplet state was excited by irradiating the crystal with light from a mercury arc lamp. Two sets of lines appear in Fig. 8 because the durene crystal contains two molecules per unit cell. The spacing between the lines of a pair is as great as 0.2 T (2000 Gauss), a substantial fraction of the nominal resonance field of 0.33 T. Detailed analysis of the spectra yields $g=2.0023$,

$D=3.0$ GHz, and $E=0.41$ GHz. The strong fine structure interaction mixes the $M=0$, ± 1 levels to such a degree that it becomes possible to observe the normally *forbidden*, $\Delta M=\pm 2$, transition between the $M=\pm 1$ levels, which occurs at approximately half the normal resonance field, i.e., at $g \simeq 4$. This *half-field* transition is relatively insensitive to the sample orientation and can be detected in materials containing a random orientation of molecules (see example in Sec. 5.2).

3.2 Transition-Metal Ions

For transition-metal ions, the observed EPR spectrum results from transitions between a few energy levels of the ion which have lower total energies than any others. In many cases, only two levels are involved, and the total number of levels almost never exceeds 8. For the purpose of characterizing such spectra, these ground-state levels may be taken to constitute an isolated set with properties described independently of other levels at higher energies. In so doing, the concept of a fictitious or *effective spin*, S_{eff}, or simply S, is introduced, defined by setting the number of ground state levels (i.e., the multiplicity) equal to $(2S+1)$. If the ground state is a doublet, then $S=1/2$, and the energies of the two levels in an applied field H_0 are $g\beta H_0 M$, with $M=\pm 1/2$. If the ground state is 4-fold degenerate, $S=3/2$, and at least one more parameter is needed to characterize the zero-field splitting. Any hyperfine interaction can also be described as occurring between S and the nuclear spin I.

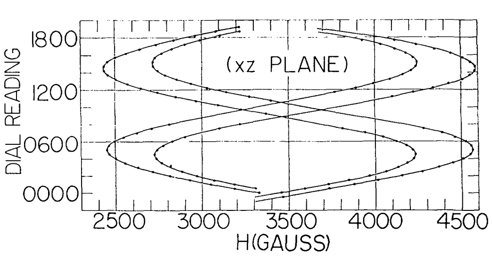

FIG. 8. Angular variation of the EPR spectrum of the excited triplet state of naphthalene molecules in a crystal of durene. Two sets of spectra appear because each unit cell of the crystal contains two molecules. (Note: 1000 divisions on the dial reading = 90°) (Hutchison and Mangum, 1961).

For ions in solids, it is necessary to take account of the effect of the host lattice. For low concentrations ($<0.1\%$) of paramagnetic ions present as impurities or deliberately "doped" into a diamagnetic host crystal, the usual method of estimating the effect the crystal has in modifying the magnetic properties of the ion is the *crystalline electric field* (*CEF*) approximation. The influence of neighboring ions is assumed to occur entirely through the electric field they produce at the site of the magnetic ion. This field exerts forces on the unpaired electrons of the ion and modifies their usual orbital motion. An order-of-magnitude estimate of the energy involved is given by that of two electrons separated by a typical nearest-neighbor distance (~ 2 Å): $e^2/4\pi\epsilon_0 r^2 \simeq 7.2$ eV $\simeq 8.4\times 10^4$ K. This is comparable to electron–electron energies within the ion (2–20 eV), and hence exerts a major influence on ionic properties.

This estimate neglects electrostatic screening of the ion's unpaired electrons if the ion's outer shells are also populated. This is most significant for ions of the rare-earth series in which the unpaired *4f* electrons lie within the closed *5s* and *5p* shells, and reduces the CEF interaction energy to roughly 10^{-2}–10^{-3} eV, which is less than typical spin–orbit interaction ($\lambda\mathbf{L}\cdot\mathbf{S}$) energies and is not comparable with electron–electron interactions. Conversely, the unpaired *3d* electrons in ions of the iron group elements are the outermost electrons, and CEF energies on the order of 5–10 eV occur.

Taking account of these factors, three cases are usually considered:

1. The weak-CEF case applies to the rare-earth and actinide (*5f*) ions in which the spin-orbit interaction dominates so that the ion's magnetic moment is determined by the total angular momentum, $\mathbf{J}=\mathbf{L}+\mathbf{S}$. The g factor is given by the Lande formula appropriate to the free ion,

$$g_L=1+\frac{J(J+1)-L(L+1)+S(S+1)}{2J(J+1)}. \qquad (19)$$

2. The intermediate-CEF case applies to the iron-group ions in which the CEF dominates. The orbital contribution to the moment is "quenched" by the CEF, and the ion's moment is due almost entirely to

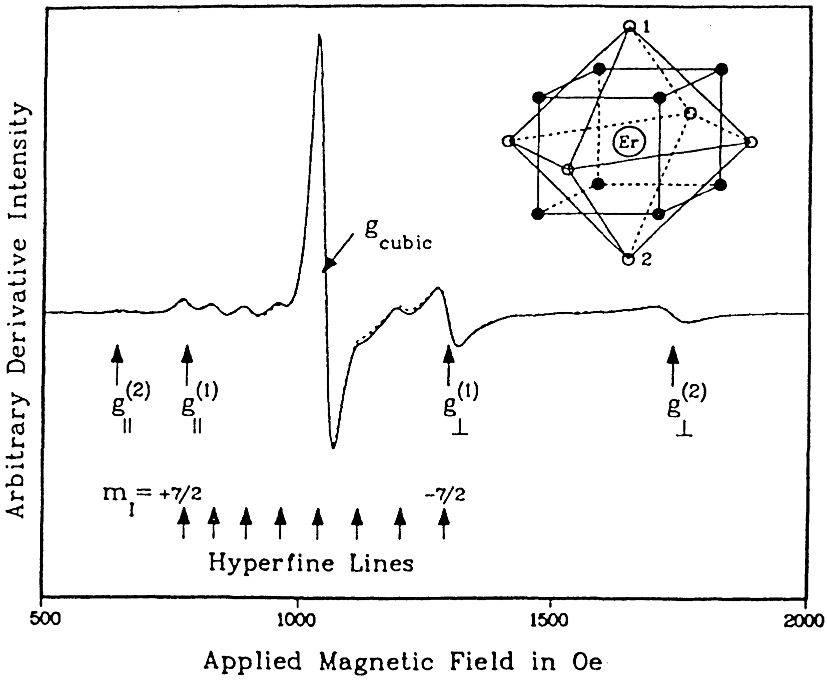

FIG. 9. Experimental (solid) and fitted (dashed) first derivatives of the Er^{3+} EPR in scandium dihydride powder. Positions of the hyperfine lines for the main (cubic site) resonance, as well as of the axial g-tensor resonances ($g_{\parallel}$ and $g_{\perp}$), are shown. The inset shows the tetrahedral (solid circles) and octahedral (open circles) hydrogen sites surrounding Er ions in the face-centered-cubic host lattice (Venturini and Richards, 1979).

electron spin. Consequently, the g factor is close to the free-electron value, and the magnetic properties of the ion in the host lattice bear little resemblance to those of the free ion.

3. The strong-CEF case applies mainly to ions of the platinum- and palladium-group elements which tend to form covalent bonds with neighbor ions.

Ions of the rare-earth element erbium, Er^{3+}, have been used to determine hydrogen site occupancies in metallic hydrides. An example is provided by the study (Venturini and Richards, 1979) of the Er^{3+} EPR in scandium dihydride, ScH_x ($1.85 \leqslant x \leqslant 1.99$), which has the cubic CaF_2 structure with Sc in the Ca positions and H in the F locations. The EPR spectrum of 0.1% Er^{3+}, which substitutes for Sc, at 2 K and 9.8 GHz, is shown in Fig. 9. This is a powder pattern resulting from Er^{3+} ions in three different CEF environments that result from the ionic charges on the adjacent hydrogens. As shown in Fig. 9, the tetrahedral (T) site hydrogens form a simple cube around an Er^{3+} ion. If there are no hydrogens in octahedral (O) sites, the cubic CEF results in an isotropic g tensor for the ground-state doublet, for which the effective spin, $S=1/2$. Since $S=1/2$, there can be no fine structure (Sec. 2.3); however, g-tensor anisotropy and hyperfine interactions can occur.

The strong resonance at ~0.1 T in the spectrum has $g=6.77$, consistent with CEF theoretical expectations and negative charges on the H ions. Weak hyperfine lines surround this resonance. These result from the 23%-abundant ^{167}Er isotope with spin $I=7/2$. The strong unsplit central line results from Er^{3+} ions whose nuclei have spin zero and no magnetic moments($^{162,164,166,168,170}Er$).

The remaining four weak lines in the spectrum are from Er ions in axially symmetric (less than cubic) CEF environments that result from the presence of one or two hydrogens in adjacent O sites, as shown in the inset in Fig. 9. The measured values are $g_{\parallel}^{(1)} = 9.0$, $g_{\perp}^{(1)}=5.42$, corresponding to a single O-site hydrogen on site 1 in the inset, and $g_{\parallel}^{(2)}=11.0$ and $g_{\perp}^{(2)}=4.05$ for 2 hydrogens on sites 1 and 2 in the inset. By measuring the integrated intensities of these lines relative to the isotropic line, the relative probability of having 1 or 2 adjacent O-site hydrogens was determined, and used to evaluate the success of theoretical calculations for site occupancy.

Finally, in this example, the shape of the strong central resonance derivative is not symmetric. This is a consequence of the metallic character of the sample (see Sec. 3.3.2).

3.3 Other Systems

3.3.1 Nonmetallic Solids. The electronic structure of nonmetallic solids (insulators and semiconductors) is characterized in terms of a band structure having a filled valence band (VB) and an empty conduction band (CB), separated from the VB by an energy gap (band gap). The chemical bonding of the valence electrons (density$\simeq 10^{23}$ cm^{-3}) normally assures that their spins are paired according to the Pauli principle, so that such a solid is diamagnetic and gives no EPR spectrum.

However, imperfections such as vacancies, interstitials, and impurities may have localized states and energy levels within the bandgap. Trapping of an unpaired electron in one of these states depends on the position of the Fermi level in the case of semiconductors, and on the availability of electrons (or holes) in the case of insulators. Exposure to light or ionizing radiation, impurity doping, and temperature, for example, may cause existing defects to become paramagnetic. Defects can also arise during crystal growth (see Sec. 2.2 and Fig. 5), ion implantation, and laser annealing (see Sec. 2.4 and Fig. 7), as well as other processes.

3.3.1.1 Amorphous Silicon (a-Si). EPR has been used to study the dominant states in the band gap as well as recombination processes and doping in this technologically important prototypical amorphous semiconductor. The EPR line shape in undoped *a*-Si films is very nearly independent of the conditions under which the film is deposited (evaporation, sputtering, glow discharge, etc.), being an essentially featureless line at $g=2.0055$. The insensitivity to large variations in local defect structures indicates a population of isolated, strongly paramagnetic centers resulting from so-called dangling Si bonds. The line shape has been shown to be the powder spectrum resulting from an assumed Gaussian distribution of g-tensors with $g_{\parallel} \simeq 2.0012$ and $g_{\perp} \simeq 2.0081$. An observed resonance and computer-simulated shapes are compared in Fig. 6 (Biegelson, 1981).

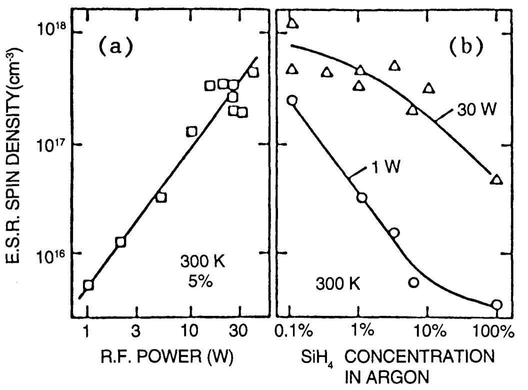

FIG. 10. Dangling-bond spin density in a-Si:H as a function of deposition parameters (a) radiofrequency power level and (b) SiH$_4$ concentration in the argon carrier gas. (Biegelson, 1981).

Although the line shape is independent of deposition conditions, the dangling-bond spin density can vary greatly, from a maximum of $\sim 3 \times 10^{19}$ cm^{-3} to an undetermined low density. Figure 10 shows the dependence of this spin density on two deposition parameters, the radiofrequency power level and the SiH$_4$ (silane) concentration in the argon carrier gas. These graphs (Biegelson, 1981) show that material with the lowest defect concentration is grown in pure SiH$_4$ at the lowest power level. Thus, EPR serves to characterize sample quality and leads to improvements in the deposition process.

3.3.1.2 Radiation-Induced Defects. Among the first defects studied with EPR, *color centers* result from an excess of metal ions in alkali halide (and other) crystals (e.g., NaCl, CaF$_2$, etc.) when heated in alkali metal vapor or when subjected to x-ray, γ-ray, etc., irradiation. The electronic structure of the simplest color center, the *F* center (from the German word for color, *Farbe*), was identified by EPR as that of an electron bound at a negative-ion vacancy. The *F*-center resonance is a Gaussian envelope of the hyperfine lines resulting primarily from interaction with the nuclear magnetic moments of the alkali-metal ions adjacent to the vacancy. The cw absorption derivative record of the *F*-center resonance in an x-rayed LiF crystal (Holton and Slichter, 1960) is shown in Fig. 11. This spec-

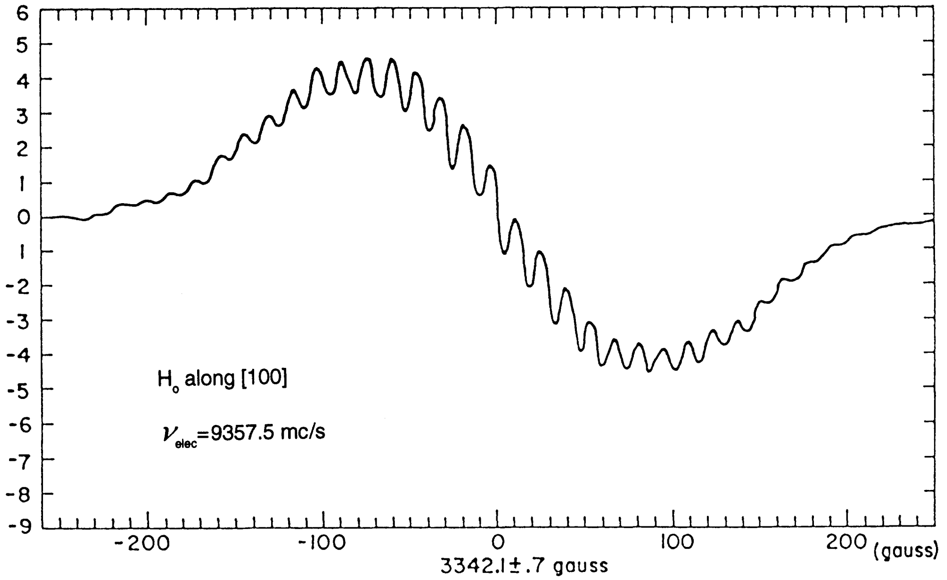

FIG. 11. EPR absorption derivative curve for x-ray irradiated single-crystal LiF at 1.3 K, showing 35 resolved hyperfine lines (Holton and Slichter, 1960).

trum was obtained at $T = 1.3$ K with H_0 parallel to the [100] direction in the crystal. The resonance is centered at $g = 2.0006 \pm 0.0006$, close to the free-electron value, and the width between derivative maxima is ~170 Gauss.

The peaks of 35 resolved hyperfine lines are evident in Fig. 11, whereas the number of hyperfine lines due solely to the six nearest-neighbor ^{7}Li nuclei (spin 3/2) is 19, corresponding to the 19 possible orientations of the total nuclear spin, $6 \times 3/2 = 9$, of the six ^{7}Li nuclei acting together $[2(6 \times 3/2) + 1 = 19]$. This shows that the wave function of the trapped electron extends well-beyond the nearest-neighbor metal ions and interacts with some distant nuclei, both ^{7}Li and ^{19}F, in this case. A detailed ENDOR study (see Sec. 5.1) of this spectrum identified hyperfine interactions from ^{7}Li and ^{19}F nuclei in the first seven neighbor shells around the vacancy. (See Sec. 5.1 and Fig. 14 for an example of *F*-center hyperfine interactions detected by ENDOR.)

A number of other color centers resulting from combinations of *F* centers have also been studied by EPR, the simplest being the *M* center formed by two adjacent *F* centers. A hole in the normally filled p^6 shell of a halogen ion may also be trapped to form a color center. The best-known one is the V_K center, identified by EPR.

3.3.2 Metallic Solids. Metallic solids are characterized by the presence of delocalized electrons (*n* per unit volume) in conduction-band states. At low temperatures, essentially all states below the Fermi energy E_F are filled and those above are empty. With increasing temperature, energy states within a range $\pm k_B T$ of E_F become partially occupied. The net magnetism of these *unpaired* conduction electrons results in the susceptibility of the entire electron gas given by $\chi_P = 3n\beta^2/2E_F$, the *Pauli spin susceptibility* (per unit volume), which is independent of temperature. The EPR signal from the unpaired electrons is readily observed in simple metals such as Li and Na. For most heavier metals the extremely short spin-lattice relaxation time T_1 broadens the resonance beyond detectability. An additional complicating feature of EPR in metallic materials results from the high electrical conductivity which severely attenuates the microwave field within a thin surface region (the *skin depth*), so that extremely small particles are required as samples. If the particles are too large, electrons moving in and out of the skin depth region result in an asymmetric resonance lineshape (see example in Sec. 3.2).

The EPR of magnetic ions (especially rare earths) dissolved in metals (including alloys and intermetallics) yields information about

1. the CEF-split ground state of the impurity ion,
2. the dynamics of the relaxation processes,
3. the sign and form of the coupling between the impurity moments and the conduction electrons (and therefore about the electronic band structure of the host metal), and
4. the onset of magnetic ordering.

The principal measured quantities in such EPR studies are the *g* value for the magnetic ions and the resonance linewidth. Both are usually functions of temperature and ion concentration in the metal. Because the ion moment interacts with the conduction electrons, the *g* value departs somewhat from the free-ion value by an amount Δg, given in first approximation by $\Delta g = JN(E_F)$, where J is the ion moment–conduction electron exchange integral and $N(E_F)$ is the conduction-electron density of states at E_F. EPR is one of the best methods for the measurement and interpretation of J.

4. SPIN RELAXATION PHENOMENA AND APPLICATIONS

As noted in Sec. 1.2, the interaction of spins with their surroundings, the "lattice," maintains the system of magnetic moments (the *spin system*) in thermal equilibrium at a temperature only slightly higher than that of the lattice while subjected to the microwave radiation field. If this did not occur, the resonance would quickly become saturated and cease to be observable. In some systems that have long spin–lattice relaxation times, it is possible to shift the field H_0 suddenly from off resonance to resonance and to observe the signal decay to zero as saturation occurs. In general, information gained from measurements of the relaxation times, T_1 and T_2, relates to the *dynamic* (fluctuating in time) components of the same interactions responsible for the *static* features of the spectrum.

4.1 Spin–Lattice Relaxation

Both steady-state (cw) and pulse methods are used to measure T_1. When the resonance linewidth, ΔH, is dominated by T_1, i.e., lifetime broadening, we have $\Delta H \propto 1/T_1$, and measurement of the temperature dependence of ΔH yields that of T_1. This method is useful for T_1's in the approximate range 10^{-8}–10^{-10} s, since otherwise either the resonance is too broad to detect or ΔH no longer depends on T_1.

In the *progressive saturation* method, the dependence of the absorption signal amplitude χ'' of Eq. (17) and its first derivative, $d\chi''/dH$, on H_1 is monitored. The presence of the saturation term $\gamma^2 H_1^2 T_1 T_2$ in the denominator of Eq. (17) leads to a linear dependence of $d\chi''/dH$ on H_1 (hence on the square root of the microwave power) for small H_1, after which $d\chi''/dH$ passes through a maximum and decreases as H_1 increases. For a homogeneously broadened line, for which T_2 may be determined from the linewidth, T_1 is then determined from the dependence of $d\chi''/dH$ on $\gamma^2 H_1^2 T_1 T_2$.

Pulse methods for measuring T_1 are based on Eq. (13) for the return of M_z to its equilibrium value M_0 following a sudden change. The simplest scheme utilizes a 90°–τ–90°–FID pulse sequence in which the first 90° pulse [see Eq. (7)] reduces M_z to zero. After a delay time τ, the recovered magnetization is given by the amplitude of the FID following the second 90° pulse. By varying τ, the time evolution of the recovery is recorded, determining T_1.

For paramagnetic ions in solids, spin–lattice relaxation (SLR) (see Sec. 1.2) results from fluctuations in the crystalline electric field (CEF) (see Sec. 3.2) that couple electrostatically to the orbital motion of the ion's magnetic electrons. CEF fluctuations are caused by lattice vibrations (phonons) that displace ions from their equilibrium lattice sites (both the magnetic ions and their nonmagnetic neighbors). The component of these fluctuations at the Larmor frequency induces transitions that transfer energy to the lattice. When an energy quantum $\hbar\omega_0$ is transferred to the lattice, a phonon of that energy is created. Finally, lattice vibrations also transfer energy to the sample's surroundings (the *bath*) which may be a cryogenic bath (e.g., liquid helium), a temperature-controlled chamber, or simply the ambient temperature in the laboratory. The rate of energy transfer from lattice to bath must exceed that from spins to lattice. If this is not the case, e.g., when the concentration of paramagnetic ions is too great, a *phonon bottleneck* occurs, and T_1 cannot be reliably determined.

The simplest relaxation mechanism is the *direct*, or *one-phonon* process in which $T_1 \propto 1/T$. This process is most important at temperatures in the liquid helium range (~ 4 K), since then the phonon distribution peaks in the range of microwave frequencies. *Two-phonon* processes become increasingly important at higher temperatures. In one of these, the *Raman* process, a phonon at frequency ω_1 is absorbed while a second at ω_2 is emitted, the difference $(\omega_2 - \omega_1)$ equaling the Larmor frequency ω_0. Although the intrinsic probability for two-phonon interaction is much less than for the direct process, there are a far greater number of ways in which the two phonons can be chosen. The Raman process yields a temperature dependence of the form $T_1 \propto 1/T^9$. The *Orbach* process is a resonant two-phonon process, involving an excited level of the magnetic ion at an energy Δ above the ground state. The temperature dependence has the form $T_1 \propto \exp(\Delta/k_B T) - 1$. This process can dominate the direct process even at low temperatures.

To summarize, the temperature dependence of the relaxation rate $1/T_1$ consists generally of three terms, the direct, Raman, and Orbach processes:

$$\frac{1}{T_1} = AT + BT^9 + C[\exp(\Delta/k_B T) - 1]^{-1}. \quad (20)$$

4.2 Spin–Spin Relaxation

With a pulse spectrometer, the spin–spin relaxation time T_2 may be measured using the *spin-echo* technique. A 90° pulse [Sec. 1.3 and Eq. (7)] tips the magnetization into the xy plane where the slightly different precession frequencies of the individual moments, due to inhomogeneities in H_0, cause them to fan out as time progresses. Application of a 180° pulse after a time interval τ reverses this process, so that the moments become *refocussed* at time 2τ, yielding an *echo* signal. As the individual moments precess in the xy plane, they experience random relaxation processes that prevent their becoming fully refocussed. The longer the time τ, the greater the loss of coherence among the spins, and the weaker the echo. This process can be followed by applying a succession of 180° pulses at equal intervals 2τ after the initial 180° pulse, as shown in Fig. 12. Pulse lengths in typical electron spin-echo (ESE) experiments range from 10 to 100 ns.

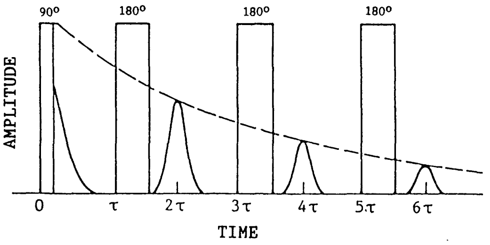

FIG. 12. Spin-echo pulse sequence consisting of an initial 90° pulse followed at equal time intervals by a succession of 180° pulses, each of which yields an echo signal. The envelope of the echo amplitudes (dashed line) decays exponentially with time constant T_2.

4.3 Exchange Interactions

The linewidth ΔH of the EPR signal of solid DPPH (Sec. 3.1) is about 0.2 mT (2 Gauss), although electrons on neighboring radicals are only ~ 6 Å apart and would be expected to give rise to a $\Delta H \propto \beta/r^3 \simeq 10$ mT. Similar reductions in ΔH are also typical of undiluted concentrations of paramagnetic ions in solids. This phenomenon of *exchange narrowing* may be understood in terms of the simultaneous reversal of antiparallel spins on adjacent sites. This corresponds to rapid movement of spins of given orientation through the solid lattice (*spin diffusion*), which averages the dipolar field seen by any specific electron moment to zero. Exchange narrowing results in a nearly Lorentzian line shape, rather than Gaussian, with intensity shifted from the center to the wings of the line.

No energy transfer occurs between spins and lattice, and so exchange narrowing is a T_2 process. Coulomb interactions between the electrons of two neighboring ions are responsible, leading through the Pauli exclusion principle to an effective interaction between spins of the form $-2J_{ij}\mathbf{S}_i \cdot \mathbf{S}_j$, where J_{ij}, the exchange interaction due to electrons on adjacent ions, is inversely proportional to the distance between the electrons.

The width and position of an EPR line are sensitive to *chemical exchange* if the resonance frequency of the unpaired electron changes when the exchange occurs. For free radicals, this may be caused by changes in the g factor, hyperfine splitting, or both. A chemical reaction in which a paramagnetic entity P associates and disassociates with a diamagnetic entity D can be characterized by the mean lifetimes, τ_P and τ_{PD}, of the two species P and PD. The exchanges themselves are assumed to occur instantaneously.

When τ_P and τ_{PD} are very long (slow exchange), the EPR spectrum consists of two lines, for P and for PD, respectively, with intensities proportional to the concentrations of P and PD. As the lifetimes become shorter, the lines acquire an additional broadening, $\Delta\omega$, over their natural widths, due to the exchange. This is a form of lifetime broadening (Sec. 1.2) with $\Delta\omega_P=\tau_P^{-1}$ and $\Delta\omega_{PD}=\tau_{PD}^{-1}$. For free radicals in solution, such linewidth changes may become apparent if $\tau < 10^{-5}$ s. At the other extreme of very short τ values (fast exchange), the unpaired electrons are unable to follow the changes in the local fields, and a single line occurs at the average resonance frequency determined by the average (i.e., population weighted) g factor, with a linewidth determined by the average of the natural linewidths. As the exchange rate slows down, this line is broadened by the changing g value, with the contribution to the width given by

$$(\Delta\omega)_{\text{exch}} \propto (\Delta\omega)^2\tau \tag{21}$$

with

$$\Delta\omega=\omega_P-\omega_{PD}=(\beta H/\hbar)(g_P-g_{PD}), \tag{22}$$

and mean lifetime τ given by

$$\tau^{-1}=\tau_P^{-1}+\tau_{PD}^{-1}. \tag{23}$$

4.4 Chemically Induced Dynamic Electron Polarization

In *chemically induced dynamic electron polarization* (CIDEP), radicals are produced with nonequilibrium spin-state populations, so that the intensity ratios of hyperfine components differ from the normal binomial-type distribution. This can happen when an excited triplet state is produced having a preferential population of certain M levels. Populations may depart so far from the Boltzmann distribution that some EPR lines appear in emission. In a typical CIDEP experiment a short (20 ns–2 μs) pulse of radiation generates free radicals in a sample located in the resonance cavity of an EPR spectrometer, which serves to monitor changes in the dynamic magnetic susceptibility of the sample as a function of time as the radicals are created and destroyed. In *photolytic* experiments the radiation pulse is electromagnetic (e.g., light, x rays, etc.), and in *radiolytic* experiments it is particle radiation (e.g., an electron beam). The resulting polarized transient signals are detected in a time-resolved experiment using a cw EPR spectrometer having a sufficiently fast response time, or by the electron spin-echo technique (ESE) (Sec. 4.3 and Fig. 12) using a pulse spectrometer.

Schematic examples of polarized transients detected in a time-resolved experiment are shown in Fig. 13. The signals decay quickly as the polarized spin system returns to equilibrium in a time that is essentially the spin–lattice relaxation time T_1 followed afterward by the slower decay of the normal absorption signal as the radicals are destroyed by chemical reaction. The polarization factor γ is defined as

$$\gamma=(|S|-|S_0|)/|S_0| \quad \text{for enhanced absorption} \tag{24}$$

and as

$$\gamma=-(|S|+|S_0|)/|S_0| \quad \text{for enhanced emission.} \tag{25}$$

Radicals may be detected with three different polarization patterns: mixed emission–enhanced absorption, pure emission, and pure enhanced absorption.

When using the ESE technique, the 90° pulse of the echo sequence (Fig. 12) occurs after a delay time t_d following a laser light flash which initiates the photolytic reaction. The echo signal following the first 180° pulse can be used to monitor the evolution of the polarization by varying the delay time t_d, keeping the pulse spacing τ constant. This evolution is determined by the rates of creation and decay of the paramagnetic species and the T_1's among the spin sublevels. This measurement determines the preferential routes by which the spin levels are populated as the photoexcited triplet state is formed.

5. ADVANCED TECHNIQUES AND APPLICATIONS

5.1 Electron-Nuclear Double Resonance (ENDOR)

In electron-nuclear double resonance (ENDOR), an EPR transition is driven nearly to saturation by applying a high microwave power level. This condition is monitored while simultaneously exciting another (nuclear) transition with a so-called pumping field. At pump frequencies related to the nuclear hyperfine interaction, the saturation condition will be relaxed and a nuclear resonance detected. In one method, the intensity of an EPR line is monitored while radio-frequency (rf) power is applied to the sample via a small auxiliary coil wrapped around the sample inside the microwave cavity. When the rf matches the separation of a pair of hyperfine levels, it induces a *nuclear* transition, $\Delta m_I = \pm 1$ (M remains unchanged). This tends to equalize the populations of the two hyperfine levels, and restores a population difference between the originally saturated levels, causing an increase in the EPR signal strength. This is an ENDOR signal. As the radiofrequency is scanned, an ENDOR signal appears on each side of the pure nuclear magnetic resonance (NMR) frequency, $\omega_N = \gamma_n H_0$, and the spacing in frequency of the ENDOR signals is exactly the hyperfine interaction frequency a.

Figure 14 shows the ENDOR lines of the nearest ^{19}F neighbor nuclei to an F center in the alkaline earth fluorohalide SrFCl (Spaeth and Koschnick, 1991). The ENDOR signals appear as increases above the noise baseline of the nearly saturated normal EPR line. Crystals such as SrFCl are important as x-ray storage phosphor materials, and have scientific interest because, since both halide vacancies can trap electrons, two different F centers having different local symmetries can be formed in the same crystal. In the example shown, the F center electron is trapped in a Cl$^-$ ion vacancy, and its hyperfine interaction is with the nearest ^{19}F nuclei.

5.2 Optically Detected Magnetic Resonance (ODMR)

A variation in the intensity of light absorbed or emitted by a material while scanning through an EPR absorption indicates that the optical transition involves particular magnetic sublevels. The variation in light intensity can be utilized to detect EPR, and the technique is known as *optically detected magnetic resonance (ODMR)*. For example, this

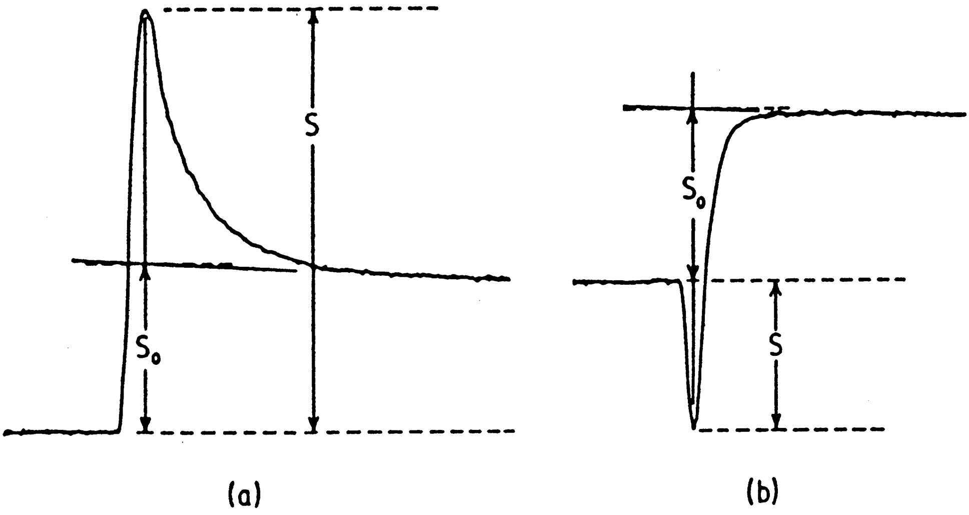

FIG. 13. Schematic (a) enhanced absorption and (b) emission transient CIDEP signals. The signal amplitudes S and S_0 are evaluated at the same point in time, so that the decay curve of the radical is extrapolated back to allow for radical decay.

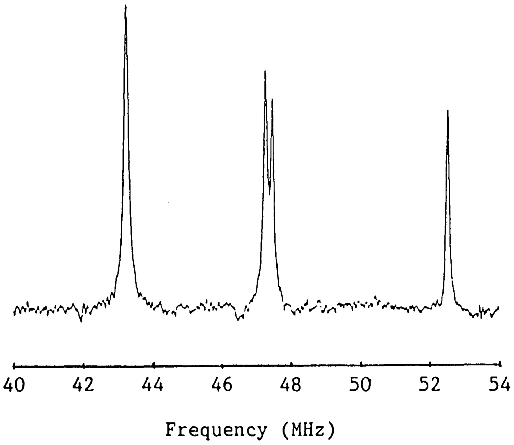

FIG. 14. ENDOR spectrum of nearest ^{19}F neighbors of the F(Cl^{-}) center in SrFCl. The frequency scale is that of the applied radio-frequency radiation, and the signals appear as increases above the noise baseline of the nearly saturated EPR signal (Spaeth and Koschnick, 1991).

may be done by monitoring an optical emission line of the material as the resonance condition is scanned, in which case the experiment yields the spin-Hamiltonian parameters of the excited optical state. Since optical spectroscopic techniques have intrinsically far greater sensitivity than microwave techniques, ODMR can greatly increase sensitivity, so that as few as 10^4 excited state spins may be detected. Optical detection may also be combined with ENDOR, yielding ODENDOR.

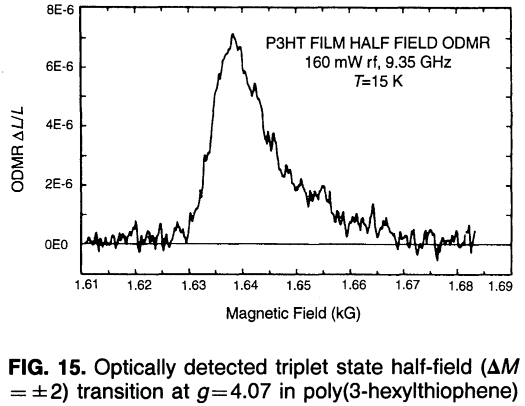

FIG. 15. Optically detected triplet state half-field ($\Delta M = \pm 2$) transition at $g = 4.07$ in poly(3-hexylthiophene) film at 15 K. The signal is detected by the enhanced photoluminescence, $\Delta L/L$, as the resonance condition is traversed by scanning the applied field, H_0 (Swanson *et al.*, 1990).

Shown in Fig. 15 is the $\Delta M = \pm 2$ (half-field) transition (see Sec. 3.2) of the triplet state exciton in the semiconducting polymer, poly(3-hexylthiophene) (P3HT), obtained by ODMR at 15 K (Swanson *et al.*, 1990). These polymers are photoluminescent, emitting light in the red region of the spectrum when illuminated with blue laser light. The resonance was recorded by monitoring the enhanced photoluminescence, $\Delta L/L$, of the sample as the magnetic field was scanned through the resonance condition at $g = 4.07$.

6. SUMMARY

Electron paramagnetic resonance (EPR) is a spectroscopic technique in which transitions between energy levels of weakly coupled electronic magnetic dipole moments in a magnetic field are detected. Such electronic moments occur in solids, liquids, and gases, and may belong to conduction electrons in metals, impurity ions in various hosts, organic free radicals, paramagnetic molecular species, and radiation-induced defects, for example. In typical laboratory magnetic field strengths on the order of a few teslas, these transitions (resonances) occur in the microwave region (5–50 GHz) of the radiofrequency spectrum. Electromagnetic interactions shift and split the simple energy-level scheme expected solely from interaction with the applied magnetic field. These include electron–electron and electron–nuclear interactions, as well as interactions of electronic orbital moments with the local electrostatic potential, each furnishing its own "signature" to the EPR spectrum that contributes to identifying and characterizing the origin and environment of the paramagnetic entity. The dynamic properties of the system of electronic moments are reflected in the rates at which energy is exchanged among the moments and between the moments and the host substance. These rates may also be measured and yield information on the nonstatic components of the interactions listed above. Examples discussed in this review include applications of EPR to the study of free radicals, impurity ions in crystalline solids, color centers, hydrogenated amorphous silicon, hydrogen in metals, and conducting polymers, among others.

GLOSSARY

Absorption Mode: Signal detected in an EPR spectrometer due to absorption of radio-frequency energy by electronic moments at resonance.

Bloch Equations: Phenomenological equations describing motion of magnetization vector in a magnetic field and subject to relaxation processes.

Chemical Exchange: Association and dissociation of paramagnetic and diamagnetic entities in a chemical reaction resulting in changes in the shift and/or width of the resonance.

CIDEP: Acronym for chemically induced dynamic electron polarization, experiments in which free radicals are produced with nonequilibrium spin-state populations.

Color Center: An electron trapped at a vacancy in an alkali halide (or similar) crystal lattice.

Contact Interaction: Magnetic hyperfine interaction of a nuclear dipole moment with the magnetic moment of an electron in an *s*-orbital which penetrates the nucleus.

Crystalline Electric Field: The electric field at a particular site in a solid arising from the electric charges on all surrounding ions.

Dipole–Dipole Interaction: Energy of a magnetic dipole moment in the magnetic field of a second dipole moment.

Dispersion Mode: Signal detected in an EPR spectrometer due to the frequency shift of the resonant circuit element by electronic moments at resonance.

ENDOR: Acronym for Electron-Nuclear DOuble Resonance, an experimental arrangement in which hyperfine structure in an EPR spectrum is detected by inducing a nuclear spin transition while saturating and monitoring the EPR transition.

Exchange Narrowing: Narrowing of the resonance linewidth due to the simultaneous reversal of antiparallel spins on adjacent sites, corresponding to spin diffusion.

Fine Structure: Splitting of an EPR transition into several transitions due to electronic spin–spin or spin–orbit interactions.

Fourier Transform Spectroscopy: Spectroscopy accomplished by Fourier transforming the time-domain response of a system to a short pulse of radiation at the resonance frequency into the frequency domain.

Free-Induction Decay: Signal induced in a resonant circuit element (cavity) by the precessing magnetization of a system of electronic moments following the application of a pulse of resonance radiation that turns the magnetization through an angle of 90°.

***g* Factor:** Ratio of the magnetic dipole moment in units of the Bohr magneton to its associated mechanical angular momentum in units of Planck's constant over 2π.

Half-Field Transition: A normally forbidden transition that occurs between the $+1$ and -1 levels of a spin-1 system, characterized by an effective g value of 4, hence occurring at half the normal resonance field strength.

Homogeneous Broadening: Broadening of an EPR line wherein all parts of the resonance line are strongly coupled to one another so that strong radio-frequency irradiation near the line center saturates the entire line.

Hyperfine Interaction: Mutual interaction energy of an electronic magnetic moment and a nuclear magnetic moment.

Hyperfine Structure: Splitting of an EPR transition into several transitions caused by a hyperfine interaction.

Inhomogeneous Broadening: Broadening of an EPR line that is an envelope of many narrow, unresolved homogeneous component lines, so that strong radio-frequency irradiation saturates only those components at the applied frequency (hole burning).

Larmor Frequency: The frequency at which a magnetic dipole moment precesses in a magnetic field.

Lattice: Term applied to all energies and degrees of freedom of a host material except for those of the system of electronic moments.

Longitudinal Relaxation Time: Characteristic time in which the component of the electronic magnetization parallel to the applied field returns to its thermal equilibrium value following a disturbance.

Magnetogyric Ratio: Ratio of the magnetic dipole moment to its associated mechanical angular momentum.

ODMR: Acronym for Optically Detected Magnetic Resonance, an experimental arrangement in which EPR is detected by changes in optical absorption or emission of the sample.

One-Phonon Process: Spin–lattice relaxation process in which a single energy quantum at the Larmor frequency is transferred from the electronic moment system to a lattice vibration.

Orbach Process: A resonant two-phonon spin-lattice relaxation process involving an excited level of the magnetic ion at an energy splitting above the ground state.

Pauli Spin Susceptibility: Magnetic susceptibility of the conduction electrons in a metal.

Phase-Coherence Time: Characteristic time for two magnetic moments initially precessing in phase with one another to become out of phase.

Phonon Bottleneck: Inability of lattice vibrations (phonons) to transfer energy to the sample's surroundings as fast as they receive it from relaxing electronic moments.

Photolytic CIDEP: CIDEP experiments in which an electromagnetic radiation pulse generates a nonequilibrium spin-state population.

Powder Pattern: EPR spectrum obtained from a polycrystalline (or amorphous) sample in which resonances arise simultaneously from crystallites at all orientations with respect to the applied field.

Precession: Regular rotation of the spin axis of angular momentum at a fixed orientation around the direction of the applied field.

Radiolytic CIDEP: CIDEP experiments in which a particle radiation pulse generates a nonequilibrium spin-state population.

Raman Process: Spin–lattice relaxation process in which a lattice vibration quantum (phonon) of one frequency is absorbed while a second at another frequency is emitted, the difference frequency of the two being equal to the Larmor frequency.

Resonance: Condition when frequency of applied electromagnetic radiation matches the natural (Larmor) precession of the magnetic dipole moment.

Saturation: Condition that results when the populations of two energy levels between which a transition occurs become equalized so that no further net absorption or emission of energy can occur.

Skin Depth: Characteristic distance in which an electromagnetic wave in a metal is attenuated to $1/e$ of its incident intensity.

Spin Diffusion: Spatial diffusion of spin orientation resulting from spin flips of adjacent spins caused by their mutual dipole–dipole interaction.

Spin-Echo: EPR signal that results when precessing spins (moments) are refocussed following a particular sequence of radiofrequency pulses.

Spin Hamiltonian: Quantum-mechanical energy operator constructed from spin operators, yielding an energy level scheme that accounts for an observed EPR spectrum.

Spin Label: Chemical group containing an unpaired electron spin that can be attached to other groups or molecules.

Spin–Lattice Relaxation: Restoration of thermal equilibrium populations of spin levels caused by exchange of energy between spins (moments) and host structure (lattice) following a disturbance.

Spin–Spin Relaxation: Restoration of thermal equilibrium values of the transverse (perpendicular to applied field) components of the magnetization following a disturbance.

Steady-State Spectroscopy: Detection of EPR transitions by methods involving negligible disturbance of equilibrium energy level populations.

Zero-Field Splitting: Any splitting of electronic moment energy levels arising from interactions that are independent of the applied magnetic field strength, e.g., crystalline electric field interactions or dipole–dipole interactions.

8.1
Introduction

The experimental study of electron–atom and electron–molecule collisions dates back to the beginning of the 20th century Lenard (1903). Later in 1914, Nobel prize winners Franck and Hertz (1914) demonstrated the energy loss of electrons scattered from mercury vapor. Theoretically, electron scattering by atoms and molecules has attracted considerable attention since the earliest days of quantum mechanics, because such processes provide a means of investigating the dynamics of many-particle systems at a fundamental level. In addition, a detailed understanding of these processes is required in many other fields, particularly in astrophysics, plasma physics, laser physics, electrical discharges, ionospheric processes in planetary atmospheres, isotope separation, and radiation chemistry and physics.

In recent years, a number of important advances have been made both on the experimental and on the theoretical side. On the experimental side, these include absolute measurements of cross sections, experiments using coincidence techniques, spin-polarized projectile beams and targets, high-energy-resolution electron beams, and bright beams of positrons. On the theoretical side, many new developments have been stimulated by the increasing availability of powerful computers that allow for detailed calculations to be carried out for complex atoms, ions, and molecules.

This review is an update to the article by Burke and Crowe (1993). As previously, we first describe recent experimental work in Section 8.2, which is followed by the theory of electron scattering by atoms, ions, and molecules in Section 8.3. We further compare theoretical predictions with recent experimental data for a few representative cases. Within the page limit of this article, we can mention only a small fraction of the ongoing work in this field. Interested readers are referred to journals such as The Physical Review A or Journal of Physics B, which contain extensive sections on electron collisions, as well as to the Proceedings and Book of Abstracts of the biannual “International Conference on Photonic, Electronic, and Atomic Collisions” (ICPEAC). Finally, in Section 8.4, we draw some conclusions and mention the areas where future work is needed.

8.2
Review of Experimental Methods

8.2.1
The Electron Spectrometer

The basic workhorse of a large number of electron scattering studies is the electron spectrometer. In principle, free electrons can be formed into a beam and their energy selected using various combinations of electrostatic and magnetic fields. In practice, the use of electrostatic fields is more common, these being more easily controlled and shielded than their magnetic counterparts. This is particularly important where it is essential to preserve the direction of low-energy electrons following the collision process.

We show in Figure 8.1 a recent example of a spectrometer that combines the characteristics of a conventional electrostatic device with a recent innovation Allan (2004). Basically, the electron gun consists of a source of electrons produced by thermionic emission from a heated filament. The electrons are collimated and focused by an electrostatic lens system onto the input aperture of a double hemispherical energy selector. Those electrons within a narrow band of energies satisfying the criteria for transmission through the selector are then focused on the gas beam produced by a nozzle arrangement. Scattered electrons from the interaction region traveling in the direction of the scattered electron analyzer are similarly focused onto the input aperture of its double hemispherical analyzer, the transmitted electrons being focused onto a single-channel electron multiplier detector.

One drawback of conventional electron spectrometers is that the angular range of the electron analyzer is limited by the physical presence of other components of the spectrometer. This was overcome by Read and Channing (1996) who applied a localized static magnetic field to the interaction region of a conventional spectrometer. The incident electron beam and the scattered electrons are respectively steered to and from the interaction region through angles set by the field (hence the common name "magnetic angle changer" ("MAC")). This steering means that electrons normally scattered into inaccessible scattering angles are rotated into the accessible angular range of the electron analyzer while the magnetic field design is such that it leaves the angular distribution of the electrons undistorted. The spectrometer shown in Figure 8.1 has a MAC fitted, thereby enabling the full angular range $0^\circ - 180^\circ$ to be accessed.

Another important development in the study of small and/or multidifferential cross sections is the increasing use of multidetection methods, usually in conjunction with toroidal analyzers. These enable simultaneous detection of scattering over a wide range of angles. Recent examples are the spectrometers of Catoire *et al.* (2007) and of Lower *et al.* (2007).

Perhaps the most novel and exciting recent experimental development in electron–atom/molecule scattering is the reaction microscope described by Ullrich *et al.* (2003). In contrast to conventional electron spectrometers, it uses recoil ion and electron momentum spectroscopy to measure the vector momenta of outgoing charged particles over large (close to 4π) solid angles.

These recent experimental innovations have been applied in studies of

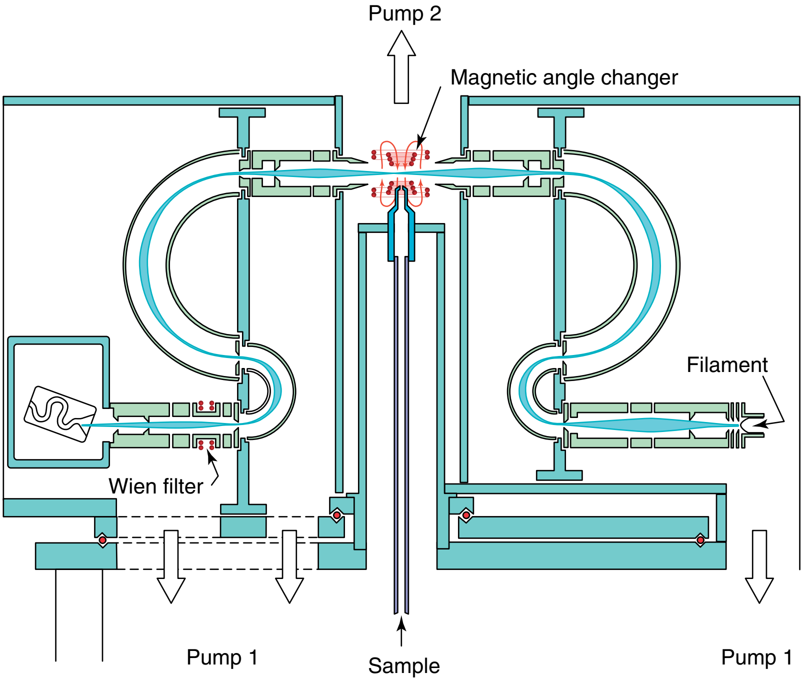

Fig. 8.1 The electron spectrometer of Allan (2004).

ionization and are discussed further in Section 8.2.4.3.

8.2.2
Elastic Scattering

Elastic scattering is characterized by the absence of energy transfer from the incident electron to the internal energy of the atom.

8.2.2.1 Differential Cross Sections

Differential elastic scattering studies are normally carried out using an electron spectrometer broadly similar to that shown in Figure 8.1. The electron analyzer is tuned to transmit only the electrons having an energy equal to the incident electron energy. Relative angular differential cross sections are determined by observation of the scattered electron signal, as the electron analyzer is rotated about the reaction region. The elastic scattering differential cross section $d\sigma\ (E,\theta)/d\Omega$ can be written as

$$\frac{d\sigma}{d\Omega}(E,\theta) = \frac{dN_S(E,\theta)}{N_i\, n\, l\, d\Omega} \qquad (8.1)$$

where $dN_S(E,\theta)$ is the number of electrons with energy E per unit time scattered into a solid angle $d\Omega$ at a scattering angle θ with respect to the incident electron beam direction, and N_i is the number of electrons per unit time incident on the target gas of number density n in a scattering cell of length l.

Various techniques have been used to place the relative cross sections on an absolute cross-section scale. The most direct method of making the cross section absolute is to measure all of the quantities on the right-hand side of Eq. (8.1). However, this is rarely done owing to the extreme difficulties in measuring both these quantities and the various efficiencies involved.

In recent years, the relative flow technique has been the most widely used method for placing measured relative cross sections on an absolute scale. The unknown cross sections are determined by comparing the measured electron scattering intensities against those of another species with known cross sections under identical experimental conditions. Details of the technique are given by Brunger and Buckman (2002) while the most recent developments are described by Khakoo *et al.* (2007).

Helium elastic scattering cross sections are the most commonly used standards. They have been accurately measured and put on an absolute cross-section scale using a phase shift analysis; see, for example, Andrick (1973). The measured values are accurately reproduced by the convergent close-coupling (CCC) theory of Fursa and Bray (1997) and the *R*-matrix with pseudostates (RMPS) method of Bartschat *et al.* (1996a). For energies up to 19 eV, that is, below the first excitation threshold, accurate variational calculations for the s-wave and p-wave phaseshifts were already performed 30 years ago by Nesbet (1979).

In Figure 8.2, we show the elastic differential scattering cross section for xenon at an electron energy of 30 eV. One of the two experiments reported by Cho *et al.* (2006) uses a MAC to cover the full range of scattering angles and the relative flow method has been used to put the data on an absolute cross-section scale. Their theories show

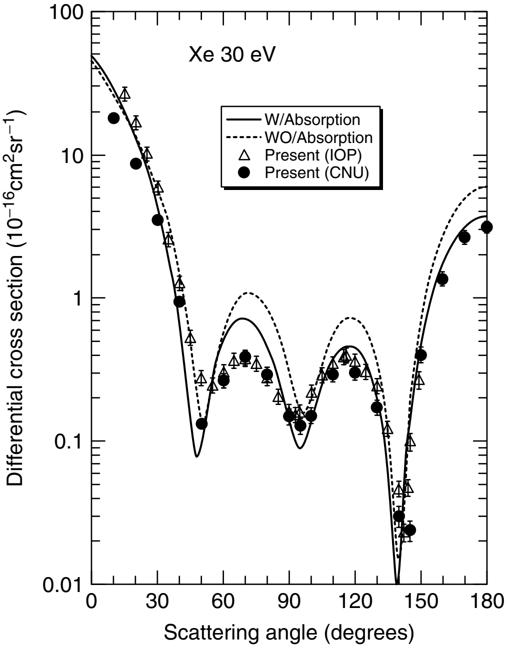

Fig. 8.2 The absolute differential elastic scattering cross section for xenon at an incident electron energy of 30 eV. (From Cho *et al.* (2006).)

the importance of including absorption effects in the theoretical description.

8.2.3
Excitation of Discrete States

The excitation process for an atomic target can be written as

$$e^-(E_i) + A_i \longrightarrow e^-(E_j) + A_j \qquad (8.2)$$

where, in atomic units, $E_i = \frac{1}{2}k_i^2$ is the incident electron energy while $E_j = \frac{1}{2}k_j^2$ is the scattered electron energy; k_i and k_j are the respective wave numbers. (In this and later equations, we use atomic units, $\hbar = m = e = 1$, where m is the mass of the electron and $-e$ is its charge.)

8.2.3.1 **Differential Cross Sections**

The scattered electron studies are conducted as for elastic scattering, except that the electron analyzer is tuned to accept electrons with energy E_j. Angular differential cross sections can then be measured for a particular excited state. An example of an angular differential cross section is shown in Figure 8.6 for the 2^1P state of helium.

For spectroscopic studies, the measurement of energy-loss spectra, where the energy of the detected electrons is varied for a fixed incident electron energy or alternatively the detected electron energy is fixed for a varying incident electron energy, is a useful technique. Electron spectroscopy is particularly valuable for the study of optically forbidden transitions.

8.2.3.2 **Integral Cross Sections**

When the excited atom is metastable, information on the excitation process can be obtained in a relatively straightforward way by making use of the fact that it can eject an electron from a surface whose work function is less than the internal energy of the atom. Time-of-flight (TOF) techniques are normally used to isolate the neutral-atom signal from that due to photons. The method has the advantage that the energy resolution of the measurements is determined by the incident electron beam resolution only. Hence, it has been used as a convenient method for the study of resonance features contributing to the excitation process, see Section 8.3.1.4, Figure 8.21. It has the disadvantage that it is difficult to isolate individual metastable states that are excited. The TOF technique can also be used to determine the energy distributions of metastable fragment atoms from molecular dissociation.

The traditional method of studying short-lived excited states is to monitor the photon intensity arising from the optical decay of the excited state as a function of the incident electron energy, giving the so-called "excitation function" of the state. Here individual states, particularly those radiating in the visible region of the spectrum, can often be readily isolated using high-resolution optical spectrometers. However, even for simple atoms, there is great difficulty relating the measured excitation function to the cross section for excitation of the state because of, often unknown, cascade contributions from higher excited states, inherent and instrumental polarization effects, or trapping of the emitted radiation prior to reaching the detector, in addition to the usual difficulties of making cross sections absolute. Again, many studies have concentrated on resonance features in the excitation functions; see, for example, the recent work of Stepanovic *et al.* (2006) in Figure 8.20 of Section 8.3.1.4. For a review of optical excitation functions for electron–atom and electron–ion excitation, see Heddle and Gallagher (1989).

Another way of measuring total cross sections takes advantage of the rapidly developing trap technology in atomic physics. In this technique, a laser is used to trap the atoms of interest, and absolute cross sections can be obtained directly from the trap loss when the laser is switched off. Examples of such measurements are the work of Schappe *et al.* (1995) and MacAskill *et al.* (2002). Lukomski *et al.* (2006) showed that the technique can, in principle, also be used to obtain total cross sections from laser-excited initial states that would be hard to measure otherwise. Another trap measurement involving metastable He atoms was carried out by Uhlmann *et al.* (2005).

Information on the excited state is also accessible through the polarization of the emitted photons. Many studies of the polarization fraction

$$P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \tag{8.3}$$

where $I_{\parallel}$ and $I_{\perp}$ are the radiation intensities observed following transmission through a polarizer with optic axis parallel and perpendicular to the incident electron beam, have been carried out.

8.2.3.3 **Angular and Polarization Correlations**

The information from polarization fraction data has limited value because it relates to the incoherent mixture of the magnetic sublevels of the excited state due to integration over all possible kinematical processes. On the other hand, if identically prepared states are produced, a coherent mixture of the magnetic sublevels of the excited state is observed. For example, an excited $^1\mathrm{P^o}$ state can be described as

$$|\psi\,^1\mathrm{P}\rangle = a_{+1}|11\rangle + a_0|10\rangle + a_{-1}|1-1\rangle \tag{8.4}$$

where the a_M are the excitation amplitudes for the sublevels $|LM\rangle$ with magnetic quantum number M. Theoretical analyses of coherent excitation can be found in Blum (1996), Andersen, Gallagher and Hertel (1988), and Andersen and Bartschat (2001).

Experimentally, the conditions for coherent excitation are produced by observation of the scattered electron responsible for excitation of the particular states at a well-defined scattering angle, in coincidence with the emitted photon. This ensures that only identically prepared excited states are observed. Information on the excited state is then determined by measuring the polarization state of the emitted radiation. This can be done directly, at least for simple systems such as $^1\mathrm{S} \to {}^1\mathrm{P^o}$ excitation in helium, by measuring the linear and circular polarization of the radiation emitted perpendicular to the scattering plane. Alternatively, the information can be deduced from the angular correlation between the scattered electron and the emitted photon.

Eminyan *et al.* (1974) carried out the first electron–photon angular correlation experiment for the $2^1\mathrm{P}$ state of helium. In this experiment, those electrons that lost 21.2 eV (the excitation energy of the $2^1\mathrm{P}$ state of helium) were detected by the electron analyzer at a fixed scattering angle. Angular correlations were then determined by observing the coincidence signal as the photon detector was rotated about the collision center.

The first polarization correlation measurement was reported for the 3^1P state of helium by Standage and Kleinpoppen (1976). Here, the linear polarizations P_1 and P_2 and the circular polarization P_3 are measured in coincidence with the scattered electrons for radiation emitted perpendicular to the scattering plane (z-direction). In the "natural coordinate system" with the z-axis defined perpendicular to the scattering plane and the x-axis chosen along the incident beam direction, these "Stokes parameters" are defined by

$$I_z P_1 = I_z(0^\circ) - I_z(90^\circ) \tag{8.5}$$

$$I_z P_2 = I_z(45^\circ) - I_z(135^\circ) \tag{8.6}$$

$$I_z P_3 = I_z(\mathrm{RHC}) - I_z(\mathrm{LHC}) \tag{8.7}$$

where $I_z(\theta)$ is the signal transmitted by a linear polarizer with optic axis at an angle θ to the electron beam, I is the total signal in that direction, and RHC and LHC refer to right-hand and left-hand circularly polarized radiation. A more complete description of excitation of states with higher angular momentum requires a further linear polarization measurement in the scattering plane (usually the y-direction),

$$I_y P_1 = I_y(0^\circ) - I_y(90^\circ) \tag{8.8}$$

This is also true for heavier targets in which relativistic effects such as the spin–orbit interaction can no longer be ignored.

Note that many other definitions of the Stokes parameters have been used in the literature, as well as a different coordinate system. The "collision frame," often used for convenience in numerical calculations, is defined with the z-axis along the incident beam and the y-axis perpendicular to the scattering plane. For a translation between the various conventions, see Andersen, Gallagher and Hertel (1988).

We show in Figure 8.3 a schematic diagram of the polarization analysis system used in Newcastle. By rotating the in-plane photon detector, the apparatus can also measure angular correlations.

We show the most recent experimental data and theory for the reduced (after fine-structure depolarization has been taken into account) Stokes parameters for 1s − 2p excitation in e − H scattering at 54.4 eV in Figure 8.4. Note that the angular correlation data of Yalim, Cvejanovic and Crowe (1997) and the polarization correlation data of Williams and Mikosza (2006) lie consistently within one standard deviation of theory.

The measured angular correlations have been analyzed in different ways. The analysis of Andersen, Gallagher and Hertel (1988) in terms of the shape and dynamics of the excited state charge cloud gives a particularly straightforward physical picture. They define the following parameters, sometimes referred to as *electron impact coherence parameters*: the alignment angle γ, the length l and width w in the scattering plane, and the height h of the charge cloud along the axis perpendicular to the scattering plane. Furthermore, $L_\perp$ is the expectation value of the angular momentum transfer perpendicular to the scattering plane while the degree of linear polarization, P_l, of the emitted light is defined in terms of l and w. As shown in Figure 8.5, these

parameters are readily related to the measured Stokes parameters and angular correlations. They have the added advantage that they can be used to describe a wide range of excited states in different atoms.

The variations of $L_{\perp}$, P_l, and γ with scattering angle are shown in Figure 8.6 for the 2^1P state in helium at an incident electron energy of 50 eV. Once again, there is excellent agreement between experiment and the most sophisticated theories currently available for this problem.

An alternative method giving the same complete information on excitation is superelastic scattering from laser-excited states. The technique involves exciting the state of interest with a laser. Electrons are then scattered from this excited state and those scattered electrons that have gained energy corresponding to the energy of the excited state (superelastically scattered) are observed as a function of the polarization of the laser photons. Compared with the correlation methods, the technique is relatively fast because it does not involve coincidence methods. On the negative side, it can be applied only to the states that are accessible by a single laser photon. The latest developments and results from excitation of $4P_1$ state of calcium can be found in Hussey *et al.* (2008) and for the $(6p)^2P_{3/2}$ state of cesium in Slaughter *et al.* (2007). Interestingly, the latter study shows that the measured Stokes parameters are insensitive to inclusion of core and relativistic effects for a heavy atom.

8.2.4
Ionization

The simplest electron-impact ionization process arises from the ejection of a single atomic electron from an outer shell:

$$e^-(E_i) + A_i \rightarrow A_j^+ + e^-(E_A) + e^-(E_B) \tag{8.9}$$

where E_i, E_A, and E_B are the incident, scattered, and ejected electron energies, respectively. They are related through energy conservation by

$$E_i = E_A + E_B + \varepsilon \tag{8.10}$$

where ε is the binding energy of the ejected atomic electron.

8.2.4.1 Total Cross Sections

These measurements are conventionally carried out by observation of the positive ions produced in the ionization process:

$$i^+ = i_0 N \sigma_i x \tag{8.11}$$

where i_0 is the incident electron beam current; N, the number density of the target gas; x, the effective target thickness; i^+, the measured positive-ion current; and σ_i, the total ionization cross section. The work of Rapp and Englander-Golden (1965) for a range of stable target atoms and molecules is widely used as a standard. For unstable targets, crossed modulated-beam techniques have been developed involving both thermal energy and fast atomic beams. Components of the total ionization cross section, for

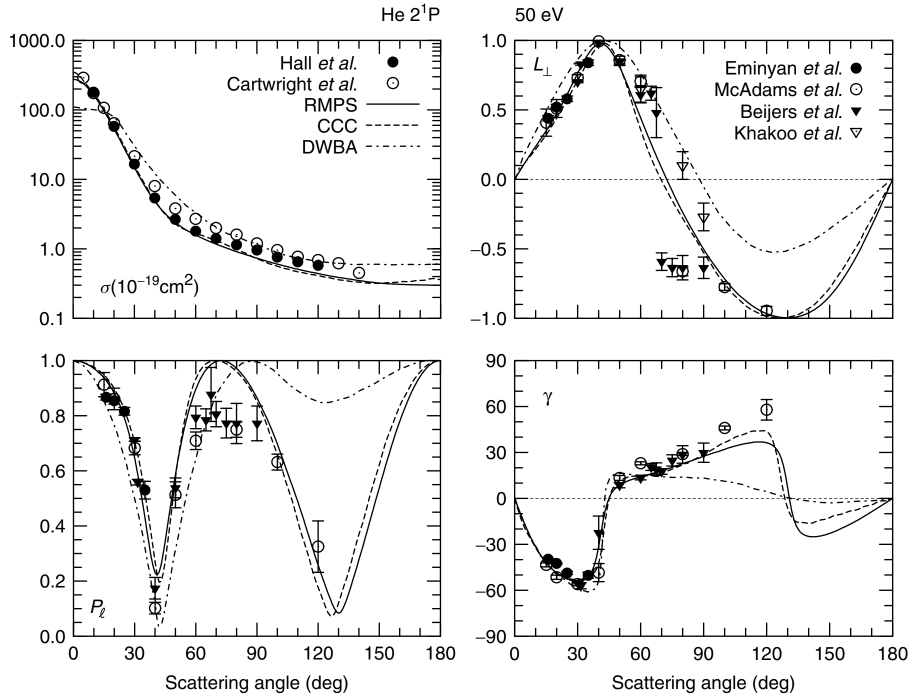

Fig. 8.6 Differential cross section (DCS) and electron impact coherence parameters $L_\perp$, γ and P_ℓ for electron impact excitation of the 2^1P^o state in helium from the ground state 1^1S at an incident electron energy of 50 eV. The theoretical curves are from: RMPS, Bartschat *et al.* (1996a); CCC, Fursa and Bray (1995); DWBA, Beijers *et al.* (1987). The sources for the experimental data are: Hall *et al.* (1973); Cartwright *et al.* (1992); Eminyan *et al.* (1974); Beijers *et al.* (1987); McAdams *et al.* (1980); Khakoo *et al.* (1986).

example, multiple ionization and dissociative ionization, can be identified by incorporating mass spectroscopic analysis in the apparatus. Accurate total and partial ionization cross sections for a wide range of atoms and molecules were recently reported by a group from Rice University; see Lindsay and Mangan (2003) and references therein.

8.2.4.2 **Double Differential Cross Sections**

The detection of a single outgoing electron as a function of its energy and angle is less valuable than in the case of excitation, because the available excess energy of the incoming electron is shared between the scattered and ejected electrons, thus leading to a continuum of energies for both electrons. Note that single differential cross sections as a function of one variable are difficult to measure.

Two distinct double differential cross sections (DDCS) $d^2\sigma/d\Omega dE$ for ionization can be measured. The angular distributions of outgoing electrons of fixed energy may be observed for a particular incident electron energy. For incident electron energies well above the ionization threshold, the general behavior of these cross sections is readily characterized. When the observed electron energy is high, the measured cross section is typical of a "scattered" electron, strongly peaked in the forward direction and falling by orders of magnitude as the scattering angle is increased. As the observed electron energy is decreased, the forward peak becomes less pronounced and the cross section is dominated by a peak typically around 60° scattering angle, due to the increasing dominance of "ejected" electrons.

Alternatively, the energy distribution of the outgoing electron can be monitored at particular scattering angles. Extensive DDCS data were recently reported at low electron energies for atomic hydrogen and helium by Childers *et al.* (2004) and Schow *et al.* (2005).

8.2.4.3 **Higher Order, including, Fully Differential Cross Sections**

In recent years, partly due to the development of more efficient coincidence electron spectrometers, a wide range of multidifferential cross sections are being measured for most direct and indirect ionization processes. These include single ionization to the ground and specific excited ion states, double excitation–autoionization, double ionization, and inner-shell ionization. Each of these is discussed in detail in the following sections.

Experimentally, these measurements are performed using electron spectrometers with some combination of electron analyzers to observe the scattered and/or ejected electrons and, if appropriate, a photon detector to observe the decay of the excited ion state. Coincidence techniques allow for identification of the ionization process of interest.

Two very different techniques have been used to dramatically increase the efficiency of spectrometers that are used to detect electrons. Catoire *et al.* (2007) describe a spectrometer using three toroidal electron analyzers in conjunction with time- and position-sensitive detectors to observe the three outgoing electrons. This setup enables the *simultaneous* observation of both the ejected electrons from double ionization over most of the scattering plane, defined by the incident electron momentum $\boldsymbol{k}_i$ and the scattered electron momentum $\boldsymbol{k}_A$, and for a reasonable range of scattering angles. Figure 8.7 shows a schematic illustration of their triple coincidence spectrometer.

A typical reaction microscope used by Dürr *et al.* (2008) to study single ionization processes is shown in Fig. 8.8. It operates on entirely different principles from conventional electron spectrometers. Briefly, a pulsed beam of electrons crosses a supersonic atom beam. The ejected electrons and the recoiling ions are extracted in opposite directions by a weak uniform electric field that is parallel to the direction of the incident electron beam. A uniform magnetic field is also applied in this direction to confine electrons that are emitted perpendicular to the electric field. After passing through field-free drift regions, the slow ejected electrons are then detected in two time- and position-sensitive multihit detectors, allowing for the vector momenta of the two particles to be calculated. Unlike most conventional coincidence electron spectrometers, including the toroidal based systems, which only enable measurements in a single plane at any one time, this technique allows for data to be collected over a large part of the full solid angle simultaneously.

8.2.4.4 (e,2e) Studies of Direct Single Ionization

The most detailed information on ionizing collisions involving ejection of a *single* electron and leaving the ion in its ground state comes from the measurement of triple differential cross sections (TDCS), $d^3\sigma_i/d\Omega_A d\Omega_B dE$. They are also referred to as (e,2e) cross sections.

The momentum transfer vector

$$\boldsymbol{K} = \boldsymbol{k}_i - \boldsymbol{k}_A \tag{8.12}$$

is an important parameter in discussing this work. Two major and distinct groups of study have been developed depending on the magnitude of the momentum transfer vector $\boldsymbol{K}$.

The magnitude of $\boldsymbol{K}$ is maximized in experiments in which the two outgoing electrons from a high-energy collision are observed with equal energies at equal angles $\theta = \theta_A = \theta_B$ relative to the incident electron beam. In such “high-energy symmetric kinematics,” the interaction approximates a binary collision between two free electrons. Conservation of momentum requires

$$\boldsymbol{k}_i + \boldsymbol{p} = \boldsymbol{k}_A + \boldsymbol{k}_B \tag{8.13}$$

where $\boldsymbol{p}$ is the momentum of the atomic electron prior to the collision. The magnitude of the struck electron momentum is then given by

$$p = [(2k_B \cos\theta - k_i)^2 + 4k_B \sin^2\theta \times \sin^2 \varphi_A/2]^{1/2} \tag{8.14}$$

Here, in principle, variation of any of the parameters k_B, θ, or φ_A allows for the electron momentum p to be scanned. It can be shown that the (e,2e) cross section is proportional to the spherically averaged electron momentum distribution of the atomic electron. Hence a measurement of the TDCS as a function of $\pm p$ reveals the atomic electron momentum distribution, which is related to the spatial wave function through a Fourier transform. Measurements of this type were extensively reviewed, for example, by Weigold and McCarthy (1999).

Measurements of the TDCS for a range of small momentum transfers $\boldsymbol{K}$ were pioneered by Ehrhardt *et al.* (1969). Using low-energy incident electrons ($< 600\,\text{eV}$), they measured angular correlations between the outgoing scattered and ejected electrons under conditions where a slow ejected electron is observed in coincidence with a fast electron scattered through small angles. Most ionizing collisions fall into this category of "low-energy asymmetric kinematics."

The early experiments by Ehrhardt's group, mostly in helium, quickly established the general trends of relative low-energy asymmetric (e,2e) cross sections measured in the scattering plane. Typical results (see Figure 8.9 for an example) are dominated by a peak in a direction close to the momentum transfer direction, referred to as the *binary encounter* peak, and a peak in the opposite direction, referred to as the *recoil peak*. Earlier advances in (e,2e) and related studies were reviewed by Lahmam-Bennani (1991).

Figure 8.10 shows the current state of the art for electron-impact ionization of atomic hydrogen close to the threshold energy and for equal sharing of the excess energy by the two outgoing electrons. The most sophisticated currently available theories for this two-electron process, convergent close-coupling (CCC), time-dependent close-coupling (TDCC), and exterior complex scaling (ECS), all of which are discussed in the theory section, yield predictions in excellent agreement with each other. These predictions also agree very well with most of the available experimental data. In fact, for the discrepancies which remain, it is not obvious that the problems lie with theory for this benchmark process.

Stevenson and Lohmann (2008) reported the first (e,2e) measurements where one of the outgoing electrons is observed over the full angular range, $0^\circ - 360^\circ$, using a MAC device. Their new data for ionization of the 3p electron in argon reveal structures in the previously unobserved angular ranges that are generally not well reproduced by the state-of-the-art calculations of Prideaux, Madison and Bartschat (2005) and Bartschat and Vorov (2005).

Recent reaction microscope measurements in three dimensions also revealed previously unobserved features in the helium TDCS. Typical data of Dürr *et al.* (2006) are shown in Figure 8.11. In the

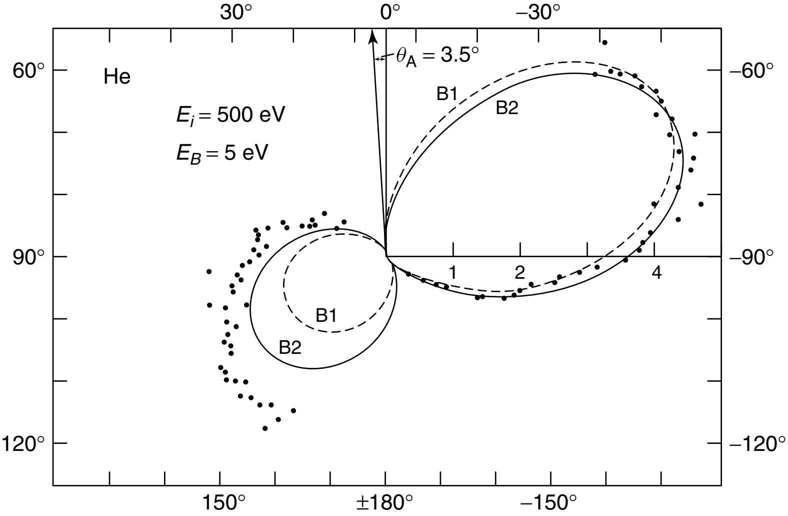

Fig. 8.9 The triple-differential cross section (in atomic units) for helium as a function of the ejected electron angle θ_B for an incident electron energy of 500 eV, an ejected electron energy of 5 eV, and a fixed detection angle of 3.5° for the fast electron. The dots are experimental data, while the curves B1 and B2 represent first-order and second-order plane-wave Born approximations. (Adapted from Ehrhardt *et al.* (1986).)

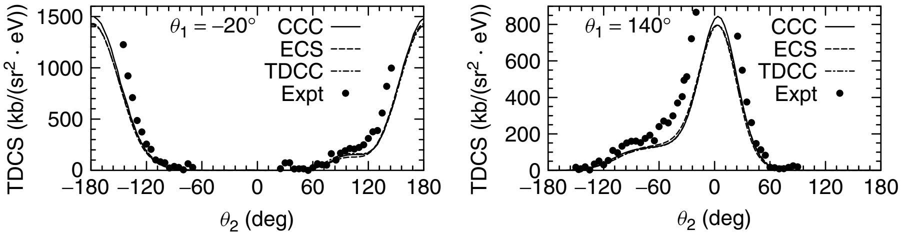

Fig. 8.10 TDCS for electron-impact ionization of H at an incident electron energy of 17.6 eV. Both outgoing electrons have an energy of 2 eV. The detection of one electron is fixed at −20° or 140°, respectively. The absolute experimental data of Röder, Baertschy and Bray (2003) are compared with predictions from CCC, time-dependent close-coupling, and exterior complex scaling models. (Adapted from Colgan and Pindzola (2006).)

scattering plane, the data are consistent with previous experiments and, after taking account of the postcollision interactions between the charged particles, with the dominance of first-order processes. However, in the plane perpendicular to the momentum transfer vector, there is a sizable cross section with maxima at angles of 70° and 290°. These are not reproduced by first-order theories Dürr *et al.* (2008), even at an incident energy as high as 1 keV.

There is an increasing interest in the use of the (e,2e) technique to study the dynamics of molecular ionization, including molecules of biological interest,

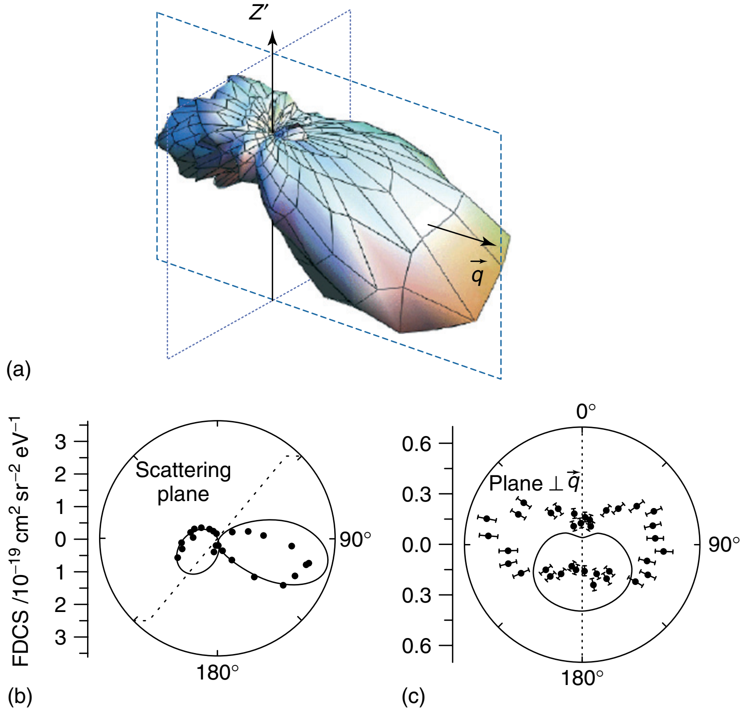

Fig. 8.11 The three-dimensional (e,2e) cross sections of Dürr *et al.* (2006) for helium at an incident electron energy of 102 eV, a scattering angle of 20° and slow outgoing electron energy of 10 eV. (a) 3-D cross section. (b) Cut in the scattering plane [dashed line in (a)]. (c) Cut perpendicular to the scattering plane [dotted line in (a)]. The dotted lines in (b) and (c) show the incident electron direction. The solid curves are the three Coulomb wave function (3C) theory. (From Dürr *et al.* (2006).)

Milne-Brownlie *et al.* (2004). This is despite the experimental complexities associated with the additional degrees of freedom arising from the nuclear motion. Even overlapping electronic states may remain unresolved in these experiments, and so far experiments have only been carried out for random orientations of the internuclear axis.

8.2.4.5 (e,3e) Studies of Double Ionization

Double electron ejection has been studied using the (e,3e) method, which involves detection of all three outgoing electrons in coincidence. The process can be written as

$$e^-(E_i) + A_i \longrightarrow A_j^{++} + e^-(E_A) + e^-(E_B) + e^-(E_C) \qquad (8.15)$$

These experiments yield fivefold differential cross sections, $d^5\sigma_i/dE_A dE_B d\Omega_A d\Omega_B d\Omega_C$.

Although the (e,3e) technique was pioneered by Lahmam-Bennani, Dupré and Duguet (1989) two decades ago, it can still be considered to be in its infancy due to the small cross sections

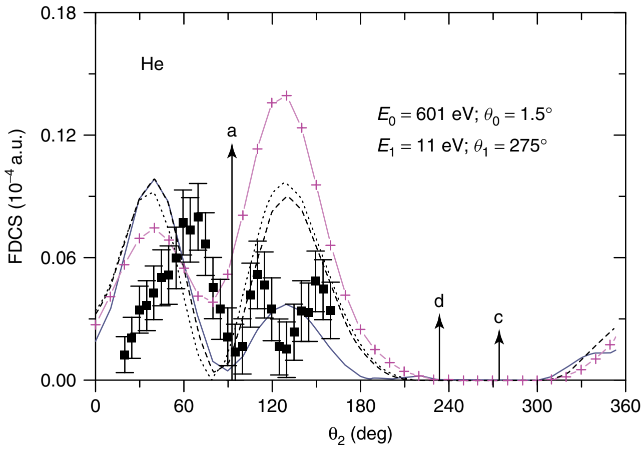

Fig. 8.12 The fivefold coplanar differential cross section in atomic units for the double ionization of helium at an incident electron energy of 601 eV. The scattered electron with an energy of 500 eV and scattered through 1.5° is observed along with an 11 eV ejected electron at 275° and the other ejected electron as a function of angle. The experimental data are from Lahmam-Bennani *et al.* (2003). Theory: first Born, dotted line; second Born, solid line with crosses; approximate 6C models, solid and dashed lines. According to general selection rules (Berakdar, Lahmam-Bennani and Dal Cappello (2003)), there should be minima at the angles denoted by "a," "c," and "d." (From Elazzouzi *et al.* (2005).)

for double ionization, the wide variation of kinematical situations arising from the presence of the second ejected electron, and the experimental complexities involved. The experimental efficiencies have been greatly enhanced by the approaches of both Catoire *et al.* (2007) and Dürr *et al.* (2007). Figure 8.12 shows typical (e,3e) data for the kinematical conditions shown. While the minima predicted by fundamental selection rules (Berakdar, Lahmam-Bennani and Dal Cappello (2003)) are reproduced by experiment, the overall agreement with the calculations shown is not good.

8.2.4.6 Excitation–Ionization

The study of ionization, where the ion is formed in an excited state, has been the subject of considerable attention recently. At least some of this work was stimulated by the desire to carry out the complete ionization experiment, analogous to the complete excitation experiments discussed in Section 8.2.3.3. Such a complete experiment would require a triple coincidence experiment, (e, 2eγ), in which the polarization of the decay photon is determined for specific kinematics by its observation in coincidence with the two outgoing electrons. Such an experiment has not been performed to date, although some progress toward its realization has been made.

Schematically, the process is written as

$$e^-(E_i) + A_i \longrightarrow A_j^{+*} + e^-(E_A) + e^-(E_B) \qquad (8.16)$$

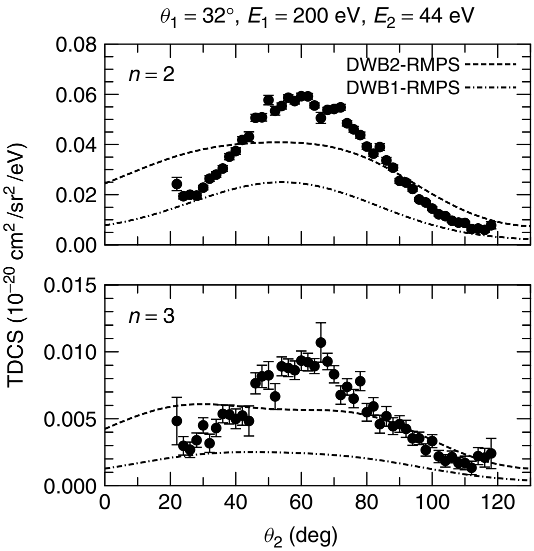

Fig. 8.13 Experimental TDCS for excitation-ionization to the $n = 2$ and $n = 3$ states of He$^+$ compared with hybrid R-matrix calculations. In each case, the outgoing scattered electron has an energy of 200 eV and the scattering angle is 32°. The ejected electron energy is 44 eV. The experimental data are from Bellm, Lower and Bartschat (2006), after combining their measured ratios with theoretical predictions for ionization without excitation. (From Bartschat *et al.* (2007).)

The excited ion state, A_j^{+*}, then decays by optical emission to a lower lying ion state,

$$A_j^{+*} \longrightarrow A_k^+ + h\nu \tag{8.17}$$

Three related types of studies have been reported. Stefani, Avaldi and Camilloni (1990) first reported an (e,2e) study of the He$^+$(n = 2) states. This produces a TDCS with the disadvantages that the 2s and 2p ion states are not resolved and that the detailed dynamical information gained from the polarization of the photon is absent. Hayes and Williams (1996) first applied the single electron–photon, (e,eγ), technique to the same system. This type of study enables the 2p state to be isolated in the study and angular correlation parameters to be determined, integrated over the slow ejected electron emission angles (Schwienhorst *et al.*, 1996). A single-electron-polarized-photon study of the 4p^{2}P$_{3/2}$ excited state of Ca$^+$ was reported by Stevenson and Crowe (2004). Sakhelashvili *et al.* (2005) carried out an (e,2eγ) experiment in helium without resolving the different He$^+$(np)^{2}P states and without regard to the direction or polarization of the emitted photons. If any isotropy in the emitted radiation is neglected as well, the data correspond to the TDCS for the (np)^{2}P states, with approximately 90% of the signal believed to be coming from the He$^+$(2p) state.

Figure 8.13 shows TDCS for the excitation-ionization to the n = 2 and n = 3 states of He$^+$ compared with hybrid R-matrix calculations. The absolute "experimental data" presented by Bartschat *et al.* (2007) were generated by combining the measured ratios of these TDCS to the n = 1 ion state by Bellm, Lower and Bartschat (2006) with CCC results for n = 1. The data show broad peaks in the forward direction. Although the kinematics are not identical, the TDCS of Dogan and Crowe (2000) for these states suggest that more interesting features in the TDCS exist outside the angular range of the data shown here. The need for higher order effects to be taken into account in theoretically describing these two-active atomic electron processes is demonstrated by comparing theoretical predictions obtained through first-order (DWB1-RMPS) or second-order (DWB2-RMPS) treatments of the projectile-target interaction, combined with a convergent *R*-matrix with pseudostates (RMPS) model for the inital bound state and the ejected-electron–residual-ion interaction.

8.2.4.7 Excitation–Autoionization

A major contribution to the ionization cross section for complex atoms and ions often arises from the process known as excitation–autoionization. In this process the target is first excited to an autoionizing or resonant state lying above the ionization threshold by the incident electron,

$$e^- + A_i \rightarrow e^- + A_j^* \qquad (8.18)$$

and the resultant resonant state A_j^* subsequently autoionizes,

$$A_j^* \rightarrow A_k^+ + e^- \qquad (8.19)$$

Hence, the total effect of these two processes is to ionize the original atom or ion. A recent example involving inner-shell excitation of Na was reported by Borovik, Zatsarinny and Bartschat (2008).

In addition, the incident electron may sometimes be captured into a resonant state that decays by the emission of two (or occasionally more) electrons:

$$e^- + A_i \rightarrow A_l^{-*} \rightarrow A_k^+ + 2e^- \qquad (8.20)$$

This process, known as resonant excitation double autoionization (REDA), interferes with the direct process given by Eqs. (8.16) and (8.17) and often dominates the cross section close to threshold. Excitation–autoionization was first observed in the ionization of Ba$^+$ by Peart and Dolder (1968) and has since been shown to be a dominant ionizing mechanism for many ions of laboratory and astrophysical interest.

Excitation–autoionization can be studied experimentally by observation of either the ejected or the scattered electron spectra. Observation of the ejected electron has the advantage that the observed spectra are independent of the inherent inhomogeneity in the incident electron energy E_i.

Autoionization spectra are characterized by asymmetric line profiles due to interference between the direct ionization and the excitation–autoionization process. The majority of single-electron spectra have been analyzed to yield the energies and widths of the resonance states.

Excitation–autoionization processes involving the $2l2l'$ states of helium have also been studied using the (e,2e) technique (see McDonald and Crowe (1993) and references therein). In these experiments, the angular variation of the Shore resonance parameters (Shore (1967)) of each of the autoionizing states was determined. In the most recent study, deHarak, Bartschat and Martin (2008) measured out-of-plane TDCS for each of these singlet states. Dogan and Crowe (2002) used the electron–photon coincidence method to observe the influence of the $3lnl'$ autoionizing states of helium on simultaneous excitation-ionization of the He$^+$2p state.

8.2.4.8 Inner-Shell Ionization

We are interested in processes of the type

$$e^- + A_i \longrightarrow A^+(J, M) + 2e^- \quad (8.21)$$

where the ion $A^+(J, M)$ has an inner-shell vacancy and can decay by either X-ray

$$A^+(J, M) \longrightarrow A^+(J'', M'') + hv \quad (8.22)$$

or Auger-electron emission

$$A^+(J, M) \longrightarrow A^{++}(J', M') + e_{\text{Auger}} \quad (8.23)$$

Except for very heavy atoms, the dominant decay mechanism is by Auger-electron emission, and hence we will concentrate on that mode of decay.

Most studies of inner-shell ionization–Auger-electron decay have involved observation of the energy-loss spectrum of a single outgoing electron. These measurements yield a spectrum of Auger-electron lines superimposed on the continuum of scattered and ejected electrons from all ionization processes. A second type of experimental study has involved measurement of the angular distribution of the Auger electrons. When an inner-shell vacancy is created with $j > \frac{1}{2}$ by a beam of particles, the initial ion A^+ will be aligned with respect to the incident beam direction, the alignment manifesting itself in an anisotropic angular distribution of the decay product. More detailed information on the alignment of the initial ion can be obtained from angular correlation measurements between the Auger electrons and a fast scattered electron, where only specific momentum transfer processes are studied. Such studies were first reported by Sewell and Crowe (1982). Recently, both the (e,2e) and (e,3e) techniques were used by Naja *et al.* (2007) to study inner-shell ionization, taking advantage of the increased efficiency of the electron detectors discussed above.

8.2.5
Electron–Molecule/Biomolecule Interactions

The experimental techniques used to study electron scattering from molecules are the same as for atoms and do not merit special attention. For example, the spectrometers of Allan (2004) and Catoire *et al.* (2007) discussed earlier have been used to study different aspects of electron–molecule scattering. In this case, the nuclear motion opens up a wealth of additional possibilities, in particular in low-energy collisions that often reveal resonance effects. Such resonance and threshold phenomena in low-energy electron collisions with molecules and clusters were reviewed by Hotop *et al.* (2003).

Experiments to determine electronic excitation cross sections, with typical energy resolutions in the range of 30 – 50 meV, can be very problematic due to the nuclear degrees of freedom. In this case, spectral deconvolution techniques are often necessary to obtain well-defined results, especially for polyatomic molecules. Brunger *et al.* (2008) give an excellent recent example of the use of deconvolution methods to obtain differential excitation cross sections for each of the six lowest lying electronic states of water.

One recent development that justifies comment is the study of biomolecules. This interest is largely generated by the important role played by low-energy electrons in radiobiology. Such low-energy ($\leq$30 eV) electrons are produced by the

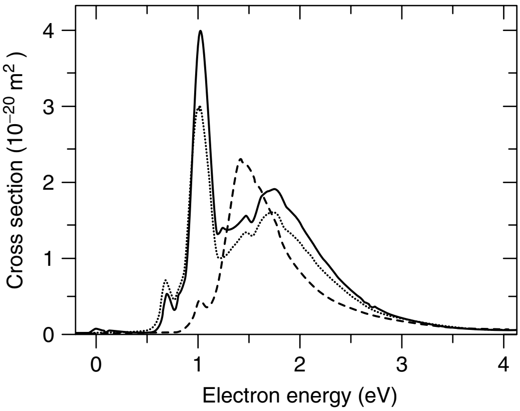

Fig. 8.14 The cross sections for formation of the most abundant negative ions formed by electron attachment to each of uracil (U), thymine (U), and cytosine (C). (U-H)$^-$ from U (dotted line); (T-H)$^-$ from T (full line and × 0.33); (C-H)$^-$ from C (dashed line). (From Denifl *et al.* (2004).)

interaction of fast ionizing radiation with cellular constituents. The vast majority of these electrons are responsible for the production of reactive negative ions and radical fragments through the formation and decay of resonances.

Advances in understanding the role of these low-energy electrons have relied to a considerable extent on the interplay between scattering from gaseous- and solid-state targets. For example, while Boudaiffa *et al.* (2000) observed single- and double-strand breaks in supercoiled DNA deposited on a cold surface, they argued that the resonances observed were similar to those seen in gas-phase electron attachment experiments. More generally the gas-phase experiments are important in distinguishing between environmental and intrinsic molecular effects.

The first gas-phase electron scattering studies on uracil and the DNA bases were performed by Aflatooni, Gallup and Burrow (1998) using their electron transmission method developed for electron–atom scattering. Another important series of systematic studies of the stable negative ions produced from uracil and the DNA bases, detected using a high-resolution quadrupole mass spectrometer, have provided considerable insight into the mechanisms of damage to DNA by low-energy electrons; see, for example, Ptasińska *et al.* (2005). Electron attachment to these biomolecules leads to dissociation into various fragments without any measurable amount of the stable parent ions. Figure 8.14 shows the cross sections for the formation of the most dominant negative ions produced from the RNA base uracil and the DNA bases, thymine and cytosine reported by Denifl *et al.* (2004). The reader is referred to the original publication for details and to the review of Sanche (2005) for a broad discussion of the effects arising from the interaction of low-energy electrons with biomolecules.

8.2.6
Electron–Ion Interactions

Experimental studies of electron-ion interactions have traditionally been sparse compared with their theoretical counterparts. Recently, this has been transformed by the adoption of heavy-ion storage rings for electron–ion studies. The technique can be considered

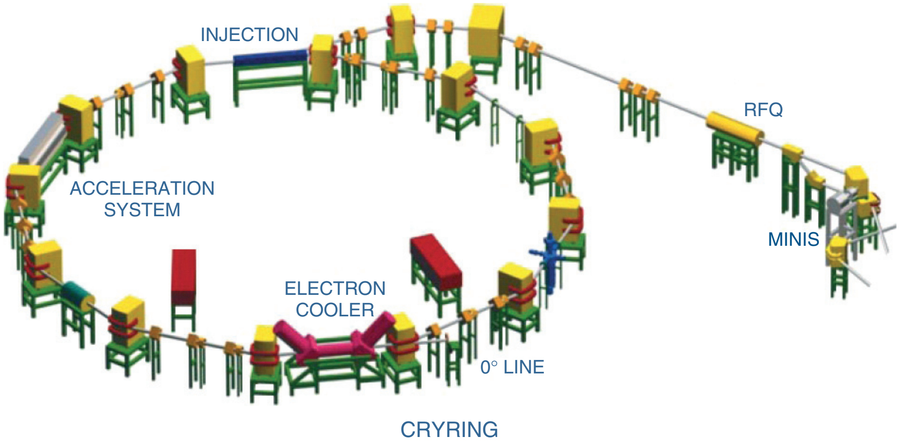

Fig. 8.15 The Stockholm ion storage ring (51.6 m circumference). (From Larsson and Thomas (2001).)

as an extension of the merged beams method, in which electron and ion beams are brought together and interact over a common path length, (Phaneuf *et al.*, 1999). One of a number of very significant advantages of the storage rings is that the ions pass through the interaction region more than 10^5 times per second, whereas the merged beams machines are single-pass devices. One of the storage rings, which has been used in atomic/molecular physics, the CRYRING device, is shown in Figure 8.15 (Larsson, 2001). Briefly, ions are extracted from the ion source MINIS, mass selected, and then injected into the storage ring and further accelerated to the required beam energy, typically $\sim$ MeV. In the straight "electron cooler" section, the stored ion beam is merged with an electron beam with the same velocity and cooled, typically for a few seconds. Electron cooling is based on the fact that the Coulomb interaction between the electrons and ions leads to heat transfer from the warm ion beam to the cold and continuously renewed electron beam. Amongst the outcomes of cooling are an ion beam with an extremely narrow momentum spread and ions in the lowest vibrational state of a molecular ion. The electron beam in the cooler also has excellent properties for electron–ion collision studies. The electron–ion interaction energy is given by the relative velocities of the two beams. In principle, this can be made zero, but in practice the lowest energy is a few milli electron-volts due to the velocity distributions and finite angular resolutions of the beams. Overall energy resolutions are typically $\sim 1 - 2$ meV. The more recent addition of a supersonic expansion ion source has also led to studies involving rotationally cold molecular ions (McCall *et al.*, 2003). A range of detection devices can be used to detect the collision products depending on the process studied.

Storage rings have been used to study a wide range of low-energy $(0 - 100\,\text{eV})$ electron–ion collisions with unprecedented resolution and often of fundamental importance in fusion and astrophysical plasmas. The cross

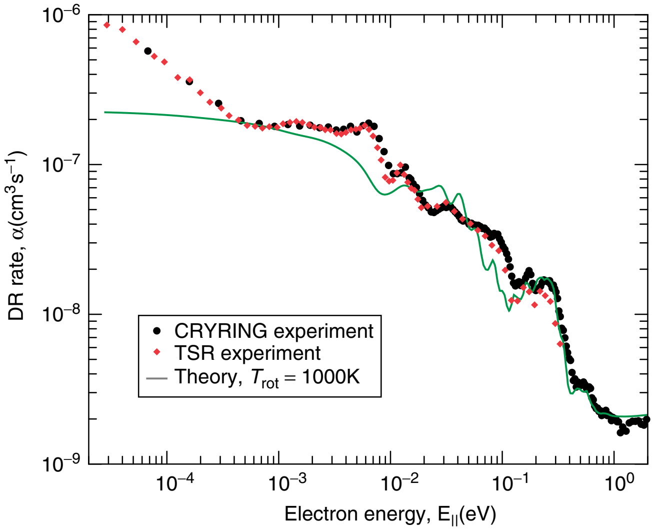

Fig. 8.16 Dissociative recombination rate of H_3^+ as a function of the incident electron energy. The theoretical predictions of dos Santos, Kokoouline and Greene (2007) are compared with experimental data from the Stockholm (CRYRING) and Heidelberg (TSR) groups.

section measurements of recombination processes are particularly important. Figure 8.16 shows an example of dissociative recombination. For many years, theory had been unable to explain the experimentally observed large rates for this process in H_3^+, which is of fundamental importance in diffuse interstellar clouds. Kokoouline and Greene (2003a) finally identified Jahn–Teller coupling as the critical mechanism that must be included in a theoretical treatment. As seen in Figure 8.16, the latest calculations of dos Santos, Kokoouline and Greene (2007) finally obtained good agreement with recent storage ring data.

8.2.7
Spin-Polarized Electron Studies

Previous discussions have involved experiments in which the electron beam was produced by thermionic emission with the spins of the electrons having arbitrary directions. Hence, for example, in discussing excitation of the 2^2P state of atomic hydrogen in Section 8.2.3.3, the analysis involves an average over all spin orientations.

It is possible to produce electron beams with a preferential orientation of the electron spin (Kessler (1985)). In general, the use of spin-polarized electron beams in electron–atom scattering provides a further definition of the initial and/or final state of the system, leading toward the "perfect" or "complete" scattering experiment. In such an experiment, all parameters that can be determined according to the limits set by quantum mechanics, are measured for a given process. This information is contained in the magnitudes and (relative) phases of the complex-valued scattering amplitudes. The concept of complete experiments was introduced by Bederson (1969). More information can be found in Andersen and Bartschat (1996); Andersen and Bartschat (2001).

Spin-polarized electron and atom beams provide a means of studying spin-dependent interactions, the details of which are often masked in experiments involving unpolarized electrons by the stronger Coulomb interaction. Two specific spin-dependent interactions have been the subject of extensive study – the exchange interaction and the spin–orbit interaction. Although both these effects are important for scattering from a wide range of atomic targets, it is useful to consider the extreme situations where only one is important.

8.2.7.1 Exchange Interaction

This is particularly important for spin$-\frac{1}{2}$, low-Z targets, including atomic hydrogen and the alkali atoms. Assuming that the total spin of the collision system (singlet and triplet) is conserved, the cross sections for scattering from such targets depend on the relative orientations of the electron and target spins, that is, $\sigma(\uparrow\downarrow) \neq \sigma(\uparrow\uparrow)$, where the arrows indicate the electron and atom spins. As an example, we give in Table 8.1 the possible scattering modes for the elastic scattering of electrons with spin parallel or antiparallel to an atom with a given spin direction ($A\uparrow$ or $A\downarrow$, together with the corresponding scattering amplitudes and cross sections. These expressions can readily be generalized to inelastic scattering (Kessler, 1985).

Scattering of spin-polarized electrons from spin-polarized atoms with spin analysis of the products yields the cross sections $|f|^2$, $|g|^2$, and $|f-g|^2$. This constitutes an extremely difficult experiment. Some information can already be obtained if either the initial electron or atom beam is spin polarized, and if either the electron or the atom polarization is measured after the collision process. However, a complete experiment requires the measurement of the relative phase of f and g as well.

Most experimental studies do not set out to obtain complete information on the scattering amplitudes. Several experiments have been carried out by scattering polarized electrons from polarized atoms and measuring the asymmetry

$$A = \frac{\sigma(\uparrow\downarrow) - \sigma(\uparrow\uparrow)}{\sigma(\uparrow\downarrow) + \sigma(\uparrow\uparrow)} \tag{8.24}$$

where $\sigma(\uparrow\downarrow)$ is the cross section for antiparallel electron and atom spins and $\sigma(\uparrow\uparrow)$ is the cross section for parallel electron and atom spins. Of particular importance for the further confirmation of the CCC theory for hydrogen-like systems (Bray (1994)) were several experiments performed by the

Tab. 8.1 Amplitudes and cross sections for scattering of spin-polarized electrons and spin-$\frac{1}{2}$ targets.

Process	Amplitude	Cross section
$e\downarrow + A\uparrow \rightarrow e\downarrow + A\uparrow$	f	$\|f\|^2$
$e\downarrow + A\uparrow \rightarrow e\uparrow + A\downarrow$	$-g$	$\|g\|^2$
$e\uparrow + A\uparrow \rightarrow e\uparrow + A\uparrow$	$f-g$	$\|f-g\|^2$

NIST group for elastic and inelastic electron scattering from Na atoms (see McClelland, Kelley and Celotta (1989), Lorentz *et al.* (1993), and references therein).

Exchange effects are also very important in spin-forbidden transitions, such as $^1S^e \rightarrow {}^3P^o$ in He, the heavy noble gases, and even mercury. If such a transition is achieved by an incident polarized electron beam, the change of the beam polarization is a measure of the relative cross section. Furthermore, an unpolarized electron beam can become polarized if an individual fine-structure level of the target is resolved. This so-called "fine-structure effect," originally suggested by Hanne (1976), has been seen in both excitation and ionization Hanne (1983), Jones, Madison and Hanne (1994), and Andersen and Bartschat (2001).

8.2.7.2 Spin–Orbit Interaction

This is particularly important for high-Z targets (e.g., Cs or Hg). In this case, relativistic effects cause a spin–orbit interaction between the incident electron and the target atom characterized by the scalar product $\boldsymbol{l} \cdot \boldsymbol{s}$, where $\boldsymbol{l}$ is the orbital and $\boldsymbol{s}$ is the spin angular momentum.

In the case of elastic scattering from closed-shell targets (like Hg), the scattering process can be described by two complex amplitudes, f, due to the Coulomb interaction, and g, due to the spin–orbit interaction (not to be confused with the direct and exchange amplitudes above). Complete determination of f and g, apart from an overall phase, requires three independent measurements. One of these is the so-called "polarization function" S_P that determines the spin polarization of an initially unpolarized electron beam after the scattering. Owing to parity conservation, the polarization vector must be perpendicular to the scattering plane. Another possibility is to measure the spin-asymmetry function S_A, which determines the left-right asymmetry in the DCS if the incident electron beam is already spin polarized. Owing to time-reversal invariance, $S_P = S_A \equiv S$ for elastic scattering (Bartschat, 1989). The other parameters, called T and U for elastic scattering from closed-shell targets, determine the change of an initial electron polarization due to the scattering process. Such experiments are highly complicated but have been performed successfully in the Münster group; see, for example, Berger and Kessler (1986). For inelastic collisions, "generalized" STU-parameters need to be defined (Bartschat, 1989), which have also been measured in several cases; see Andersen *et al.* (1997) for a summary of available data.

Using a spin-polarized incident electron beam also vastly increases the possibilities for the polarization properties of the emitted radiation. Not surprisingly, "generalized" Stokes parameters (Andersen and Bartschat (2001)) have to be defined that depend on the electron polarization as well as the position and the setting of the light analyzers. In addition to performing very difficult angle-resolved electron–photon coincidence experiments, it has become evident that some interesting information can already be obtained by only observing the polarization of the emitted light. For properly chosen transitions, observing the circular polarization of the emitted light can be used to optically measure the electron polarization Eminyan and Lampel (1980), Gay (1983), Goeke, Kessler and Hanne (1987), while observation of the linear polarization P_2 can give an indication about the importance of explicitly spin-dependent effects on the collision process Bartschat *et al.* (1981), Bartschat and Blum (1982). Recent data for the "integrated Stokes parameter" in spin-polarized electron-impact excitation of Zn were reported by Pravica *et al.* (2007).

8.2.7.3 A Typical Apparatus and Some Illustrative Results

Figure 8.17 shows the apparatus of Sohn and Hanne (1992) used to determine generalized Stokes parameters for electron-impact excitation of mercury. More importantly, from the point of view of this review, it illustrates the essential features of many polarized-electron studies. Today's sophisticated experiments have only become feasible with the development of highly efficient GaAs polarized-electron sources. The polarized electrons are produced from the GaAsP cathode by photoemission using circularly polarized light, the direction of polarization coinciding with the axis of the incident laser beam. The electron beam is then guided through an electron-optical system, which also includes the possibility of rotating the polarization vector via a Wien filter. After scattering from a beam of target atoms, the scattered electrons and the emitted photons (with their polarization analyzed as well) are observed in coincidence. Finally, the polarization of the incident beam is determined by measuring the left-right asymmetry of the accelerated outgoing electrons (without a target beam) scattered from a gold foil, making use of the spin–orbit effect in a so-called "Mott detector."

Similar apparatus were built by Berger and Kessler (1986) to measure the (generalized) STU-parameters for electron collisions with mercury and heavy noble gases, and by the Bielefeld group (Baum *et al.* (2002); Baum *et al.* (2004))

to measure several spin asymmetries for elastic and inelastic e–Cs collisions. For such heavy targets, both exchange effects and the spin–orbit interaction are often important, and it is by no means trivial to disentangle the various effects. Some sophisticated recipes for performing complete, or almost complete, experiments were discussed by Andersen and Bartschat (1996;2001). The general idea is to look for parameters that would vanish if a particular interaction is not important for the outcome of the collision process. If such an observable is found to be nonzero experimentally, it is generally a good candidate to test this particular aspect of a theoretical model.

Figure 8.18 shows two such examples, namely, the integrated Stokes parameter P_2 for e–Hg excitation and the spin-asymmetry function S_A for elastic e–Cs scattering. Both observables would be zero in any nonrelativistic calculation. In both cases, we note excellent agreement with theoretical predictions that include relativistic effects. However, numerous examples remain where the agreement between theory and experiment is much less satisfactory, in particular for more complex targets such as the heavy noble gases.

Spin-polarized electron beams have also been used in the study of ionization processes, either in ionization asymmetries using a spin-polarized atomic beam as well (see, for example, Baum *et al.* (1993;1992)), or in studies where a p-electron is ejected from a noble gas such as Xe and the fine-structure of the residual ion is resolved (see Bellm *et al.* (2008) and references therein). Finally, relatively few polarized-electron experiments have been performed with molecular targets to date. In many cases, spin-effects are largely masked by the averaging over molecular orientations. However, Green *et al.* (2004) recently found an example of circularly polarized molecular fluorescence induced

by spin exchange. Another pioneering experiment was performed by Mayer and Kessler (1995) who verified electron optic dichroism.

8.2.8
Positron Scattering

The scattering of positrons from atoms and molecules is an interesting area in itself, but is also important in testing some aspects of the theory of electron collisions as a result of the various comparisons and contrasts between the two situations. For example, the static potential associated with the Coulomb interaction is attractive for electrons and repulsive for positrons, while the polarization potential is attractive for both particles. Exchange effects occur only for electron collisions. On the other hand, for positrons, the rearrangement channel of positronium formation can become very important during the interaction.

A detailed discussion of positron-atom/molecule scattering lies outside the scope of this review. The reader is referred to the review by Surko, Gribakin and Buckman (2005) for details of the numerous recent experimental and theoretical developments in this field.

8.3
Review of Theoretical Methods

The ongoing rapid development of computational resources has resulted in a variety of new methods to treat electron/positron collisions with atoms, molecules, and ions. Some of these approaches are, at least in principle, universally applicable over the entire energy range of interest. Consequently, we will no longer use the traditional classification in terms of "low-energy" and "high-energy" methods. Instead, our first separation will be made according to whether an approach is based on the close-coupling expansion or on the Born series. While both expansions, if carried to infinity, would lead to exact results (within limits such as a nonrelativistic or a relativistic formulation), these expansions are cut off or approximated in practical applications and, via the details of the procedure, result in different classifications of a particular method.

Another important aspect concerns the traditional distinction between excitation, including elastic scattering and ionization. As is shown below, theoretical methods originally developed for excitation processes have been very successful in treating ionizing collisions as well. This is sometimes achieved by reinterpreting the results obtained for excitation of a positive-energy pseudostate as an ionization process. However, in that case, special measures are required to extract the information that is actually measured in the corresponding experiments.

8.3.1
The Close-Coupling Expansion

8.3.1.1 The Wave Equation, Scattering Amplitude, and Cross Section

We start by considering elastic scattering and excitation of atoms and atomic ions by electron impact in a nonrelativistic framework and consider the process

$$e^- + A_i \longrightarrow e^- + A_j \qquad (8.25)$$

where A_i and A_j are the initial and final N-electron bound states of the target.

The Schrödinger equation for the $(N+1)$-electron collision system (target electrons plus projectile) for a target with nuclear charge Z is given by

$$H_{N+1}\Psi = E\Psi \tag{8.26}$$

where E is the total energy of the system. In atomic units, the $(N+1)$-electron Hamiltonian H_{N+1} is

$$H_{N+1} = \sum_{i=1}^{N+1}\left(-\tfrac{1}{2}\nabla_i^2 - \frac{Z}{r_i}\right) + \sum_{i>j=1}^{N+1}\frac{1}{r_{ij}} \tag{8.27}$$

Here $r_{ij} \equiv |\boldsymbol{r}_i - \boldsymbol{r}_j|$, with $\boldsymbol{r}_i$ and $\boldsymbol{r}_j$ denoting the vector coordinates of the electrons i and j, respectively. The origin of the coordinate system is taken to be the target nucleus, which is assumed to have infinite mass.

Next, we introduce the target eigenfunctions Φ_i and corresponding eigenenergies w_i by

$$\langle\Phi_i|H_N|\Phi_j\rangle = w_i\delta_{ij} \tag{8.28}$$

where H_N is the target Hamiltonian defined by Eq. (8.27) with $N+1$ replaced by N.

We look for a solution of Eq. (8.26) corresponding to the process defined by Eq. (8.25), where an electron is incident upon the target in some state Φ_i and is scattered leaving the target in some other state Φ_j. The asymptotic form of the wave function in the case of a neutral target is

$$\Psi_i \xrightarrow[r\to\infty]{} \Phi_i \chi_{m_i} e^{ik_i z} + \sum_j \Phi_j \chi_{m_j} \times f_{ji}(\theta,\varphi)\frac{e^{ik_j r}}{r} \tag{8.29}$$

Here χ_{m_i} and χ_{m_j} are the spin eigenfunctions of the incident and scattered electrons and f_{ji} is the scattering amplitude. In numerical calculations, the direction of spin quantization is usually taken to be the incident beam direction (the so-called "collision system"). The wave numbers k_i and k_j of the incident and scattered electrons are related to the total energy E of the collision system by

$$E = w_i + \tfrac{1}{2}k_i^2 = w_j + \tfrac{1}{2}k_j^2 \tag{8.30}$$

The outgoing-wave term on the right of Eq. (8.29) contains contributions from all target states that are energetically allowed, that is, for which $k_j^2 \geq 0$. The remaining states, for which $k_j^2 < 0$, can only occur virtually in the collision. Although they do not contribute to the asymptotic form, they can play an important role during the process giving rise, for example, to intermediate resonance states. Finally, when the target is an ion, the exponents in Eq. (8.29) must be modified by including logarithmic phase factors due to the distortion by the Coulomb field. These factors introduce no essential complications, and hence we shall not include them explicitly below.

The angle-differential cross section for a transition from a state $|\boldsymbol{k}_i, \Phi_i, \chi_{m_i}\rangle$ to a state $|\boldsymbol{k}_j, \Phi_j, \chi_{m_j}\rangle$ can be calculated by considering the incident and scattered fluxes in Eq. (8.29). One finds

$$\frac{d\sigma_{ji}}{d\Omega} = \frac{k_j}{k_i}|f_{ji}(\theta,\varphi)|^2 \tag{8.31}$$

The fundamental problem is to solve the Schrödinger equation (8.26) to obtain the scattering amplitude and the cross section corresponding to the process given by Eq. (8.25). We start by expanding the total wave function in the form

$$\Psi_i^\Gamma(\boldsymbol{X}_{N+1}) = \mathcal{A}\sum_j \overline{\Phi}_j^\Gamma(\boldsymbol{X}_N;\widehat{\boldsymbol{r}}_{N+1}\sigma_{N+1})F_{ji}^\Gamma(r_{N+1}) + \sum_j \chi_j^\Gamma(\boldsymbol{X}_{N+1})a_{ji}^\Gamma \tag{8.32}$$

Here $\boldsymbol{X}_{N+1} = \boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_{N+1}$ represents the space and spin coordinates of all $N+1$ electrons, $\boldsymbol{x}_i \equiv \boldsymbol{r}_i\sigma_i$ denotes the space and spin coordinates of the ith electron, and $\mathcal{A}$ is the operator that antisymmetrizes the first summation with respect to any pair of electrons in accordance with the Pauli exclusion principle. The channel functions $\overline{\Phi}_j^\Gamma$ are obtained by coupling the orbital and spin angular momenta of the target with those of the scattered electron to form eigenstates of $\Gamma = LSM_LM_S$ and parity π that are conserved in the collision. The role of the square-integrable, fully antisymmetrized correlation functions χ_j^Γ is further discussed below.

Equation (8.32) is the so-called "close-coupling expansion." To be complete, it should include all discrete bound states as well as the continuum states of the target. In practice, of course, exact completeness is impossible to achieve in a numerical treatment, and hence the expansion has to be cut off. In the simplest case, only one target state might be retained, allowing for elastic scattering from this state to be described in the "static exchange approximation." Traditionally, the expansion was cut after a few discrete target states, thereby enabling the calculation of transitions between all the states retained in the expansion. However, it was soon realized that such a severe cut in the expansion typically limits the applicability of the method to "low" energies, generally below the threshold of the highest target state kept in the expansion. Consequently, significant work has been devoted in recent years to account in some approximate way for the high-lying discrete and even the continuum states of the target. This resulted in the convergent close-coupling (CCC) method, originally developed by Bray and Stelbovics (1992), and the R-matrix with Pseudostates (RMPS) method proposed by Bartschat *et al.* (1996b) based on the same idea. Both methods are further discussed below.

By substituting Eq. (8.32) into the Schrödinger equation (8.26), projecting onto the channel functions $\overline{\Phi}_j^\Gamma$ and onto the square-integrable functions χ_j^Γ, and eliminating the coefficients a_{ji}^Γ, one obtains coupled integro-differential equations for the reduced radial functions F_{ji}^Γ representing the motion of the scattered electron. These are of the form

$$\left(\frac{d^2}{dr^2} - \frac{l_j(l_j+1)}{r^2} + \frac{2Z}{r} + k_j^2\right)F_{ji}^\Gamma(r) = 2\sum_l \left(V_{jl}^\Gamma + W_{jl}^\Gamma + X_{jl}^\Gamma\right)F_{li}^\Gamma(r) \tag{8.33}$$

where l_j is the orbital angular momentum of the scattered electron and V_{jl}^Γ, W_{jl}^Γ, and X_{jl}^Γ are partial-wave decompositions of the local direct, nonlocal exchange, and nonlocal correlation potentials, respectively.

The direct potential can be written as

$$V_{ij}^\Gamma(r_{N+1}) = \left\langle \overline{\Phi}_i^\Gamma(\boldsymbol{X}_N;\, \widehat{\boldsymbol{r}}_{N+1}\sigma_{N+1}) \right| \sum_{i=1}^N \frac{1}{r_{i\,N+1}} \left| \overline{\Phi}_j^\Gamma(\boldsymbol{X}_N;\widehat{\boldsymbol{r}}_{N+1}\sigma_{N+1}) \right\rangle \tag{8.34}$$

where the integral is taken over all $N+1$ electron space and spin coordinates, except for the radial coordinate of electron "$N+1$." This potential has the asymptotic form

$$V_{ij}^{\Gamma}(r) = \frac{N}{r}\delta_{ij} + \sum_{\lambda=1}^{\lambda_{\max}} a_{ij}^{\lambda} r^{-\lambda-1}, \quad r > a \tag{8.35}$$

where a is the range beyond which the bound orbitals in $\overline{\Phi}_i^{\Gamma}$ and $\overline{\Phi}_j^{\Gamma}$ are negligible. The long-range potentials with $\lambda \geq 1$ play an important role in low-energy electron–atom scattering.

The exchange and correlation potentials, unlike the direct potential, are both nonlocal, with the exchange potential vanishing exponentially for large r. Explicit expressions for these potentials are complicated and, except for hydrogen-like targets, are not written down explicitly in practice. Instead, they are calculated by general computer programs.

To determine the cross section, we look for solutions of Eqs. (8.33) satisfying $\boldsymbol{K}$-matrix asymptotic boundary conditions:

$$F_{ji}^{\Gamma}(r) \xrightarrow[r\to\infty]{} k_j^{-1/2}(\sin\theta_j\delta_{ji} + \cos\theta_j K_{ji}^{\Gamma})$$

for open channels ;

$$F_{ji}^{\Gamma}(r) \xrightarrow[r\to\infty]{} 0,$$

for closed channels (8.36)

Here

$$\theta_j = k_j r - \tfrac{1}{2} l_j \pi + \frac{z}{k_j}\ln 2k_j r + \sigma_j \tag{8.37}$$

with $z = Z - N$ as the residual charge on the ion and $\sigma_j = \arg\Gamma(l_j + 1 - iz/k_j)$ denoting the Coulomb phase shift. The (scattering) $\boldsymbol{S}$-matrix is related to the (transition) $\boldsymbol{T}$-matrix and the (reactance) $\boldsymbol{K}$-matrix with elements defined by Eqs. (8.36) by the matrix equations

$$\boldsymbol{S}^{\Gamma} = \boldsymbol{T}^{\Gamma} - \boldsymbol{1} = \frac{\boldsymbol{1} + i\boldsymbol{K}^{\Gamma}}{\boldsymbol{1} - i\boldsymbol{K}^{\Gamma}} \tag{8.38}$$

The hermiticity and time-reversal invariance of the Hamiltonian ensure that $\boldsymbol{K}^{\Gamma}$ is real and symmetric while $\boldsymbol{S}^{\Gamma}$ is unitary and symmetric.

The scattering amplitude defined by Eq. (8.29) and hence the differential cross section can be readily related to the $\boldsymbol{S}$-matrix. The resultant expression is given by Burke (1985). Computer programs to calculate scattering amplitudes, the DCS, and many other observables were published by Bartschat and Scott (1983), Bartschat (1983); Bartschat (1996), and Grum-Grzhimailo (2003). The total cross section is obtained by averaging the differential cross section over initial spin states, summing over final spin states, and integrating over all scattered electron angles. One obtains

$$\sigma_{\text{tot}}(i \to j) = \frac{\pi}{k_i^2} \sum_{\substack{LS\pi \\ l_i l_j}} \frac{(2L+1)(2S+1)}{2(2L_i+1)(2S_i+1)} \times |S_{ji}^{\Gamma} - \delta_{ji}|^2 \tag{8.39}$$

for a transition from an initial target state $\alpha_i L_i S_i$ to a final target state $\alpha_j L_j S_j$, where α_i and α_j represent any additional quantum numbers that are required to define the initial and final target states. It is also useful to define the collision strength by

$$\Omega(i,j) = k_i^2(2L_i+1)(2S_i+1)\sigma_{\text{tot}} \times (i \to j) \tag{8.40}$$

It is dimensionless and symmetric with respect to interchange of the initial and final states denoted by i and j.

There are many different ways to solve the close-coupling equations in practice. These include packages based on the R-matrix method, on the reduction of Eqs. (8.33) to linear algebraic equations, on the noniterative integral equations method, and on the Kohn variational method. These computational methods and early associated program packages were reviewed by Burke and Seaton (1971) and by Burke and Eissner (1983). The R-matrix method, in particular, has been applied in numerous calculations. An overview of the method and key papers in the development can be found in Burke and Berrington (1993) and in Burke, Noble and Burke (2006). The most important recent developments of the R-matrix method include the RMPS formulation mentioned above Bartschat *et al.* (1996a), Gorczyca and Badnell (1997), and an entirely independent formulation developed by Zatsarinny and coworkers. The program package BSR (Zatsarinny (2006)) is based on the use of basis splines ("B-splines") as a universal and effectively complete basis to expand the wave function of the projectile inside the R-matrix box. In addition, great flexibility is achieved by allowing for the use of term-dependent, nonorthogonal sets of orbitals to describe the target structure. As is shown by the examples below, the method is particularly advantageous in the treatment of electron collisions with complex atoms, such as noble gases and target states involving several open shells. In these cases, it is well worth to pay the price of a more complicated setup of the Hamiltonian matrix, in return for a highly accurate target description with a relatively small number of individually optimized configurations.

8.3.1.2 **Extension of the Close-Coupling Method to Intermediate and High Energies**

As mentioned above, a severe limitation to the applicability of the close-coupling method was the traditional cut-off of the expansion after a few low-lying target states. Early attempts to address this problem augmented the expansion (8.32) by adding a few well-chosen pseudostates to represent the remaining infinity of omitted eigenstates (Burke and Schey (1962); Damburg and Karule (1967); Burke and Webb (1970); Callaway and Wooten (1973)). These pseudostates are not target eigenstates but instead are chosen to optimize the representation of the short-range correlation effects or long-range polarization effects. In this way, part of the continuum is included in expansion (8.32), and the pseudostates allow approximately for loss of flux into all open channels including the ionizing channels.

Although a number of calculations had been carried out using this approach, particularly for e–H scattering, early calculations suffered from the appearance of unphysical pseudostate thresholds and pseudoresonances in the intermediate energy region of interest. Burke, Noble and Scott (1987) proposed an intermediate-energy R-matrix (IERM) theory, in which two electrons are allowed to occupy continuum orbitals in the wave function expansion. This method gave accurate results for electron and positron scattering by hydrogen atoms, although special care had to be taken in the averaging of unphysical structures in the $\boldsymbol{T}$-matrix elements at intermediate energies.

Bray and Stelbovics (1992) finally achieved a breakthrough by developing the CCC method. The basic idea is to include a large number of systematically generated square-integrable pseudostates in the close-coupling expansion and check for convergence of the final results. Such L^2 methods were already suggested and reviewed by Reinhardt (1979) and Broad (1983), but they met with various difficulties at the time. The CCC method was formulated in momentum space, based on the Lippman-Schwinger equation for the $\boldsymbol{T}$-matrix. To date, the method has been applied with great success to electron and positron collisions with hydrogen-like Bray and Stelbovics (1995) and helium-like Fursa and Bray (1995) systems, including electron-impact ionization as well as single and double ionization by photon impact Bray *et al.* (2002). If necessary, inner shells are represented by sophisticated core potentials. The most recent extension of the method is a fully relativistic formulation for scattering from quasi-one-electron systems such as Cs Fursa and Bray (2008).

An equivalent method based on the R-matrix approach in coordinate space is the "R-matrix with Pseudostates" (RMPS) method proposed by Bartschat *et al.* (1996b) and further developed by Gorczyca and Badnell (1997). Once again, many square-integrable states, obtained by diagonalizing the target hamiltonian in a given basis (e.g., Sturmian or Laguerre type), are included in the close-coupling expansion. When used in connection with the standard expansion of the projectile wave function in terms of a basis set, the method is generally restricted to low and intermediate energies. However, the computer program is general and hence accurate results can readily be obtained for complex targets as well.

The above developments have, to a large extent, replaced the use of optical-potential methods based on the close-coupling expansion. However, semiempirical potentials are sometimes employed to represent the effect of inner closed shells, core polarization, and even exchange. Some examples are discussed below.

8.3.1.3 Inclusion of Relativistic Effects

As the nuclear charge Z of the target increases, relativistic effects become important even for low-energy electron scattering. There are two ways in which relativistic effects play a role. First, there is a direct effect corresponding to the relativistic distortion of the wave function describing the scattered electron by the strong nuclear Coulomb potential. Second, there is an indirect effect caused by the change in the charge distribution of the target due to the use of relativistic target wave functions.

For atoms and ions with small and intermediate Z values, the scattering calculations can first be performed in LS-coupling; the $\boldsymbol{K}$-matrices are subsequently recoupled to yield transitions between fine-structure levels. For atoms and ions with high$Z$ values, relativistic terms must be retained in the Hamiltonian. One method of achieving this is to use the Breit–Pauli Hamiltonian

$$H_{N+1}^{\mathrm{BP}} = H_{N+1}^{\mathrm{NR}} + H_{N+1}^{\mathrm{REL}} \tag{8.41}$$

where H_{N+1}^{NR} is the nonrelativistic Hamiltonian given by Eq. (8.27) and H_{N+1}^{REL} contains the one-body spin–orbit, Darwin, and mass correction terms, as well as possibly two-body relativistic terms. The total wave function is expanded in a form analogous to Eq. (8.32), except that the target states must also be generated using the Breit–Pauli Hamiltonian, and the wave function is an eigenstate of the total electronic angular momentum J, its z-component M_J, and the parity π rather than of LSM_LM_S and π.

Alternatively, for high-Z atoms and ions, the Dirac-Coulomb Hamiltonian

$$H^D_{N+1} = \sum_{i=1}^{N+1}\left(c\boldsymbol{\alpha}\cdot\boldsymbol{p}_i + \beta c^2 - \frac{Z}{r_i}\right) + \sum_{i>j=1}^{N+1}\frac{1}{r_{ij}} \tag{8.42}$$

may be used, where $\boldsymbol{\alpha}$ and β are the usual Dirac matrices and c is the speed of light.

Figure 8.18 showed two examples of close-coupling results obtained with the Breit–Pauli R-matrix method for e − Hg scattering by Bartschat *et al.* (1984), who included the $(6s^2)^1S^0$, $(6s6p)^3P^o_{0,1,2}$, and $(6s6p)^1P^o_1$ target states in the expansion of the total wave function, and with the fully relativistic CCC (Fursa and Bray (2008)) and the fully relativistic B-spline R-matrix method (Zatsarinny and Bartschat (2008)) for elastic e − Cs collisions. The good agreement between experiment and theory indicates that the three main effects of strong channel coupling, electron exchange, and the spin–orbit interaction are correctly represented by the theories in these cases. However, these are still comparatively simple targets resembling quasi-one-electron and quasi-two-electron systems. Significantly, more challenges are expected for heavy noble-gas targets such as Kr and Xe, or for cases in which inner-shell excitation plays an important role.

8.3.1.4 **Illustrative Results**

Figure 8.19 shows the angle-integrated cross section for elastic scattering and electron-impact excitation from the $(1s)^2S$ state of atomic hydrogen. The excellent agreement between predictions from the CCC, RMPS, and IERM methods, as well as with the experimental data of Williams (1988), indicates that these sophisticated methods can indeed solve this problem to a very high degree of accuracy.

Stepanovic *et al.* (2006) recently measured the angle-integrated cross sections for electron-impact excitation of the 3^3S and 3^1S states of helium shown in figure 8.20. For a direct comparison with the experimental data, the 69-state B-spline R-matrix (BSR-69) results, originally generated on a very fine energy mesh with a stepsize of 10^{-5} Ry, were convoluted with a Gaussian function of width 37 meV (FWHM), corresponding to the energy resolution in the experiment. The dashed line in the top graph for the 3^3S state represents the theoretical predictions for direct excitation, while the solid lines represent the emission cross sections, that is, including the cascade contributions from the higher-lying $n = 3, 4, 5$ states. The experimental data were normalized to the BSR-69 results with cascade contribution at 23.20 eV for both the 3^3S and 3^1S states, because the cross sections exhibit only a smooth energy dependence around this energy and hence the energy resolution does not play a role. For a detailed analysis of the resonances (see Stepanovic *et al.* (2006)), the right part of the figure exhibits the theoretical excitation cross sections without convolution with the experimental energy resolution.

Figure 8.21 exhibits results for the production of metastable neon atoms.

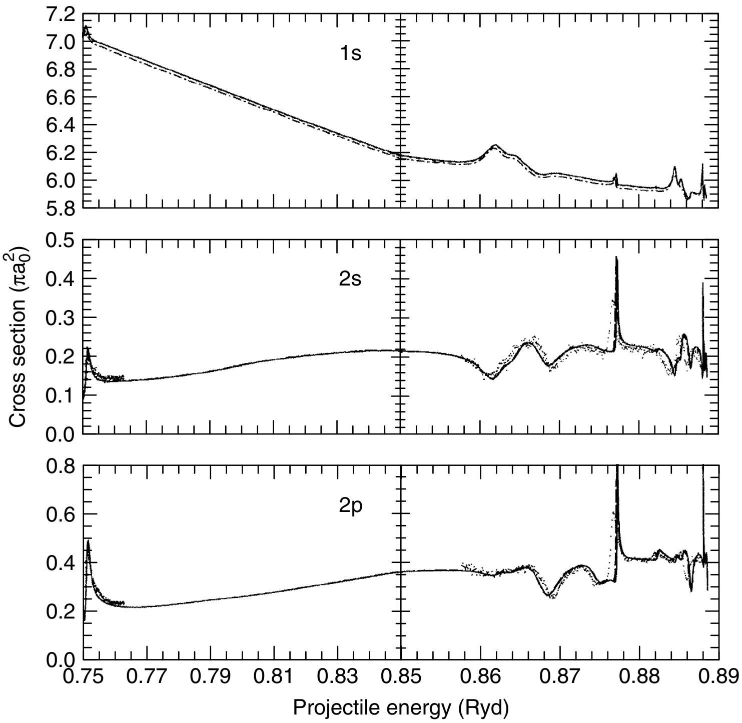

Fig. 8.19 Elastic and excitation cross sections for e–H scattering at incident electron energies between the $n = 2$ and $n = 3$ thresholds. The RMPS (solid line), IERM (dashed line), and CCC (dash-dotted line) curves are barely distinguishable. The small dots represent the experimental data of Williams (1988). (From Bartschat *et al.* (1996c).)

After renormalizing the published experimental data of Buckman *et al.* (1983) (within the given overall experimental uncertainty) and including the cascade contributions, the semirelativistic BSR method of Zatsarinny and Bartschat (2004) obtains essentially perfect agreement with experiment regarding the energy dependence in the near-threshold region. These results represent a considerable improvement over previous theoretical predictions. The predicted metastable cross sections were then used to calibrate and interpret new experimental data obtained with an energy resolution of ≈4 meV by Bömmels *et al.* (2005). For example, a very sharp Feshbach resonance was theoretically predicted and experimentally confirmed at 18.527 eV.

The enormous importance of FeII, the singly ionized species of the iron element, for astronomical observations is well known. A meaningful interpretation of the spectral lines critically depends on an accurate knowledge of the electron-induced collision strengths, as well as the so-called "effective collision strengths," which are obtained by integrating the energy-dependent results over a Maxwellian distribution for a range of electron temperatures. Because

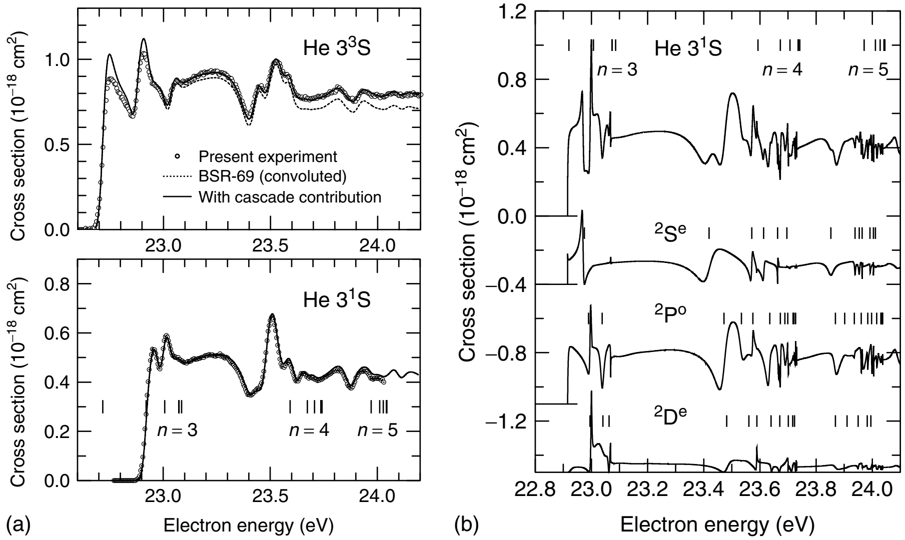

Fig. 8.20 (a) Angle-integrated cross sections for electron-impact excitation of the 3^3S and 3^1S states in helium. The theoretical results without (dashed line) and with (solid line) cascade contributions were convoluted with a Gaussian of 37 meV (FWHM). The vertical bars in the lower panel represent the thresholds for the He target states. (b) Angle-integrated cross section for electron-impact excitation of the 3^1S state. The thick solid line at the top exhibits the predictions from a 69-state BSR model summed over all partial waves, while the remaining thin solid lines (offset to increase the visibility) show the most important individual partial-wave contributions. The vertical bars represent the thresholds for the He target states at the top and prominent He$^-$ resonances found in a detailed partial-wave analysis. (From Stepanovic *et al.* (2006).)

of the importance of these data and the complete lack of experiments, major theoretical and computational efforts have been devoted to this system for more than two decades.

Figure 8.22 exhibits results for the collision strength for the (3d^{6}4s)a^{6}D – (3d^7)a^{4}F transition. Predictions of Ramsbottom *et al.* (2004) and Zatsarinny and Bartschat (2005) for contributions to the collisions strength from selected partial-wave symmetries are compared and exhibit overall satisfactory agreement. The difference in the intensity of some narrow resonances may be caused by the fact that finer energy steps of 10^{-5} Ry were used in the BSR calculations than the 10^{-4} Ry energy mesh chosen by Ramsbottom *et al.* (2004). A notable exception is a broad structure in the ^{5}D^e partial wave around 0.15 Ry. While there are differences at such detailed level, good overall agreement among the calculations was obtained after summing up the individual partial-wave contributions and integrating over a Maxwellian distribution. Because there are no experimental data available for these cases, such independent checks are very important in assessing the reliability of the data before providing them to the astrophysical community.

Having established reliable results in a nonrelativistic framework, an important next step involves fine-structure

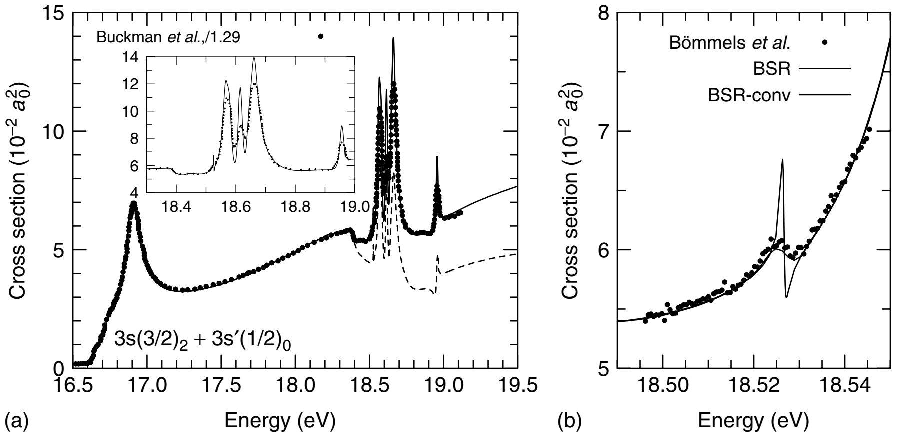

Fig. 8.21 (a) Angle-integrated cross section for production of neon atoms in the metastable $3s[3/2]_2$ and $3s'[1/2]_0$ states (from Zatsarinny and Bartschat (2004).) The experimental data of Buckman *et al.* (1983) (thick dots) were re-normalized by a factor of 1.29 to provide a good visual fit to the BSR theory at energies just above the excitation threshold. The solid line includes the cascade contributions from all the states included in the model, while the thin dotted line (starting around 18.4 eV) represents the results without cascades. (b) A very narrow resonance predicted by Zatsarinny and Bartschat (2004) and later found in the experiment of Bömmels *et al* (2005).

transitions. Ramsbottom *et al.* (2007) recently carried out a 262-state Breit–Pauli *R*-matrix calculation with about 1800 coupled channels to study fine-structure forbidden transitions in e–FeII collisions. This knowledge is required in many astrophysical applications.

FeII is just one example of a target with an open d-shell, which represents a major challenge to atomic collision theory. On the other hand, collisions systems involving such targets are very important in practical applications. An example is e – Mo, which may be a suitable candidate for a mercury-free lighting source (Petrov *et al.* (2004); Bartschat *et al.* (2004a)). Another case of interest involves electron collisions with tungsten and its ions, which are important impurities in fusion devices such as ITER.

Finally, as mentioned above, an important development has been the extension of the close-coupling method to intermediate and even high energies, and the inclusion of relativistic effects, either by recoupling of nonrelativistic results, perturbatively through the Breit–Pauli hamiltonian, or in a fully relativistic treatment. Figure 8.23 shows the total cross section for electron collisions with Cs atoms. Overall, there is good agreement between results from a nonrelativistic CCC model, a semirelativistic Breit–Pauli *R*-matrix approach, and a fully relativistic Dirac-based *B*-spline *R*-matrix treatment.

8.3.1.5 **Resonances and Quantum Defect Theory**

We have already seen in previous sections that resonances play an important role in low-energy scattering of electrons by atoms and ions. The general theory of resonances has been discussed by Fano (1961), Fano (1983),

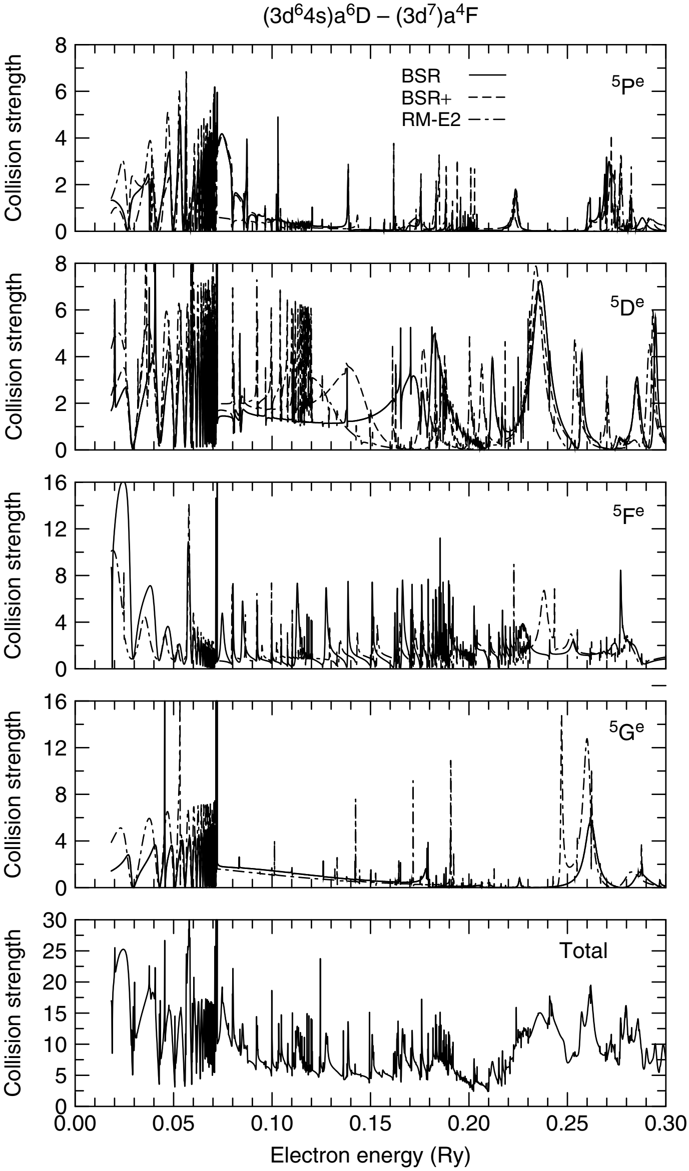

Fig. 8.22 Important partial-wave contributions, indicated in the top four panels, and total (bottom) collision strength for the electron-induced transition (3d^{6}4s)^{6}D – (3d^7)^{4}F in Fe$^+$. (From Zatsarinny and Bartschat (2005).)

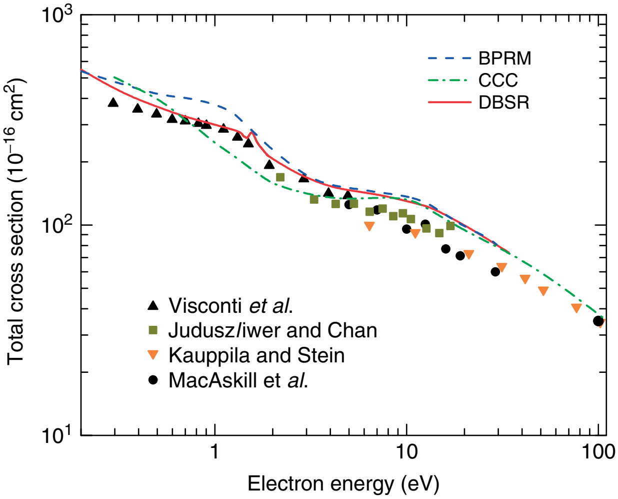

Fig. 8.23 Total electron scattering cross section from the ground $(6s)^2S$ ground state of Cs. The 12-state DBSR results of Zatsarinny and Bartschat (2008) are compared with various sets of experimental data (Visconti, Slevin and Rubin (1970), Jaduszliwer and Chan (1992), Kauppila and Stein (2001), MacAskill *et al.* (2002)), as well as predictions from a 40-state semirelativistic Breit–Pauli *R*-matrix (BPRM)calculation by Bartschat and Fang (2000) and a nonrelativistic CCC model presented by MacAskill *et al.* (2002). (From Zatsarinny and Bartschat (2008).)

Burke (1968), Schulz (1973a), and Schulz (1973b). Here, we review their principal features.

It is useful to distinguish two types of resonances, namely, open-channel or "shape" resonances, and closed-channel or "Feshbach" resonances. Shape resonances occur when the effective potential between the electron and the target has a characteristic shape with an inner attractive well and an outer repulsive barrier, the latter usually caused by the centrifugal repulsion. Examples of such resonances include a dominant *p*-wave shape resonance in low-energy elastic e – Mg collisions Bartschat *et al.* (2004b) and a broad *d*-wave shape resonance in e – CH_4 scattering Gianturco and Scialla (1987).

On the other hand, Feshbach resonances occur for incident electron energies just below excitation thresholds. The scattered electron is captured temporarily into a bound state with the target in an excited state. We have seen several examples of such resonances in the previous sections.

Calculations based on expansion (8.32) are a very convenient and appropriate way of describing Feshbach resonances, provided that the relevant open and closed channels are included in the expansion. For example, bound states caused by the long-range attractive Coulomb potential in the closed channels for electron–ion scattering give rise to Rydberg series of resonances when the coupling to the open channels is included.

One of the motivations for the development of multichannel quantum defect theory (MQDT) (Seaton (1958); Seaton (1983)) is to treat entire series of resonances rather than an individual resonance. Seaton showed that the $\boldsymbol{K}$-matrix defined by Eq. (8.36) can be written as

$$\boldsymbol{K}^{\Gamma} = \boldsymbol{K}^{\Gamma}_{\mathrm{oo}} - \boldsymbol{K}^{\Gamma}_{\mathrm{oc}}(\boldsymbol{K}^{\Gamma}_{\mathrm{cc}} + \tan\pi\boldsymbol{\nu}_c)^{-1}\boldsymbol{K}^{\Gamma}_{\mathrm{co}} \tag{8.43}$$

where the elements of the submatrices $\boldsymbol{K}^{\Gamma}_{\mathrm{oo}}$, $\boldsymbol{K}^{\Gamma}_{\mathrm{oc}}$, $\boldsymbol{K}^{\Gamma}_{\mathrm{co}}$, and $\boldsymbol{K}^{\Gamma}_{\mathrm{cc}}$ are obtained by analytically continuing the $\boldsymbol{K}$-matrix from above the threshold to which the resonances converge to below this threshold, where "o" refers to the channels that remain open below this threshold, and "c" refers to the channels that become closed. In these closed channels ($k_i^2 < 0$), the components ν_i of the vector $\boldsymbol{\nu}_c$ are defined by

$$k_i^2 = -(Z-N)^2/\nu_i^2 \tag{8.44}$$

The factor $\tan\pi\boldsymbol{\nu}_c$ causes the last term in Eq. (8.43) to have an infinite series of poles that give rise to the Feshbach resonances. When the $\boldsymbol{K}$-matrix is calculated by solving Eqs. (8.36) at a few energies above threshold, it can be extrapolated to yield an infinite series of resonances below threshold. This approach was extended by Gailitis (1963) to predict the average behavior of electron–ion cross sections in resonance regions.

8.3.1.6 **Dielectronic Recombination**

It was pointed out by Burgess (1964); Burgess (1965) that Rydberg resonance series play a fundamental role in dielectronic recombination. This process is illustrated, for example, in the case of $\mathrm{e} - \mathrm{C}^{3+}$ scattering by the equation

$$\begin{aligned}\mathrm{e}^- + \mathrm{C}^{3+}(1\mathrm{s}^2 2\mathrm{s}) &\rightarrow \mathrm{C}^{2+*}(1\mathrm{s}^2 2\mathrm{p}\; nl)\\ &\rightarrow \mathrm{C}^{2+}(1\mathrm{s}^2 2\mathrm{s}\; nl) + h\nu\end{aligned} \tag{8.45}$$

The electron is captured into a member of a Rydberg series of resonances converging to the $1\mathrm{s}^2 2\mathrm{p}$ excited state of the C^{3+} ion. These resonances can stabilize by radiative decay, thereby leaving the C^{2+} ion in an excited bound state. This process can often yield dielectronic recombination coefficients α^{DR} that are two orders of magnitude larger than radiative recombination coefficients, basically because of the very large number of resonance levels that contribute.

In the isolated-resonance approximation, α_i^{DR} is given by

$$\alpha_i^{\mathrm{DR}} = \left(\frac{2\pi}{kT}\right)^{3/2} \sum_n \frac{g_n}{2g_i} \frac{\Gamma_n^a \Gamma_n^r}{\Gamma_n^a + \Gamma_n^r} e^{-E_n/kT} \tag{8.46}$$

where i refers to the initial state of the target ion and n to the intermediate resonance state. The coefficient g is the statistical weight of the state, Γ_n^a is the autoionization width, Γ_n^r is the radiative width of the resonance state, and E_n is the energy of the resonance state relative to the ground state of the target ion. The velocity distribution of the electrons is assumed to be Maxwellian corresponding to a temperature T. The summation over n in Eq. (8.46) converges for large n because Γ_n^a behaves as n^{-3} along a Rydberg resonance series while Γ_n^r becomes independent of n. In practice, very high n values often contribute.

Dielectronic recombination measurements have been made on a number of ions, while many calculations have been carried out illustrating the importance of this recombination process in hot gaseous plasmas. More information, including an extensive list of references, can be found in Pindzola, Griffin and Badnell (2006).

8.3.2
Born Series Methods

8.3.2.1 Elastic Scattering and Excitation of Atoms and Ions at Intermediate and High Energies

We now consider electron–atom and electron–ion scattering at electron impact energies greater than the ionization threshold of the target. In this case, an infinite number of channels are open, so that they cannot all be included in the expansion of the total wave function. Several approaches have been developed to treat scattering at these energies. Before the recent extensions of traditionally low-energy methods based on the close-coupling expansion, variants of the Born approximation were developed to address such problems. Being computationally much less demanding than CCC, RMPS, and the "initial-value methods" to be discussed below, the "distorted-wave"(DW) method in particular continues to be of practical importance for applications to complex targets, especially for ionization processes. The method has also proven to be an accurate way of calculating partial-wave cross sections for high angular momenta, and thus to obtain converged results with the number of partial waves. Finally, by studying the effect of different distortion potentials, including varying orders of the perturbation, and moving (parts of) the perturbation to the exact treatment by including it into the calculation of the scattering wave function, it is possible to study the importance of individual physical effects on the outcome of a collision process. Such effects may include the polarization of the atomic charge cloud due to the incident projectile, exchange, absorption (i.e., loss of flux into inelastic channels), or the long-range Coulomb interaction between three (or more) charged particles in the final state.

8.3.2.2 The Born Series

In the "high-energy" domain, which extends from several times the ionization threshold upward, methods based on the Born series are appropriate. Ignoring exchange for the moment, the Born series for the direct scattering amplitude can be written as (Walters (1984); Joachain (1987))

$$f = \sum_{n=1}^{\infty} f_{\mathrm{B}n} \tag{8.47}$$

The nth Born term $f_{\mathrm{B}n}$ contains the interaction V_{pt} between the scattered electron and the target atom n times and the direct Green's operator, $G_0^+ = (E - K_{\mathrm{p}} - H_N + i\varepsilon)^{-1}$, $n-1$ times. Here H_N is again the N-electron target hamiltonian while K_{p} is the kinetic energy operator for the projectile.

It is important to retain consistently all terms in the Born series with similar energy and momentum-transfer ($\Delta = |\boldsymbol{k}_i - \boldsymbol{k}_j|$) dependences. For elastic scattering, the scattering amplitude converges to the first Born approximation for all Δ, but at lower energies, it is necessary to include $\mathrm{Re}\{f_{\mathrm{B3}}\}$ as well as the second Born terms to obtain the cross section correct to k^{-2}. In the forward direction, convergence to the first Born approximation is slow because of contributions from $\mathrm{Im}\{f_{B2}\}$, which allow for loss of flux into the open channels.

For inelastic scattering, the first Born approximation does not give the correct high-energy limit for large Δ. Instead, this comes from $\mathrm{Im}\{f_{B2}\}$. Physically we can understand this by noting that inelastic scattering into large scattering angles involves a collision with the nucleus, followed or preceded by an inelastic collision with the bound electron to give excitation. In the forward direction, $\mathrm{Re}\{f_{B3}\}$ must again be retained to yield the high-energy limit correct to k^{-2}.

Because the third Born term is difficult to calculate directly, Byron and Joachain (see Joachain (1987)) suggested that, to third order, the scattering amplitude should be calculated using the eikonal Born series (EBS)

$$f_{\mathrm{EBS}} = f_{\mathrm{B1}} + f_{\mathrm{B2}} + f_{\mathrm{G3}} + g_{\mathrm{Och}} \tag{8.48}$$

where f_{G3} is the third-order term in the expansion of the Glauber amplitude (Glauber (1959)) in a power series of the projectile–target interaction V_{pt}, while g_{Och} is the Ochkur electron exchange amplitude (Ochkur (1964)). The EBS method has been very successful when perturbation theory converges rapidly, that is, at high energies, at small and intermediate angles, and for light atoms.

8.3.2.3 The Distorted-Wave (DW) Method

Distorted-Wave (DW) methods are characterized by the fact that the interaction is separated into two parts, one of which is treated exactly while the other is included using first-order perturbation theory. A semirelativistic first-order DW approximation (DWBA) was introduced by Madison and Shelton (1973) and later modified by Bartschat and Madison (1987) to treat electron collisions with heavy noble gases and also with mercury. Other variants include the first-order many-body theory (FOMBT) of the Los Alamos group Machado, Leal and Csanak (1982), the semirelativistic version developed and described by Dasgupta, Blaha and Giuliani (2000), and the relativistic distorted-wave (RDW) method of the Toronto group Zuo, McEachran and Stauffer (1991). The basic idea behind all these methods is to calculate distorted waves for the projectile electron by solving the differential equation

$$\left[\frac{d^2}{dr^2} - \frac{l(l+1)}{r^2} - 2\left\{U(r) + V_r(r) - E\right\}\right] \chi_{E,l}(r) = 0 \tag{8.49}$$

Here $U(r)$ is the static Coulomb potential, often modified by including terms to account for electron exchange and the charge distortion (polarization) of the target, while V_r contains relativistic effects. [Instead of (8.49), the fully relativistic RDW solves the corresponding Dirac equation.] The distorted waves are then used to calculate transition matrix elements, treating to first order the part of the projectile–target interaction not explicitly included in the distortion potentials.

A detailed description of the DWBA method, including a computer program, was provided by Madison and Bartschat (1996). Here we only mention the principal advantages and disadvantages. The DWBA approach has proven particularly useful for electron scattering by highly ionized ions where it is assumed that only the two channels corresponding to

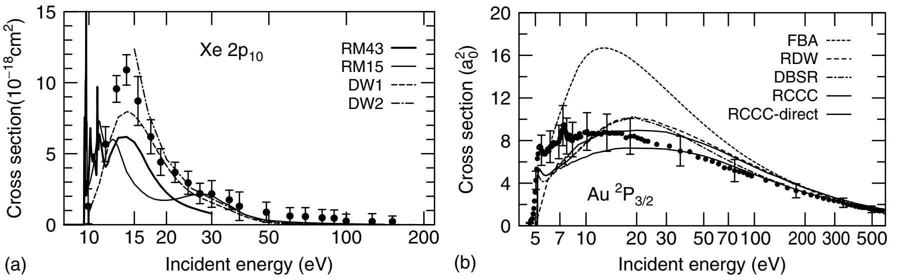

Fig. 8.24 Angle-integrated cross section for electron-impact excitation of the ($5p^5 6p$) "$2p_{10}$" state in Xe (a) and the $(6p)^2 P_{3/2}$ state in Au (b). The figures show the comparison of various DW and Breit–Pauli *R*-matrix (RM) predictions for Xe and results from a plane-wave first-order Born approximation (FBA), as well as the relativistic distorted-wave RDW, relativistic Dirac *B*-spline *R*-matrix (DBSR), and relativistic convergent close-coupling (RCCC) for Au with experimental data from the Wisconsin (Xe) and Flinders (Au) groups. The difference between the RCCC and RCCC-direct results is due to cascade effects. (Adapted from Bartschat, Dasgupta and Madison (2004) for Xe and from Maslov *et al.* (2008) for Au.)

the initial and final states in Eq. (8.32) need to be considered. The dominant diagonal potentials are treated exactly and the off-diagonal potentials coupling these channels are accounted for to first order. The method becomes more accurate at intermediate energies as $z = Z - N$ increases. As mentioned previously, the DWBA has also proven to be an accurate way of calculating partial-wave cross sections for high angular momenta. The angular momentum barrier in this case depresses the importance of the coupling potential.

The DWBA approach can also be a useful way of predicting the total and differential cross sections of inelastic electron–atom at intermediate energies well removed from threshold. Furthermore, the method is fast and relatively easy to implement. In principle, it allows for significant flexibility in the target description for the initial and final states because the orbitals can be specifically optimized for the states of interest in a given transition.

The major problem with the DW approach is the fact that channel coupling is neglected. Consequently, the method cannot account for near-threshold Feshbach-type resonances, it is generally much less reliable for optically forbidden than for optically allowed transitions, and further problems can occur if the calculation is performed without explicit unitarization of the scattering matrix; see Dasgupta *et al.* (2001).

Figure 8.24 exhibits a comparison of results for angle-integrated cross sections obtained in a variety of Born-based and close-coupling-based approximations. In both cases, the first-order DW models do quite well compared to the close-coupling approximations, while the first-order plane-wave approach generally overestimates the cross section near the maximum. However, in many cases of practical interest, the (plane-wave) FBA can still be used to get reasonably accurate results for excitation of optically allowed transitions by performing a rescaling transformation of the results as suggested by Kim (2001).

8.3.3
Initial-Value Methods

In this section, we briefly discuss the basic idea behind two highly successful methods developed using a somewhat different philosophy. These are the TDCC and the ECS approaches. The goal of both methods is the construction of a highly accurate numerical solution of the Schrödinger equation by propagating a known initial state. The matching to sometimes highly complicated boundary conditions, especially for the ionization processes to be discussed below, is avoided through a different way of extracting the relevant information from the wave function after large propagation times or sufficiently far away from the interaction region.

8.3.3.1 Time-Dependent Close-Coupling (TDCC)

With the recent development of massively parallel supercomputers, the use of more direct numerical approaches has become very popular. One example is the TDCC method recently reviewed by Pindzola *et al.* (2007). For a target with one or two electrons outside a closed shell, they derive the time-dependent close-coupling equations for the radial parts of the wave function describing the projectile and the active target electron or electrons. For each partial-wave symmetry, these equations are propagated in time over a two- or three-dimensional lattice.

The initial wave function is written as the properly symmetrized product of a bound state, represented on the lattice, and a Gaussian wavepacket for the projectile. The width of the package is chosen in such a way that any overlap between the projectile and the target wave function before the collision can be neglected. The electron wave function is then propagated for a sufficiently long time to ensure that the final state after the collision has been reached. However, note that the propagation time has to be small enough to ensure that boundary effects, due to collisions with the wall of the lattice, do not disturb the result. Cross sections for elastic scattering, excitation and ionization are obtained from projections of the final-state wave function on individual asymptotic channel functions.

The principal advantage of the method lies in the fact that the radial part of the wave function, which contains all the dynamics of the collision, is not described by a finite basis set as in the time-independent close-coupling approaches discussed above. On the other hand, the computational resources needed for such calculations are extensive. Hence, the method is so far effectively restricted to (quasi-)one- and (quasi-)two-electron targets. Also, often only the lowest few partial waves are treated in this way, while contributions from higher partial waves are handled by simpler methods, such as the first-order DWBA approximation mentioned above.

Figure 8.25 shows the development of a wavepacket propagated in the TDCC approach. This particular example is for the $^1S^e$ partial-wave symmetry in $e - Be^+$ collisions at an incident projectile energy of 50 eV. Initially, we have a properly symmetrized product of a Gauss packet for the projectile and the active 2s electron in Be^+, which then develops into a complex object containing contributions from elastic scattering, excitation, and ionization. The latter can be identified by the wavepacket having nonzero magnitude in the region where the radial

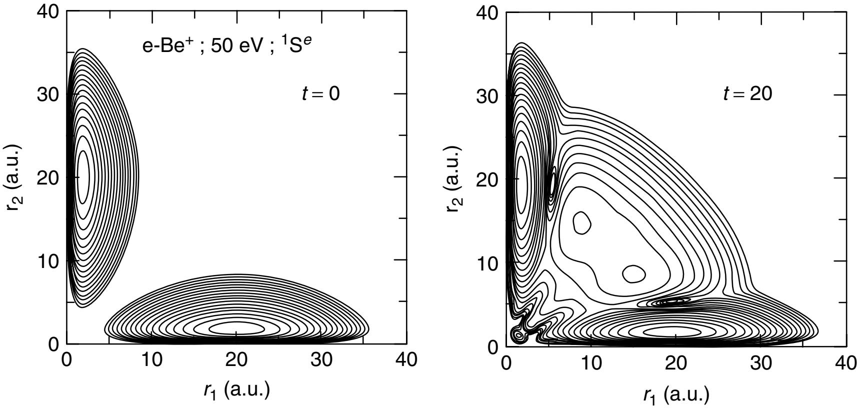

Fig. 8.25 Magnitude of the wave function for e − Be$^+$ collisions in the $^1S^e$ partial wave as a function of the radial coordinates of the projectile and the active electron for an incident projectile energy of 50 eV. After developing for 20 a.u. of time, the initial wavepacket on the left contains contributions from elastic scattering, excitation, and ionization. (Adapted from Pindzola *et al.* (1997)).

coordinates of both electrons (r_1 and r_2) are large.

8.3.3.2 Exterior Complex Scaling (ECS)

The exterior complex scaling method is another attempt to obtain the full wave function more directly than in the standard close-coupling or Born series approaches. The basic idea is to separate the wave function into two parts, namely, an incident part Φ_{in} and a scattered part Ψ_{sc}. The Schrödinger equation is rewritten as

$$(E - \boldsymbol{H})\Psi_{\text{sc}} = (\boldsymbol{H} - E)\Phi_{\text{in}} \tag{8.50}$$

In other words, the incident wave function is the driving term in the equation for the scattering wave function.

The critical point in what follows is the fact that Ψ_{sc} *only* contains outgoing waves. Hence, by making the variable transformation

$$z(r) \to \begin{cases} r & \text{if } < R_0 \\ R_0 + (r - R_0)\, e^{i\theta} & \text{if } r \geq R_0 \end{cases} \tag{8.51}$$

for all radial coordinates beyond some value R_0, any outgoing oscillating wave is transformed to an exponentially decreasing function. In this way, the complicated three-body Coulomb boundary conditions can be avoided in the solution of the driven Schrödinger equation. The physical information can be extracted inside the region defined by R_0 by using a variety of formulas for the scattering amplitude and the cross section. Of course, R_0 has to be chosen sufficiently large to ensure converged and stable results.

The ECS method was applied with great success to the electron-impact ionization of atomic hydrogen by Rescigno *et al.* (1999). As an example, Figure 8.26 shows the scattering wave function on a 2D radial grid for a particular set of angular momentum quantum numbers. A review of other applications was given by McCurdy, Baertschy and Rescigno (2004). The numerical efficiency of the method was greatly enhanced by a propagation algorithm (the PECS approach) described by Bartlett

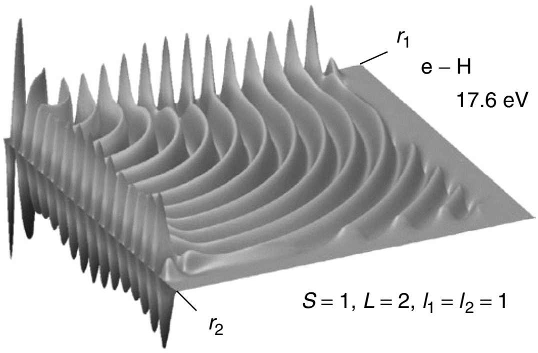

Fig. 8.26 Real part of the wave function for e – H collisions for an incident projectile energy of 17.6 eV in the triplet spin channel for individual angular momenta $l_1 = l_2 = 1$ and a coupled angular momentum $L = 2$. Note how the oscillatory parts of the scattering wave function vanish at large values of the radial coordinates r_1 and r_2. (Adapted from McCurdy, Baertschy and Rescigno (2004)).

(2006). The ECS method has recently been combined with a variety of numerical schemes, including *B*-splines and finite-element discrete-variable representations (FEDVR). Calculations for He, in the so-called "*S*-wave model" with all orbital angular momenta being zero, were reported by Bartlett *et al.* (2007), thus suggesting that the full problem with three active electrons will likely be treated in the near future.

8.3.4
Ionization of Atoms and Ions

In this section, we discuss the process whereby electrons are ejected from the target giving rise to ionization. We are mainly concerned with single ionization or (e,2e) reactions of the type discussed in Section 8.2.4, that is,

$$e_i^- + A_i \longrightarrow A_j^+ + e_A^- + e_B^- \qquad (8.52)$$

where A_i is the initial bound state of the target atom (or ion) and A_j^+ is the final state of the ion.

8.3.4.1 The Ionization Amplitude and Cross Section

The scattering amplitude for the direct ionization process is given by the integral expression Rudge and Seaton (1965)

$$f_i(\boldsymbol{k}_A, \boldsymbol{k}_B) = -(2\pi)^{1/2} \times \exp[i\chi(\boldsymbol{k}_A, \boldsymbol{k}_B)] \times \langle\!\langle (H_{N+1} - E)\Phi|\Psi_i^{(+)}\rangle \qquad (8.53)$$

Here $\Psi_i^{(+)}$ is an exact solution of Eq. (8.26) satisfying plane-wave plus outgoing-wave boundary conditions (8.29) and Φ is a solution of the equation

$$(H_{N+1} - V - E)\,\Phi = 0 \qquad (8.54)$$

satisfying ingoing-wave boundary conditions. Also, $\boldsymbol{k}_A$ and $\boldsymbol{k}_B$ are the momenta of the two outgoing electrons defined in terms of E_A and E_B in Eq. (8.9) by $\frac{1}{2}k_A^2 = E_A$ and $\frac{1}{2}k_B^2 = E_B$.

In practice, V is chosen so that Φ has a simple form. Thus, for electron scattering by H-like ions with nuclear charge Z, V is often chosen as

$$V = -\frac{Z - Z_A}{r_1} - \frac{Z - Z_B}{r_2} + \frac{1}{r_{12}} \qquad (8.55)$$

An approximate final-state wave function is then defined by

$$\Phi(\boldsymbol{r}_1, \boldsymbol{r}_2) = \psi_C^{(-)}(Z_A, \boldsymbol{k}_A, \boldsymbol{r}_1) \times \psi_C^{(-)}(Z_B, \boldsymbol{k}_B, \boldsymbol{r}_2) \qquad (8.56)$$

where $\psi_C^{(-)}$ is a one-electron Coulomb wave function satisfying ingoing-wave boundary conditions while Z_A and Z_B are the effective charges "seen" by the outgoing electrons. In order that the scattering amplitude not contain a divergent phase factor, Z_A and Z_B must satisfy the condition

$$\frac{Z_A}{k_A} + \frac{Z_B}{k_B} = \frac{Z}{k_A} + \frac{Z}{k_B} - \frac{1}{|\boldsymbol{k}_A - \boldsymbol{k}_B|} \tag{8.57}$$

in which case the phase $\chi(\boldsymbol{k}_A, \boldsymbol{k}_B)$ is given by

$$\chi(\boldsymbol{k}_A, \boldsymbol{k}_B) = \frac{Z_A}{k_A} \ln \frac{k_A^2}{k_A^2 + k_B^2} + \frac{Z_B}{k_B} \ln \frac{k_B^2}{k_A^2 + k_B^2} \tag{8.58}$$

The exchange ionization amplitude can be obtained from the theorem

$$g_i(\boldsymbol{k}_A, \boldsymbol{k}_B) = f_i(\boldsymbol{k}_B, \boldsymbol{k}_A) \tag{8.59}$$

first derived by Peterkop (1961). This result follows from the fact that the two amplitudes $f_i(\boldsymbol{k}_B, \boldsymbol{k}_A)$ and $g_i(\boldsymbol{k}_A, \boldsymbol{k}_B)$ describe the same physical process, in which the electron at $\boldsymbol{r}_N$ has momentum $\boldsymbol{k}_B$ and the electron at $\boldsymbol{r}_{N+1}$ has momentum $\boldsymbol{k}_A$. In practice, the Peterkop theorem will not be valid if approximate wave functions are used to calculate the ionization amplitudes. Therefore, a relative phase $\tau_i(\boldsymbol{k}_A, \boldsymbol{k}_B)$ between the two amplitudes is sometimes introduced by

$$g_i(\boldsymbol{k}_A, \boldsymbol{k}_B) = \exp[i\tau_i(\boldsymbol{k}_A, \boldsymbol{k}_B)] f_i(\boldsymbol{k}_B, \boldsymbol{k}_A) \tag{8.60}$$

Note that different choices for $\tau_i(\boldsymbol{k}_A, \boldsymbol{k}_B)$ can lead to significant variations in the predicted cross sections.

An important development in ionization theory was the adaptation of the continuum distorted-wave eikonal-initial-state (CDW-EIS) approach, which was put on a firm mathematical footing for heavy-particle impact by Crothers and McCann (1983), to electron impact. In particular, Brauner, Briggs and Klar (1989) used the so-called 3C wave function, which has the correct asymptotic behavior originally proposed by Redmond (1973), when all three particles are infinitely far apart from each other. In fact, Jones and Madison (2000) showed that the wavefunction is accurate when at least one particle is far away from the other two. The 3C function for a system of three free Coulomb particles (specifically two electrons and a proton) for the final state of an (e,2e) process on atomic hydrogen is given by

$$\begin{aligned} \Phi^-(\boldsymbol{r}_1, \boldsymbol{r}_2) = {} & \\ & (2\pi)^{-3} \exp i \times (\boldsymbol{k}_1 \cdot \boldsymbol{r}_1 + \boldsymbol{k}_2 \cdot \boldsymbol{r}_2) \\ & \times C(\alpha_1, \boldsymbol{k}_1, \boldsymbol{r}_1) \times C(\alpha_2, \boldsymbol{k}_2, \boldsymbol{r}_2) \\ & \times C(\alpha_{12}, \boldsymbol{k}_{12}, \boldsymbol{r}_{12}) \end{aligned} \tag{8.61}$$

Here $\boldsymbol{k}_{12} \equiv \mu(\boldsymbol{k}_1 - \boldsymbol{k}_2)$ is the relative wave vector of the two particles while $\mu = 1/2$ is the reduced mass of the two electrons. Furthermore, the Sommerfeld parameters are given by $\alpha_1 = -1/k_1, \alpha_2 = -1/k_2$, and $\alpha_{12} = \mu/k_{12}$, respectively. Distortion effects due to the Coulomb potential are contained in the function

$$\begin{aligned} C(\alpha, \boldsymbol{k}, \boldsymbol{r}) \equiv {} & \Gamma(1 - i\alpha) \exp(-\pi\alpha/2)_1 \\ & \times F_1(i\alpha, 1; -ikr - i\boldsymbol{k} \cdot \boldsymbol{r}) \end{aligned} \tag{8.62}$$

where ${}_1F_1$ and Γ are the hypergeometric and gamma functions, respectively.

Since 1989, several further modifications to the 3C function have been proposed. These include a suggestion by Alt and Mukhamedzhanov (1993) to use locally defined rather than global wave vectors, Berakdar's "dynamically screened" DS3C function (Berakdar (1996)), the use of the full CDW-EIS function to account for initial-state effects by Jones and Madison (1998), and the development of a DW version by Prideaux, Madison and Bartschat (2005). While improvements have been achieved in some cases, especially regarding the account of the postcollision interaction, the major drawback of the approach has been the fact that 3C-type wave functions are generally not sufficiently accurate at short distances from the target center. Here "short" is typically only a few atomic units (Foster *et al.* (2006); Bartschat, Weflen and Guan (2007)), but that is where the actual ionization process occurs.

Ionization cross sections are obtained by taking the ratio of the number of ionization events per unit time and per unit target atom to the incident electron flux. For random electron spin orientations in targets with one active electron, for example, the triple-differential cross section (TDCS) for ionization from an initial state $|i\rangle$ is given by

$$\frac{d^3\sigma_i}{d\Omega_A d\Omega_B dE} = \frac{k_A k_B}{k_i} \times \left[\frac{1}{4}|f_i + g_i|^2 + \frac{3}{4}|f_i - g_i|^2\right] \tag{8.63}$$

As discussed in Sections 8.2.4.2 and 8.2.4.3, various double and single differential cross sections can be formed by integrating the TDCS with respect to $d\Omega_A$, $d\Omega_B$, and/or dE. By integrating Eq. (8.63) over all outgoing electron scattering angles and energies, we obtain the total ionization cross section

$$\sigma_i = \frac{1}{k_i}\int_0^{E/2} dE\, k_A k_B \int d\Omega_A \int d\Omega_B \times \left[\frac{1}{4}|f_i + g_i|^2 + \frac{3}{4}|f_i - g_i|^2\right] \tag{8.64}$$

Because the two electrons are indistinguishable, the upper limit of integration over the energy variable is $E/2$ to avoid double counting. For atomic targets, the plane-wave Born program of Bartlett and Stelbovics (2003) allows for a fast way of obtaining reasonably accurate total ionization cross sections that are needed in many applications. The "Binary Encounter Bethe" model of Kim and Rudd (1994), Kim *et al.* (2008) has also been highly successful in the production of ionization cross sections for complex atoms and molecules, including radicals, that are important for the modeling of many processes in plasmas.

8.3.4.2 Threshold Behavior of the Ionization Cross Section

In a fundamental paper, Wigner (1948) pointed out that the derivation of threshold laws does not require a detailed knowledge of the collision dynamics in the "reaction zone," where all the particles are close together. Instead, they are determined by the asymptotic form of the wave function as the particles move apart. Wigner used this result to obtain threshold laws for two particles escaping from each other.

Wannier (1953) extended Wigner's theory to single ionization of atoms or ions by electrons. He considered the division of configuration space into three regions. In analogy with Wigner's analysis, it is not necessary to know the detailed behavior of the electrons in the reaction zone ($R < R_0$), but only to assume that the distribution in phase space of the two escaping electrons is uniform (i.e., quasiergodic) as they enter the Coulomb zone ($R_0 < R < R_1$). Wannier then assumed that for large enough R_0 the Coulomb potential varied sufficiently slowly for classical mechanics to be valid in the Coulomb zone even when the total energy $E = E_A + E_B$ tends to zero. Finally, at very large $R > R_1$, the combined kinetic energies of the electrons is larger than the potential energy, and hence the electrons move freely. As $E \to 0$, the free zone recedes and the Coulomb zone extends to infinity. The threshold behavior of the ionization cross section is therefore determined by the motion of the two electrons in the Coulomb zone.

Wannier showed that the threshold ionization cross section for hydrogenlike ions is dominated by the region in the neighborhood of a saddle point in the potential energy surface at $\alpha = \pi/4$ and $\theta_{12} = \pi$, where $\tan\alpha = r_1/r_2$ and θ_{12} is the angle between the two electron vectors $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$. By expanding the potential around this saddle point, he showed that for total angular momentum $L = 0$, the threshold law for the total ionization cross section is given by

$$\sigma_{\text{ion}} \sim E^m \tag{8.65}$$

where

$$m = -\frac{1}{4} + \frac{1}{4}\left(\frac{100Z - 9}{4Z - 1}\right)^{1/2} \tag{8.66}$$

When $Z = 1$, then $m = 1.127$; as $Z \to \infty$, $m \to 1$. A further important result, obtained by Vinkalns and Gailitis (1967), is that the width of the angular distribution in θ_{12} is

$$\Delta\theta_{12} \sim E^{1/4} \tag{8.67}$$

with a maximum at $\theta_{12} = \pi$. Hence the angular distribution becomes more concentrated as $E \to 0$.

Greene and Rau (1982, 1983) extended the Wannier theory to other $LS\pi$ values. They showed that in all states, except for $^3\text{S}^\text{e}$ and $^1\text{P}^\text{e}$, the wave function can remain finite at the saddle point, and hence the Wannier threshold law will pertain. In the $^3\text{S}^\text{e}$ and $^1\text{P}^\text{e}$ states, on the other hand, the symmetry of the wave function forces a node to occur at the saddle point, thereby giving rise to an exponent of $3m$ rather than m in Eq. (8.65).

Figure 8.27 shows the cross section and the spin asymmetry for electron impact ionization of atomic hydrogen in the near-threshold regime. The PECS results of Bartlett (2006) are compared to a variety of other theoretical and experimental results. As seen from the figure, the PECS theory agrees particularly well with the analytical threshold law and the experimental data. This is mostly due to the fact that the wave function can be integrated out in a stable way to very large distances.

8.3.4.3 **Ionization at Intermediate and High Energies**

The integral expression (8.53) for the direct ionization amplitude provides a starting point for the calculation of the cross section when some approximation is made for $\Psi_i^{(+)}$. The simplest approximation is to represent $\Psi_i^{(+)}$ by the incident plane-wave term. This gives a variety of first Born approximations, depending on the choice of phase in Eq. (8.60). However, this approximation can only be expected to be accurate at high energies.

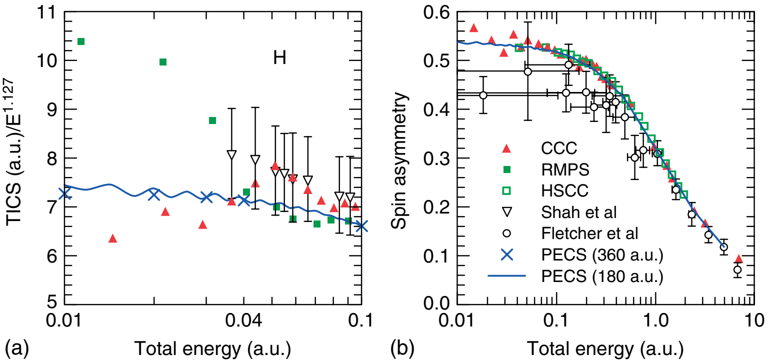

Fig. 8.27 Cross section (a) and spin asymmetry (b) for electron impact ionization of atomic hydrogen in the near-threshold regime. The PECS results of Bartlett (2006) are compared to a variety of other theoretical and experimental results. (Adapted from Bartlett (2006)).

To obtain cross sections that are reliable at lower energies, more sophisticated approximations must be made for $\Psi_i^{(+)}$. For example, $\Psi_i^{(+)}$ in Eq. (8.53) has been represented by coupled eigenstate plus pseudostate expansions of the form of Eq. (8.32). This is the basic idea behind the highly successful application of the CCC method to ionization processes, and it could be used in the RMPS and IERM methods as well. Alternatively, the ionization cross section can be obtained directly from the asymptotic form of $\Psi_i^{(+)}$. This is done, for example, in the TDCC and ECS approaches mentioned above.

Another approximation is a hybrid method introduced by Jakubowicz and Moores (1981) and later implemented into an R-matrix framework by Bartschat and Burke (1987). Starting from Eq. (8.53), the N-electron target in the initial state and the $(N-1)$-electron residual ion plus ejected electron in the final state are both expanded as in Eq. (8.32), whereas the ionizing electron is represented by plane or distorted waves in both the initial and final states. This approximation is appropriate for situations in which the ejected electron moves much slower than the ionizing electron, and it becomes increasingly accurate at all energies for ionization of ions as Z increases. After further development, it has become possible to account, at least approximately, for second-order effects in the Projectile–target interaction (Reid, Bartschat, and Raeker (1998)) and to represent the initial bound-state and the ejected-electron–residual-ion interaction by a convergent R-matrix with pseudostates expansion. As seen in Figure 8.13, the method has been fairly successful in describing simultaneous ionization plus excitation of He and other quasi-two-electron systems. Bartschat and Vorov (2005) also applied it with some success to direct ionization of the outermost p and s electrons in heavy noble gases. However, the most recent experimental data of Stevenson and Lohmann (2008) suggest that further improvements are necessary to obtain good agreement with experiment over the full angular range.

At high energies, methods based on the plane-wave Born series become valid. The TDCS for $e-\text{He}$ in Figure 8.9

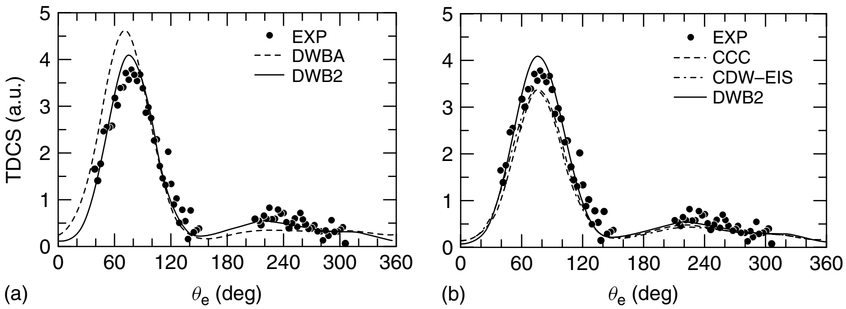

Fig. 8.28 The triple-differential cross section (in atomic units) for atomic hydrogen as a function of the ejected electron angle θ_e for an incident electron energy of 250 eV, an ejected electron energy of 5 eV, and a fixed detection angle of 8° for the fast electron. The dots are experimental data of Ehrhardt *et al.* (1986), while the various theoretical curves represent first-order and second-order B1 and B2 DW Born approximations, CCC and continuum distorted-wave plus eikonal-initial-state (CDW-EIS) model. (Adapted from Chen *et al.* (2004)).

shows that the second Born approximation correctly predicts the change in height and shift of the binary and recoil peaks from that given by the first Born approximation.

Replacing the plane waves by distorted waves allows for the Born-type methods to reach lower energies. This is shown in Figure 8.28 for 250 eV electron-impact ionization of atomic hydrogen.

8.3.4.4 **Excitation–Autoionization**

Excitation–autoionization discussed in Section 8.2.4.7 can be described using the hybrid method described above. In this case, it is necessary that the relevant resonant states are included in the expansion describing the scattering of the ejected electron from the $(N-1)$-electron residual ion. These resonances occur in Rydberg series converging to the excited states of the residual ion. However, this theory is appropriate only if the scattered electron is sufficiently fast that it can be adequately described by a distorted wave. In particular, this theory will fail if the incident electron forms a resonant state with the target ion as in Eq. (8.20).

When the incident electron interacts strongly with the target, it is often possible to obtain an accurate estimate of this cross section by assuming that the two processes defined by Eqs. (8.18) and (8.19) occur independently and can thus be calculated separately. This is equivalent to assuming that the lifetimes of the autoionizing states are large compared with their excitation time, and hence that these states can be treated as if they were bound states lying in the continuum. The total wave function describing the excitation process is then expanded as in Eq. (8.32), where the first summation includes the initial state of the target as well as all important autoionizing states. The ionization cross section is then obtained by solving the coupled integro-differential equations (8.33) either directly or by using a DW approximation and then summing the excitation cross section to all autoionizing states that decay into the continuum. This theory also describes the REDA process, because the intermediate states in Eq. (8.20) appear as resonances in the scattering process defined by Eq. (8.18). This approach has been widely used to obtain excitation–autoionization cross sections for complex ions (Müller, 1990).

8.3.5
Scattering by Molecules

The processes that occur in electron scattering by molecules are more varied than those that occur in electron scattering by atoms and ions because of the possibility of exciting degrees of freedom associated with the motion of the nuclei as well as electronic degrees of freedom. In addition, the multicentered and nonspherical nature of the electron–molecule interaction considerably complicates the solution of the scattering problem by reducing its symmetry.

There are two other distinctive features of electron–molecule scattering. First, there is the crucial role that resonances play in vibrational excitation and dissociative attachment (Hotop *et al.*, 2003). For example, it is mainly near resonances that the scattered electron spends sufficient time in the neighborhood of the molecule to be able to excite the nuclear motion with significant probability. Second, the long-range interaction between an electron and a molecule is more complicated than that between an electron and an atom. Thus, for a linear molecule, the potential has the asymptotic form

$$V(\boldsymbol{r}, \widehat{\boldsymbol{R}}) \xrightarrow[r\to\infty]{} -\frac{\mu}{r^2}P_1(\cos\theta) - \frac{Q}{r^3}P_2 \times (\cos\theta) - \frac{\alpha_0}{2r^4} - \frac{\alpha_2}{2r^4}P_2(\cos\theta) \qquad (8.68)$$

where $\boldsymbol{R}$ is a unit vector along the internuclear axis, $\boldsymbol{r}$ is the coordinate of the scattered electron with respect to the center of gravity of the molecule, and $\cos\theta = \widehat{\boldsymbol{r}} \cdot \widehat{\boldsymbol{R}}$. For polar molecules, the dipole moment μ is nonzero and the corresponding term in Eq. (8.68) dominates the angular distribution in the forward direction and gives rise to bound and virtual states that often lead to threshold peaks in the vibrational excitation cross sections. Furthermore, the long-range nature of the quadrupole (Q) and polarization (α_0 and α_2) terms in the potential lead to enhanced rotational excitation cross sections.

8.3.5.1 Laboratory Frame Representation

We first consider the derivation of the basic equations describing electron–molecule scattering in the laboratory frame of reference. Our discussion closely parallels that given in Section 8.3.1.1 for electron–atom scattering. The Schrödinger equation describing the electron–molecule system is

$$(H_m + K + V)\Psi = E\Psi \qquad (8.69)$$

where H_m is the Hamiltonian for the target molecule, K is the kinetic energy of the scattered electron, and V is the electron–molecule interaction potential

$$V(\boldsymbol{R}, \boldsymbol{r}_m, \boldsymbol{r}) = \sum_j \frac{1}{|\boldsymbol{r} - \boldsymbol{r}_j|} - \sum_j \frac{Z_j}{|\boldsymbol{r} - \boldsymbol{R}_j|} \qquad (8.70)$$

Here $\boldsymbol{R}$ stands symbolically for the positions $\boldsymbol{R}_j$ of all the nuclei, $\boldsymbol{r}_m$ for the set of coordinates $\boldsymbol{r}_j$ of the electrons in the target molecule, and $\boldsymbol{r}$ for the coordinate of the scattered electron. The total energy E refers to the frame of reference where the center of mass of the whole system is at rest.

We again introduce the target eigenstates and possible pseudostates Φ_i by the equation

$$\langle \Phi_i | H_m | \Phi_j \rangle = w_i \delta_{ij} \tag{8.71}$$

and then expand the total wave function Ψ, in analogy with Eq. (8.32) for atoms and ions, in the form

$$\Psi_i = \mathcal{A} \sum_j \Phi_j(\boldsymbol{R}, \boldsymbol{r}_m) \mathcal{F}_{ji}(\boldsymbol{r}) + \sum_j \chi_j(\boldsymbol{R}, \boldsymbol{r}_m, \boldsymbol{r}) \alpha_{ji} \tag{8.72}$$

Here, we have suppressed the spin variables for notational simplicity and have not carried out a partial-wave decomposition of the wave function $\mathcal{F}_{ji}$ representing the scattered electron. The subscripts i and j now represent the ro-vibrational and electronic states of the target molecule.

Coupled equations for the functions $\mathcal{F}_{ji}$ can be obtained by substituting expansion (8.72) into Eq. (8.69) and projecting onto the target states Φ_i and the square-integrable function χ_j. After eliminating the coefficients α_{ji}, we obtain the following coupled integro-differential equations that are satisfied by the functions $\mathcal{F}_{ji}$:

$$(\nabla^2 + k_j^2) \mathcal{F}_{ji}(r) = 2 \sum_l (V_{jl} + W_{jl} + X_{jl}) \mathcal{F}_{li}(\boldsymbol{r}) \tag{8.73}$$

Here

$$k_j^2 = 2(E - w_j) \tag{8.74}$$

and V_{jl}, W_{jl}, and X_{jl} are again the direct, nonlocal exchange, and nonlocal correlation potentials. By expanding the $\mathcal{F}_{ji}$ in partial waves we obtain a set of coupled radial integro-differential equations, analogous to Eqs. (8.33) for atoms and ions, which can, in principle, be solved numerically.

The scattering amplitude and cross section can be obtained from the asymptotic form of the total wave function, which is written in a form analogous to Eq. (8.29). The differential cross section for a transition from an initial state $|\boldsymbol{k}_i, \Phi_i, \chi_m\rangle$ to a final state $|\boldsymbol{k}_j, \Phi_j, \chi_m\rangle$ is then given by Eq. (8.31), except that the scattering amplitude $f_{ji}(\theta, \phi)$ now represents transitions between ro-vibrational states in addition to electronic states.

8.3.5.2 **Molecular Frame Representation**

The theory described in the previous section is completely general and has been the basis of a number of early calculations for light diatomic molecules. However, a major difficulty arises because of the very large number of ro-vibrational and electronic channels that need to be included in expansion (8.72) for all but the simplest low-energy calculations.

This difficulty can, to a large extent, be overcome by adopting an approximation similar to that used in molecular bound-state calculations, where a Born-Oppenheimer separation of the electronic and nuclear motion is made. The electronic motion is first determined with the nuclei held fixed. This is referred to as the *fixed-nuclei approximation*. The molecular rotational and vibrational motion is then included in a second step in the calculation. The entire procedure is called the *adiabatic-nuclei approximation*. It owes its validity to the large ratio of the nuclear mass to the electronic mass

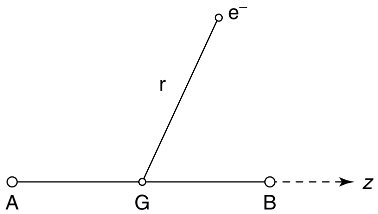

Fig. 8.29 Molecular frame for a diatomic molecule.

and can be adopted in electron–molecule scattering processes when the collision time is much shorter than the period of molecular rotation and/or molecular vibration. The approximation is thus expected to be valid when the scattered electron energy is not close to threshold or when the energy does not coincide with that of a narrow resonance. In these cases, further developments are needed to obtain reliable cross sections.

The fixed-nuclei approximation is not new, having been used in the 1930s to describe the scattering of electrons by homonuclear diatomic molecules by Stier (1932) and Fisk (1936). However, since the early 1970s, it has gained general acceptance as the basis of *ab initio* computational methods that are yielding the most accurate cross sections for complex molecules.

To formulate the collision in this representation, we adopt a frame of reference that is rigidly attached to the molecule, as illustrated in Figure 8.29 for a diatomic molecule. In this figure, A and B are the two nuclei, G is the center of gravity that is taken as the origin of coordinates, and the z-axis is chosen along the internuclear axis.

The fixed-nuclei approximation starts from the Schrödinger equation

$$(H_{el} + K + V)\psi = E\psi \tag{8.75}$$

where H_{el} is the electronic part of the target Hamiltonian defined by assuming that the target nuclei have fixed coordinates denoted by $\boldsymbol{R}$. It follows that H_{el} is related to H_m in Eq. (8.69) by

$$H_m = H_{el} + K_R \tag{8.76}$$

where K_R is the kinetic energy operator for the rotational and vibrational motion of the nuclei. The remaining quantities K and V are the same as in Eq. (8.69).

The solution of Eq. (8.75) proceeds in an analogous way to the solution of Eq. (8.26) for electron–atom or electron–ion scattering. We adopt an expansion similar to Eq. (8.32), where we now expand the function representing the motion of the scattered electron in terms of symmetry-adapted angular functions that transform as an appropriate irreducible representation (IRR) of the molecular point group (Burke, Chandra and Gianturco, 1972). Substituting this expansion into Eq. (8.75) and projecting onto the corresponding channel functions and the square-integrable functions yields the coupled integro-differential equations

$$\left(\frac{d^2}{dr^2} - \frac{l_j(l_j+1)}{r^2} + k_j^2\right) F_{ji}^{\Delta}(r) = 2\sum_l (V_{jl}^{\Delta} + W_{jl}^{\Delta} + X_{jl}^{\Delta}) F_{li}^{\Delta}(r) \tag{8.77}$$

Now the channel indices i, j, and l represent the component of the IRR as well as the electronic state of the target, Δ refers to the conserved quantum numbers that include the IRR and the total spin, l_j is the angular momentum of the scattered electron, and

$$k_j^2 = 2(E - \varepsilon_j) \tag{8.78}$$

Finally, V_{jl}^{Δ}, W_{jl}^{Δ}, and X_{jl}^{Δ} are the direct, nonlocal exchange, and nonlocal correlation potentials that depend parametrically on the internuclear coordinates $\boldsymbol{R}$.

The final step is to solve Eqs. (8.77), for each set of coordinates $\boldsymbol{R}$, subject to $\boldsymbol{K}$-matrix boundary conditions analogous to Eqs. (8.36). The scattering matrix in the molecular frame of reference, and hence the cross section, can then be obtained in a straightforward way.

A number of general computer-program packages have been developed to solve Eqs. (8.77). As for electron–atom or electron–ion scattering, these include packages based on the reduction of these equations to linear algebraic equations, on the Schwinger variational method, on the R-matrix method, and on the complex Kohn method. All of these approaches use standard quantum-chemistry structure packages that have been appropriately modified for scattering. More details about the methods can be found in the book edited by Huo and Gianturco (1995).

For scattering calculations involving only the ground electronic state, a number of approaches have been developed that replace the nonlocal exchange and correlation potentials by local potentials and hence make the resultant equation easier to solve. See, for example, Gianturco and Jain (1986), Gianturco and Lucchese (2004), or Tonzani and Greene (2005).

8.3.5.3 Inclusion of the Nuclear Motion

We now discuss how observables involving the nuclear motion, such as rotational and vibrational excitation cross sections and dissociative attachment cross sections, can be obtained from the solutions of the fixed-nuclei equations.

One of the most widely used approaches is the adiabatic-nuclei approximation proposed by Drozdov (1955, 1956) and by Chase (1956) in studies of neutron scattering by nuclei. As an illustration of this approach, we write the relevant scattering amplitude for a diatomic molecule in a $^1\Sigma$ state as

$$\begin{aligned} &A_{ivjm,i'v'j'm'}(\widehat{\boldsymbol{k}}, \widehat{\boldsymbol{r}}) = \\ &\quad \langle \chi_{iv}(R) Y_{jm}(\widehat{\boldsymbol{R}}) \times |A_{ii'}(\widehat{\boldsymbol{k}} \cdot \widehat{\boldsymbol{r}}; \boldsymbol{R})| \\ &\quad \times \chi_{i'v'}(R) Y_{j'm'}(\widehat{\boldsymbol{R}})\rangle \end{aligned} \tag{8.79}$$

where $A_{ii}''(\widehat{\boldsymbol{k}} \cdot \widehat{\boldsymbol{r}}; \boldsymbol{R})$ is the fixed-nuclei scattering amplitude obtained by solving Eqs. (8.77) and $\chi_{iv}(R)$ and $Y_{jm}(\widehat{\boldsymbol{R}})$ are the molecular vibrational and rotational eigenfunctions. This approximation is valid provided that the collision time is short compared with the vibration and/or rotation time. It has been widely used for nonresonant scattering away from threshold.

The adiabatic-nuclei approximation breaks down close to threshold or in the neighborhood of narrow resonances as discussed by Morrison (1988). A rather straightforward way of including nonadiabatic effects that arise in vibrational excitation is to retain the vibrational terms in the Hamiltonian but still to treat the rotational motion adiabatically. Hence, instead of Eq. (8.75), we solve the equation

$$(H_{\mathrm{el}} + K_{\mathrm{vib}} + K + V)\widetilde{\psi} = E\widetilde{\psi} \tag{8.80}$$

Here K_{vib} is the kinetic energy operator for the nuclear vibrational motion, while the other quantities have the same meaning as in Eq. (8.75). Adopting a frame of reference in which the molecule has fixed spatial orientation, and separating out the angular variables of the scattered electron, we can derive a set of integrodifferential equations coupling the target vibrational as well as electronic eigenstates. This approach has been used with success by several authors, but it is computationally demanding because the number of coupled channels can become very large.

Earlier, we noted that vibrational excitation and dissociative attachment are particularly important in resonance regions. As a result, a number of approaches have been developed for describing these processes based on electron–molecule resonance theories (Herzenberg (1984), Domcke (1991)). The basic idea is to introduce a series of fixed-nuclei resonance states ψ_n^r for a range of values of R either by imposing Siegert (1939) resonance boundary conditions or by introducing Feshbach projection operators. The amplitude for a transition from an initial electronic-vibrational state iv to a final state $i'v'$ is then given by

$$T_{iv,i'v'} = \sum_n \langle \chi_{iv}(R)\zeta_{ni}(R)|G_n^r(R, R')| \times \zeta_{ni'}(R')\chi_{i'v'}(R')\rangle \qquad (8.81)$$

where $\chi_{iv}(R)$ are the vibrational eigenfunctions, $\zeta_{ni}(R)$ are the "entry amplitudes" from the resonance states ψ_n^r into the initial or final electronic states, and $G_n^r(R, R')$ are the Green's functions that describe the propagation in the intermediate resonance states ψ_n^r.

We now consider the frame-transformation theory of Chang and Fano (1972) which has been influential in electron–atom scattering as well as laying the foundations of work on nuclear motion effects in electron–molecule scattering. Following earlier work by Fano (1970), who considered the extension of the quantum defect theory of Seaton (1958, 1983) to molecular photoabsorption, Chang and Fano pointed out that the electron–molecule interaction exhibits qualitatively different physical features when the distance r of the scattered electron from the center of gravity of the molecule lies in different regions.

We illustrate the main features of frame-transformation theory in the upper part of Figure 8.30. We see in this figure that configuration space is partitioned into two main regions labeled A and B. If vibrational motion is not considered, then in region A, where $r \leq a_2$, the molecular frame of reference can be used to describe the scattering process and the electron–target atom complex can be described as in molecular bound-state calculations. However, at larger distances in region B, where $r > a_2$, the coupling of the scattered electron to the molecular axis no longer dominates and the laboratory frame of reference is appropriate. In this case, the rotational quantum number j of the molecule and the orbital and spin quantum numbers (ℓ, s) of the scattered electron label the scattering channels, where the total angular momentum $\boldsymbol{J} = \boldsymbol{j} + \boldsymbol{\ell} + \boldsymbol{s}$ is conserved in the collision. When the vibrational motion of the molecule is being considered, region A must be partitioned into two subregions Aa and Ab. In subregion Aa, where $r \leq a_1$, the scattered electron spends only a short time compared with the vibration time and

Fig. 8.30 The upper part of the figure shows the partitioning of configuration space in frame-transformation theory of electron–molecule scattering with the quantum numbers relevant to different ranges of the electron–molecule distance r. The lower part of the figure shows the partitioning of configuration space adopted in electron–molecule scattering calculations.

hence the Born-Oppenheimer separation of the nuclear and electronic motion can be adopted and the collision wave function can be determined as a function of the internuclear coordinate R. On the other hand, in regions Ab and B, where $r > a_1$, the vibrational motion must be included nonadiabatically and the vibrational channels included explicitly in the expansion of the electron–molecule scattering wave function.

In the lower part of Figure 8.30 we compare the frame-transformation partitioning of configuration space with the partitioning of configuration space adopted in electron–molecule scattering calculations using one of the general computer-program packages discussed in Section 8.3.5.2. In this case, the subdivision is determined by the need to include electron–electron exchange and correlation effects in an internal region $r \leq a_0$ where the scattered electron penetrates the electronic cloud corresponding to the target states of interest. A multicenter configuration-interaction expansion of the total electron–molecule wave function in the molecular frame of reference can be adopted in this region. However, when $r > a_0$, the scattered electron lies outside the target electronic cloud and moves in the long-range local multipole potential of the residual molecule, including molecular polarization terms, which can be conveniently represented by a single-center expansion. If the rotational and vibrational motions of the molecule are being considered, a transformation from the molecular frame of reference to the laboratory frame of reference is applied to the single-center wave function at a_0, a_1, or a_2 as appropriate. In addition, we observe that, although a_0 is shown to be less than a_1 in Figure 8.30, this is not necessarily always the case. In particular, in applications where electron collisions with excited molecular states are considered, it may be necessary for a_0 to be greater than a_1 to

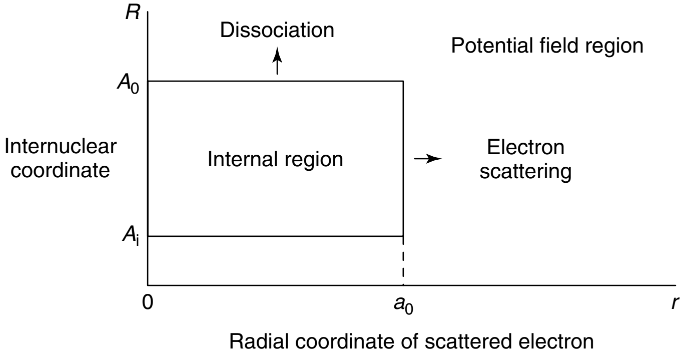

Fig. 8.31 Partitioning of configuration space in electron–molecule scattering calculations allowing for dissociative processes.

include electron exchange and correlation effects arising from the long-range tail of the wave functions corresponding to excited states. The solutions in the internal region of the potential field region can then be determined and matched on the boundary $r = a_0$, using one of the general electron–molecule computer packages discussed in Section 8.3.5.2.

The theory must be further extended to enable dissociative processes as well as rotational, vibrational, and electronic processes to be calculated. In the case of diatomic molecules, we consider the following processes:

$$\begin{array}{llll} & & AB_{i'v'} + \mathrm{e}^- & \text{vibronic excitation} \\ & \nearrow & & \\ \mathrm{e}^- + AB_{iv} & \longrightarrow & A_{i'} + B^-_{i''} & \text{dissociative attachment/recombination} \\ & \searrow & & \\ & & A_{i'} + B_{i''} + \mathrm{e}^- & \text{dissociation} \end{array} \quad (8.82)$$

where i, i' and i'' label the electronic states, v and v' label the vibrational states and where, for notational convenience, we have omitted the rotational quantum numbers. The partitioning of configuration space adopted in electron–molecule scattering calculations allowing for dissociative processes, which generalizes the lower part of Figure 8.30, is shown in Figure 8.31. The internal region is taken to be a rectangle defined by $0 \le r \le a_0$ and $A_i \le R \le A_0$, where a_0 is defined as in Figure 8.30, A_i is chosen to exclude the nuclear Coulomb repulsion singularity at $R = 0$ where the wave function describing the nuclear motion is negligible, and A_0 is chosen so that the target vibrational states of interest have negligible amplitude for $R > A_0$. For $r > a_0$ the collision complex separates into an electron plus a residual molecule, which may be rotationally, vibrationally, and electronically excited. For $R > A_0$ the molecule separates into an atom plus negative ion or into two atoms corresponding to dissociative attachment or dissociation. The solutions in the internal region and the two external regions are then matched on the boundaries between them. In the internal region, the calculation can be carried out in the molecular frame using one of the general computer program packages discussed in Section 8.3.5.2, while the calculations for the external regions can be carried out in the laboratory frame. The corresponding procedure using *R*-matrix theory was introduced by Schneider, Le Dourneuf and Burke (1979); Schneider, Le Dourneuf and Vo Ky Lan (1979) and has been reviewed by Burke and Tennyson (2005).

The extension by Fano (1970) of MQDT to molecular photoabsorption has led to an increasing interest in recent years in its application to the study of electron–molecule scattering and molecular photoionization and dissociation processes. As we saw in Figures. 8.30 and 8.31, configuration space can be partitioned into different regions depending on the distance of the electron from the molecule or the distance apart of the dissociating atoms or ions. In each of these regions the collision process can be analyzed in a frame of reference that reflects the physical characteristics of the region, for example the relative importance of electron–electron exchange and the relative motion of the electron and nuclear components. This enables the calculation and analysis of the process to be carried out in each region using the most appropriate frame of reference and, using MQDT, allows for the *S*-matrix describing the scattering process to be expressed in terms of analytic functions of the energy, thereby enabling it to be continued through thresholds as discussed in Section 8.3.1.5.

Following the application by Fano (1970) of MQDT to the high-resolution photoabsorption spectrum of H_2 near threshold, observed by Herzberg (1969), Jungen and Atabec (1977) developed and applied the method to rovibronic interactions in the photoabsorption spectrum of H_2 and D_2. This work was later extended by Jungen and Dill (1980) to treat rotational and vibrational preionization channels of H_2, obtaining good agreement with photoionization data of Dehmer and Chupka (1976). Further theoretical developments were made by Giusti (1980), Giusti-Suzor and Jungen (1984), Jungen (1984), and Stephens and Greene (1995). A review of molecular applications of MQDT was written by Greene and Jungen (1985). An *ab initio* study of vibrational inelastic processes in H_2 scattering below 5 eV was carried out by Robicheaux (1991), using the frame-transformation method proposed by Greene and Jungen (1985). Also, a noniterative eigenchannel *R*-matrix approach combined with MQDT was developed by Gao, Jungen and Greene (1993). It was applied to predissociation of H_2 in the $3p\pi D\ {}^1\Pi_u^+$ state, and a unified MQDT treatment of both molecular ionization and dissociation was developed by Jungen and Ross (1997).

Finally, we briefly discuss recent theoretical dissociative recombination studies of the triatomic ion H_3^+ by Kokoouline and Greene (2003a, 2003b) and by dos Santos, Kokoouline and Greene (2007). Kokoouline and Greene (2003b, 2005) also considered dissociative recombination of the triatomic ions D_3^+ H_2D^+ and D_2H^+. As mentioned in Section 8.2.6, where complementary experimental studies from the Stockholm (CRYRING) and the Heidelberg (TSR) groups were discussed, dissociative recombination of the H_3^+ ion is a fundamental process in diffuse interstellar clouds. Also, as the simplest triatomic ion, detailed theoretical studies can be seen as a prototype for the study of electron scattering by more complex polyatomic atoms and ions.

In contrast to dissociative attachment/recombination in diatomic molecules and ions given by Eq. (8.82), there is an additional three-body dissociative pathway for H_3^+. Thus we have the following possibilities

$$
\begin{array}{ccc}
 & & H_3^+ + e^- \\
 & \nearrow & \\
e^- + H_3^+ & \longrightarrow & H_2 + H \\
 & \searrow & \\
 & & H + H + H
\end{array}
\tag{8.83}
$$

Here we have omitted the electronic, vibrational, and rotational labels, as well as processes in which H or H_2 are ionized. We see from Eq. (8.83) that dissociative recombination of H_3^+ is inherently a four-body problem. To represent the Jahn–Teller coupling between the electronic and vibrational motion, it is in principle necessary to take into account at least two degrees of freedom of vibrational motion. Finally, the third vibrational coordinate should be introduced to describe the dissociative channel.

The theoretical approach developed by Kokoouline and Greene (2003a, 2003b) combined MQDT to represent the closed channels, the adiabatic hyperspherical coordinate approach to represent the motion of the nuclei, which is discussed in detail by Kokoouline and Masnou-Seeuws (2006), and included outgoing-wave Siegert (1939) pseudostates to represent the vibrational continuum. The Siegert pseudostates, which are analogous to the pseudostates discussed in Section 8.3.1.1, are introduced to let dissociative flux escape if it reaches the hyper-radial boundary. In the later work by dos Santos, Kokoouline and Greene (2007), accurate vibrational wave functions were used and a larger number of possible rotational states of the H_3^+ ground state were included. This resulted in better agreement with the experimental storage-ring data shown in Figure 8.16. It was also shown that the Jahn–Teller coupling between the electronic and vibrational motion plays an important role in this process. In conclusion, this work has shown that recent state-of-the-art *ab initio* calculations on dissociative recombination in simple polyatomic molecules are now capable of accurately describing this complex process.

8.3.5.4 **Illustrative Results for Molecules**

In this section we present a few examples of recent work that illustrate what theory is capable of in this field. We will show a variety of angle-integrated and angle-differential cross sections, for elastic scattering, excitation, and finally ionization.

To begin with, Figure 8.32 shows the angle-differential cross section for vibrationally elastic electron scattering from water molecules at an energy of 4 eV. There is very good agreement between the predictions of Faure, Gorfinkiel and Tennyson (2004) and the experimental data of Cho, Lee and Park (2003). The theoretical results were obtained by the *R*-matrix method within the fixed-nuclei approximation. To compare directly with experiment, they represent the sum over rotational excitations.

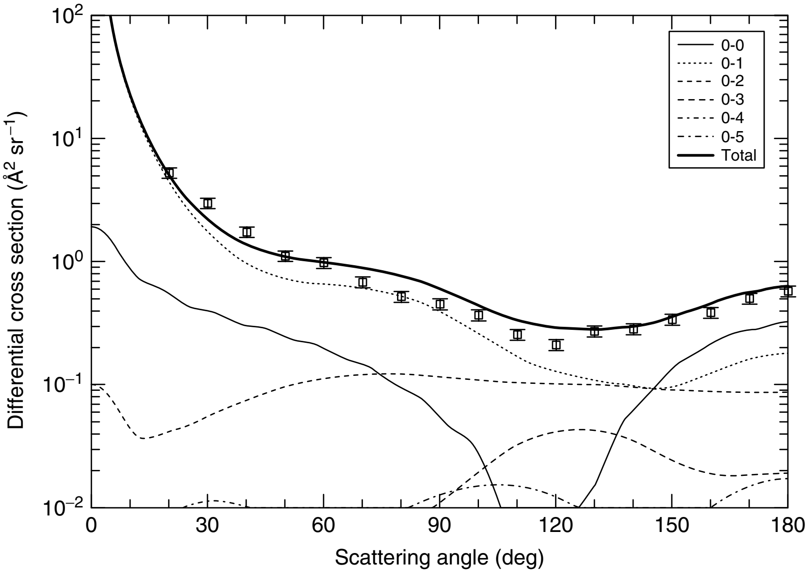

Fig. 8.32 Angle-differential cross section for vibrationally elastic electron scattering from water at an incident electron energy of 4 eV. The thick solid line is the rotationally summed result of Faure, Gorfinkiel and Tennyson (2004) while the squares represent the experimental data of Cho, Lee and Park (2003). Also shown are partial cross sections for individual rotational transitions. (From Faure, Gorfinkiel and Tennyson (2004).)

Next, Figure 8.33 exhibits results for elastic scattering and electron-induced vibrational excitation of NO. For this problem, Trevisan *et al.* (2005) employed a nonlocal treatment of the nuclear dynamics, which significantly improved agreement with experiment compared to results obtained in earlier treatments with a local complex potential. Nevertheless, the agreement between theory and experiment is still far from perfect, indicating the remaining difficulties even for diatomic molecules. An extensive review on the subject was published by Brunger and Buckman (2002).

The situation becomes even more complicated for polyatomic molecules. Most calculations are restricted to elastic scattering. Examples include elastic electron scattering from C_2H_4 by Winstead, McKoy and Bettega (2005) and very large molecules such as uracil treated by Gianturco and Lucchese (2004), by Tonzani and Greene (2005), and by Winstead and McKoy (2006). Examples of recent experimental work on molecules of biological interest include the papers by Allan (2007) on tetrahydrofuran and by Khakoo *et al.* (2008) on methanol amd ethanol.

Figure 8.34 exhibits the challenges associated with electron-impact excitation of electronic states in di-atomic and even more so poly–atomicmolecules. Both experiment and theory are very difficult. For the CO transition, there is qualitative agreement between theory and experiment, whereas the predictions and the measurements are orders of magnitude apart for the $\tilde{B}^1A_1$

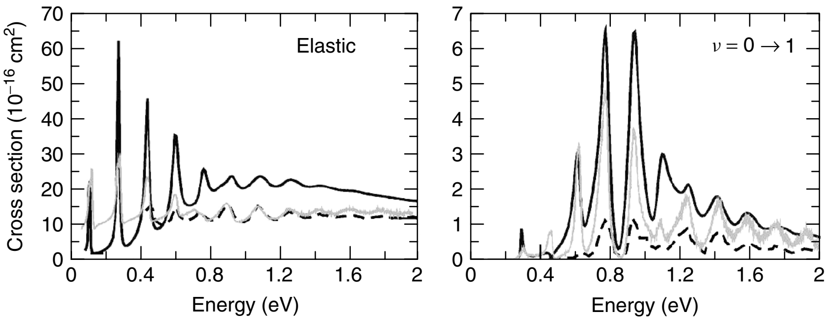

Fig. 8.33 Angle-integrated cross section for elastic scattering and excitation of the $v = 0 \rightarrow 1$ transition in NO. The theoretical predictions of Trevisan *et al.* (2005) (dark solid line) are compared with two sets of experimental data by Jelisavcic, Panajotovic and Buckman (2003) and Allan (2005). (Adapted from Trevisan *et al.* (2005).)

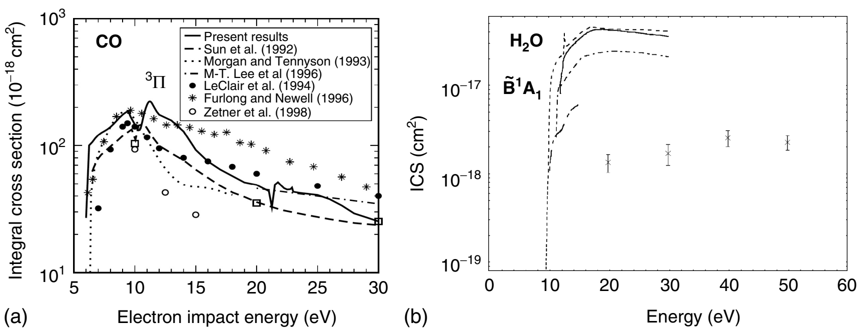

Fig. 8.34 Angle-integrated cross section for electron-impact excitation of the $^3\Pi$ state of CO (a) and the $\tilde{B}^1A_1$ state of water (b). (Adapted from da Costa *et al.* (2007) (CO) and Thorn *et al.* (2007) (H_2O).)

state in water. While there are obvious problems in reconciling the experimental and theoretical magnitudes, Gil *et al.* (1994) achieved impressive qualitative agreement with the (relative) electron energy loss spectra measured at a few fixed angles by Trajmar, Williams and Kuppermann (1973) for water. Further progress was made recently in the fully *ab initio* *R*-matrix calculation on methanol reported by Bouchiha *et al.* (2007). Good agreement with experiment was achieved regarding the total (elastic plus excitation) cross section. Unfortunately, no experimental data are available to test the individual predictions for the excitation processes, including some Feshbach resonances.

For optically allowed transitions, the semiempirical "Binary Encounter f-scaling" method of Kim (2001) often allows for a quick and accurate estimate of the excitation cross section. This is shown for excitation of CO in Figure 8.35.

Figure 8.36 shows the results of Gorfinkiel and Tennyson (2005) for ionization of H_2 by electron impact. These *ab initio* results were obtained using the molecular *R*-matrix with pseudostates

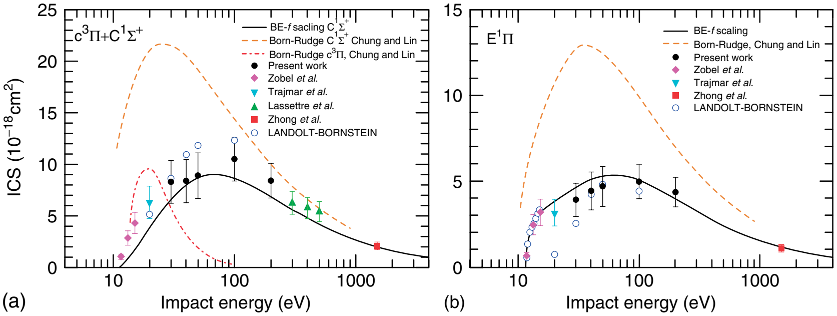

Fig. 8.35 Angle-integrated cross section for electron-impact excitation of the $C^1\Sigma + c^3\Pi$ (a) and the $E^1\Pi$ (b) states of CO. (Adapted from Kawahara *et al.* (2008).)

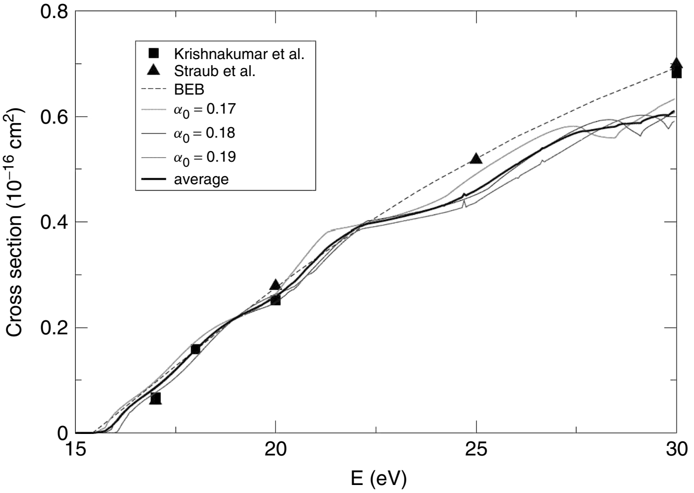

Fig. 8.36 Angle-integrated cross section for electron-impact ionization of H_2. The various values of α_0 refer to the basis used. See Gorfinkiel and Tennyson (2005) for details.

(MRMPS) method. Clearly, the results for the ionization problem are very encouraging. On the other hand, the very same model predicted a resonance structure in the excitation cross section that was not seen in most other calculations, nor in the few available experimental data.

We finish this section with the triple-differential cross section of electron-impact ionization of N_2. For this, and certainly for large molecules, such calculations are extremely difficult due to the complex molecular structure and the need to average over the molecular orientations that are usually not resolved in experiments with molecules in the gas phase. To address this problem, Gao, Madison and Peacher (2005a) suggested the "orientation averaged molecular orbital" (OAMA) approach. The major advantage of the method is the fact that it

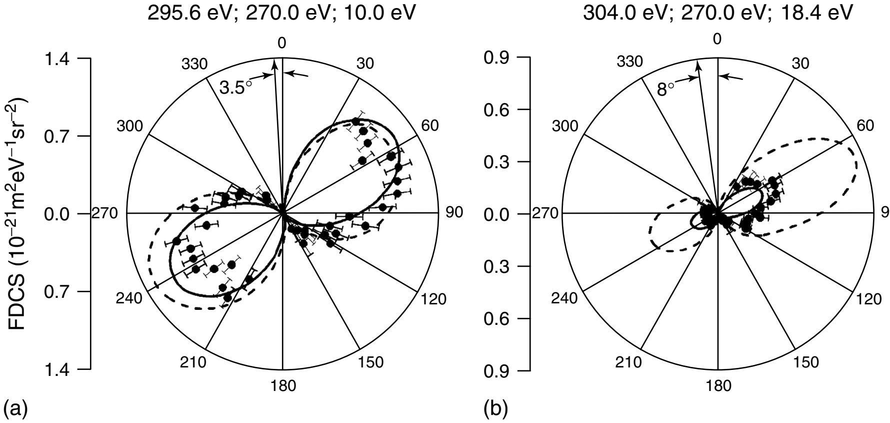

Fig. 8.37 Fully differential cross section for electron-impact ionization of the $3\sigma_g$ state in N_2 for coplanar asymmetric scattering. The incident electron energy is 295.6 eV (a) and 304.0 eV (b). The faster of the two outgoing electrons with energy 270 eV is detected at a scattering angle $\theta_a = 3.5^\circ$ (a) or $\theta_a = 8.0^\circ$ (b), while the detection angle of the slower electron (10.0 eV or 18.4 eV) is varied. The absolute experimental data are from Avaldi *et al.* (1992). The solid and dashed lines represent the M3DW and DWBA results, respectively, see Section 8.3.5.4, normalized to the experiment at the single point at 295.6 eV where $\theta_a = 3.5^\circ$ and $\theta_b = 68^\circ$. (From Gao, Madison and Peacher (2005b).)

is adaptable to the DW theory developed for (e,2e) processes with atoms. However, note that it is restricted to molecular orbitals of appropriate symmetry.

Figure 8.37 shows results for electron-impact ionization of the $3\sigma_g$ state in N_2 for the coplanar asymmetric geometry. For this system, the Rolla group extended the orbital average method further and also included the proper asymptotic three-body Coulomb boundary condition. Comparison between their results obtained in the standard DWBA approach and their molecular 3DW (M3DW) method shows that both calculations reproduce in a satisfactory way the shape of the angular distributions. However, the experimental data of Avaldi *et al.* (1992) are cross-normalized, that is, only a single normalization factor is necessary (and allowed) to put the experimental data on an absolute scale. The figure shows that the M3DW is far superior to the DWBA in reproducing the proper cross normalization. Further applications, for example, to water Kaiser *et al.* (2007) showed some encouraging qualitative agreement between theory and experiment, although discrepancies remained that call for a more sophisticated theoretical treatment.

8.4
Conclusions and Future Work

We have presented an overview of electron scattering by atoms, ions and molecules both from an experimental and from a theoretical standpoint. These areas have seen major advances during the past decade, and our knowledge of these processes is now much more secure than only ten years ago. In particular, advances in experimental methods involving multihit coincidence techniques, high-resolution electron beams, the MAC, spin-polarized projectile and target beams, and the reaction microscope are now providing critical benchmark data against which theory can be tested.

However, much work needs to be done before a complete picture emerges. In the case of electron–atom scattering, there is still an incomplete understanding of collisions involving highly excited states. While a full quantal description of low-energy ionization has been achieved for the atomic hydrogen target and also for helium without excitation, this is not the case for more complex targets or for more correlated processes such as ionization with simultaneous excitation, double ionization, and out-of-plane ionization. Another interesting example is the need to develop a complete quantal theory of excitation—autoionization near threshold. More work is also required to fully understand collisions with heavy atoms and ions, where relativistic effects are important. Examples include fine-structure transitions in collisions of astrophysical importance, such as the $e - Fe^+$ system, and generally atomic and ionic targets with open d-shells. Important examples include e—Mo or e—W collisions for mercury-free alternative lighting concepts or understanding and diagnosing the effects of impurities in fusion devices.

Turning to electron–molecule scattering, we have, in addition to the problems mentioned above for atoms and ions, the need to account fully for the nuclear motion, particularly in the role that it plays during electronic excitation. Experimentally, the resolution of well-defined states will remain a challenge while exciting new information can be expected from studies with "fixed in space" nuclear axes. Also, while new computer-program packages and rapidly increasing computational power have allowed for some *ab initio* calculations on polyatomic molecules, going beyond elastic scattering from biological molecules remains a significant challenge for the future. Some *ab initio* calculations, in the fixed-nuclei approximation, have recently become possible. The inclusion of vibrational excitation in such calculations is the next grand challenge in this field.

It is also worth pointing out that many of the techniques originally developed for steady-state electron collisions with atoms, ions, molecules, and even surfaces are now being used to treat such collisions on ultrashort time scales, involving strong-field laser-atom interactions that lead to excitation, single and multiple ionization. For recent examples, see Guan *et al.*, (2007); Guan, Bartschat and Schneider (2008), Feist *et al.*, (2008), and references therein.

The need for electron–atom, electron–ion, and electron–molecule collision cross sections in many applications provides an important stimulus for experimental and theoretical studies of electron collisions. Important questions involving highly ionized ions in hot plasmas that are difficult to resolve otherwise have already been theoretically explained. However, there are still plenty of unresolved topics, particularly in low-temperature discharges involving neutral atomic and molecular species, where more research is needed before final answers can be given. These questions from researchers in adjacent fields will continue to provide the motivation for work in this field for many years to come.

INTRODUCTION

For several decades, structures used in condensed-matter physics research and in many device areas have been getting smaller and have incorporated many ingenious schemes for confining electrons and, in some cases, holes. This has made it possible to realize structures in which carrier motion is effectively constrained to two, one, or most recently zero dimensions, where in the last case we consider carriers with no freedom to move in any direction. Such low-dimensional systems have been considered in physics and mathematics textbooks for a long time, but now can be realized, can be studied experimentally, and can form the basis for novel devices and applications. This has been made possible by substantial advances in growth and fabrication processes and in lithography, and the resulting field is one in which technology, materials science, and physics have all played essential roles.

This article focuses on the physics of low-dimensional structures and deals mainly with structures and effects involving electrons in semiconductors. Similar effects occur for holes, but generally require more complicated analysis because of the more complicated valence-band structures of most semiconductors. Low-dimensional effects are also found in metals and semimetals, but such examples will not be considered here.

As structures in solids continue to shrink, they eventually approach atomic size. There has been in recent years a growing interest in atomic clusters (see MOLECULAR AND ATOMIC CLUSTERS), and these two regimes, one starting from an atomic picture and the other starting from a picture based on bulk materials, will begin to merge. The approach in this article is based on a modification of the properties of bulk materials when the carriers are confined.

Although the new physical effects associated with reduced dimensionality are quite dramatic, many of them—with the exception of some of the optical effects—weaken as the temperature increases. Many of the phenomena to be discussed here are, therefore, most pronounced at low temperatures.

Part of the material in this article is based on lectures given in Trieste at the 1990 Spring College in Condensed Matter, on Physics of Low-Dimensional Semiconductor Structures (Stern, 1992).

1. DIMENSIONALITY

Although we live in a world with three space dimensions, it is easy to visualize situations in which motion can be constrained to a smaller number of dimensions. A one-dimensional system, for example, has one direction in which motion is relatively unimpeded, while motion in the other two space dimensions is constrained. Structures with one-dimensional motion are often called quantum wires. Fully confined or zero-dimensional structures are called quantum dots, or quantum boxes.

Physical confinement of electrons arises when some dimension of a sample is small on a relevant physical scale. There are many such scales, of which we discuss only three. The scale important for understanding many transport properties in solids is the phase-breaking length, the average distance over which a carrier loses phase coherence. In many cases, this can be approximated by the mean distance through which a carrier diffuses between inelastic scattering events such as electron–phonon and electron–electron scattering, and is approximately given by $(2dD\tau_{\text{in}})^{1/2}$, where d is the dimensionality, D is the diffusion constant (with dimensions $\text{cm}^2\ \text{s}^{-1}$), and τ_{in} is the mean time between inelastic scattering events. At low temperatures, the diffusion constant of most semiconductors and metals is only weakly dependent on temperature, while the inelastic scattering rate, τ_{in}^{-1}, varies as a power of the absolute temperature T. The phase-breaking length gets longer as the temperature is reduced, and can be of order μm or longer at temperatures of order 1 K in many semiconductors and metals. This leads to an interesting class of transport phenomena sometimes grouped under the heading weak localization (*q.v.*; see also ELECTRONIC TRANSPORT IN SOLIDS), a subject that has been actively studied since about 1980.

Another physical length is the carrier mean free path, an effective distance traveled between collisions, both elastic and inelastic. In systems with high carrier mobility at low temperatures, this length can be of order 5 μm or larger. In a sufficiently small structure, carriers can traverse the entire device without scattering and are in the ballistic regime, with analogies to motion in free space.

The third physical scale length, and the one of direct interest in this article, is related to the wavelength of the electron, given by Planck's constant divided by the electron momentum. At low temperatures, the physical length scale for carrier confinement is best given by k_{F}^{-1}, the inverse of the wave vector at the Fermi surface. The Fermi wave vector in a simple solid with an isotropic, nondegenerate energy band is related to the carrier density by $n = k_{\text{F}}^3/3\pi^2$.

Reduced dimensionality manifests itself physically in a number of ways. Physical properties such as conductance are anisotropic and respond in an anisotropic way to external electric and magnetic fields. The energy-level structure, as reflected in electrical and optical properties, often shows a distinct signature of the dimensionality. For example, the first clear evidence for the existence of a two-dimensional electron system was the characteristic appearance of equally spaced peaks in the conductance of a silicon inversion layer in a magnetic field versus gate voltage, measured by Fowler *et al.* (1966). Collective effects, such as plasma modes, also carry a distinctive signature of the dimensionality, as in the plasmon dispersion described in Sec. 3.2.

The study of layered materials and of bulk materials with one-dimensional conducting strands has evolved separately from the study of low-dimensional structures in semiconductors. For historical reasons and because the materials covered are somewhat different, these fields have almost disjoint sets of researchers, of conferences, and of publications. (See GRAPHITE; INTERCALATION COMPOUNDS.)

Much of the theoretical work on thermodynamic properties of low-dimensional systems is concerned with phase transitions (*q.v.*; see also METAL-INSULATOR TRANSITIONS). We shall touch on one example below, in Sec. 6.

2. STRUCTURES AND FABRICATION

The methods developed for confining carriers can be grouped into several major categories, including compositional confinement, electrostatic confinement, geometrical confinement, localized damage, and selective growth. Confinement in actual structures usually involves more than one of these, and new combinations and fabrication schemes continue to be developed. Schematic pictures of three such structures are shown in Fig. 1.

Compositional confinement arises from the barrier to carrier motion imposed by a change—either abrupt or graded—in chemical composition. One example is the barrier, about 3 eV, for electrons at the interface between Si and SiO_2, an interface of great technological importance because of the dominant role of silicon in semiconductor device applications. Another is the conduction-band offset at the interface between GaAs and $Al_xGa_{1-x}As$. This interface is widely studied because there is little difference in lattice constants through the $Al_xGa_{1-x}As$ alloy system, allowing layers of various compositions to be deposited successively epitaxially with very little strain. The conduction-band offset is about 0.3 eV if the AlAs fraction x is 0.3. Thus a quantum well structure that confines a layer of GaAs between layers of $Al_{0.3}Ga_{0.7}As$ will create a well 0.3 eV deep for electrons. Holes will also be confined in such a quantum well, by about 0.15 eV. Many other structures, including multiple quantum wells and superlattices, are possible in the $Al_xGa_{1-x}As$ system and also in other materials (see HETEROSTRUCTURES AND SUPERLATTICES, SEMICONDUCTOR).

Electrostatic confinement was one of the first means used to create a true quantum-confined two-dimensional system, the inversion layer of a metal-oxide-silicon (MOS) field-effect transistor (FET) structure. Applying a voltage between the metallic gate and the silicon in an MOS structure produces an electric field that attracts carriers toward the semiconductor surface, with a corresponding charge density per unit area, but of opposite sign, on the gate. The conduction-band discon-

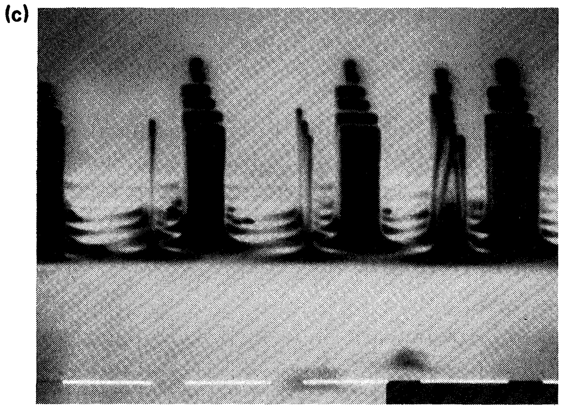

FIG. 1. Schematic illustrations of some low-dimensional structures: (a) Band bending in a silicon inversion layer, showing conduction- and valence-band edges, the Fermi level, and the energy of one subband. (b) Two-gate structure for producing an array of quantum wires. A positive voltage is applied to the upper gate and induces electrons at the $Si-SiO_2$ interface, below the openings in the lower grating gate. [After Warren *et al.* (1986).] (c) Scanning electron micrograph of GaAs nanostructures containing quantum dots. Vertical confinement is provided by a quantum well in each column. The horizontal bars are 0.5 μm wide. [After Reed *et al.* (1990), (1991).]

tinuity between silicon and SiO_2 prevents the carriers from entering the oxide, and leads—if the electric field is large enough—to a thin layer of carriers near the silicon surface. For the case when the silicon is *p* type, i.e., with holes as the majority carriers, the surface layer is called an inversion layer if the gate voltage is positive and electrons are attracted toward the Si–SiO_2 interface, and is called an accumulation layer if the gate voltage is negative and holes are attracted toward the interface. Band bending in an inversion layer is shown schematically in Fig. 1(a). Such metal-oxide–semiconductor systems underlie the field-effect transistors, or MOSFETs, that are the basis of many semiconductor devices used in computers and in other electronic equipment (see TRANSISTORS, FIELD EFFECT). Silicon inversion layers were the first widely studied two-dimensional system. Some of the extensive literature of the physics of this system is covered by Ando *et al.* (1982).

Electrostatic confinement can also be used to reduce the dimensionality further. Suitably patterned gates, such as narrow gates, split gates, grating gates, and other variants, can be used to shape the electrostatic confining potential in ways which, when combined with one or more barriers due to compositional confinement, lead to effectively one- or zero-dimensional systems. A double-gate structure used by Warren *et al.* (1986) for electrostatic confinement of arrays of quantum wires in silicon is shown in Fig. 1(b).

Geometrical confinement is the simplest mechanism to consider, although not necessarily the easiest to realize. One or more sample dimensions are made suitably small either by an appropriate growth technique or by removing material from a larger sample, for example, by etching. Posts of material with diameter of order 100 nm or less have been prepared from a GaAs-based heterostructure, and the combination of compositional and geometrical confinement has been used to fabricate structures for optical studies, including lasers, and for tunneling experiments. Figure 1(c) shows such a structure, used in quantum dot tunneling experiments in 1988 by Reed *et al.* (1990, 1991). One of the limitations of geometrical confinement is the presence of surface states that may deplete charges from a region near the surface or have adverse effects on carrier mobility, surface recombination velocity, or other properties of the device. Methods for mitigating these effects by chemical or other surface treatments continue to be investigated.

Some processes that introduce localized damage, such as bombardment by ions or electrons, lead to changes in the surface or bulk properties of the material that have been used to confine carriers. While the effectiveness of these methods has been demonstrated and can be understood in part to result from the creation of trapping states in the energy gap, work remains to be done to clarify the microscopic structure of the defects and the processes by which they are created.

Selective growth on a terraced semiconductor surface, as obtained for example by using a surface slightly tilted from a $\{001\}$ plane, can lead to a wirelike structure whose width can be controlled by the growth conditions and the terrace width and whose thickness can be as small as a monolayer. Selective growth can also be used on the etched or cleaved surface of a superlattice or other compositionally modulated structure to yield lateral confinement.

Methods have also been developed to fabricate small particles in an inert matrix—for example, small particles of semiconductor material in a glassy matrix. See, for example, Ekimov *et al.* (1989).

An ingenious method has been devised to confine excitons (*q.v.*) by use of strain effects. (An exciton, an electron and hole coupled together by their Coulomb attraction, is neutral and therefore cannot easily be confined electrostatically.) See, for example, the article by Kash (1990), which summarizes work on optical properties of quantum wires and quantum dots in III-V semiconductors.

Many of the methods we have described can be used to fabricate quantum wires or quantum dots, or arrays of wires or dots that may or may not interact with each other. Alternatively they can be used to add spatial modulation, as, for example, to introduce linear or rectangular grating modulations onto a two-dimensional electron system. Such modulated systems allow a transition from one dimensionality to another as the strength of the modulation is varied.

Structures with very fine spatial features, of order 0.1 μm or less, usually require advanced fabrication technology and tend to be made in large laboratories equipped with focused electron or ion beams or with x-ray lithography. Structures that do not require such elaborate facilities can also exhibit spatial confinement. The number of laboratories making low-dimensional structures and devices continues to increase.

2.1 Induced Charge

Fabricating a particular low-dimensional structure, as briefly described above, may suffice for structures to be studied optically, but for electrical studies it is also necessary to supply mobile carriers. In bulk semiconductors, donor impurities are added to supply electrons, or acceptor impurities to supply holes, but in a homogeneous system the impurities and the carriers occupy the same region of space, leading to strong scattering and usually to low carrier mobility. In several categories of low-dimensional systems, carriers can be introduced without impurities or they can be spatially separated from them.

The metal-oxide–semiconductor (MOS) structure briefly described in the Introduction is an example of the first mechanism for introducing charge. The semiconductor is one plate of a capacitor, and application of a voltage V across the insulator induces a charge, approximately given by $C_{ox}(V-V_{th})$, where C_{ox} is the oxide capacitance and V_{th} is the threshold voltage. At voltages below the threshold, the charge need not drop abruptly to zero; there is, for example, a thermally activated subthreshold charge, not considered further here. The maximum surface charge that can be induced is related to the breakdown electric field of the insulator. For a good insulator such as SiO_2, with a breakdown field close to 10^7 V/cm, the density of induced surface charges can exceed 10^{13} cm^{-2}.

Dopant atoms placed on the high-barrier side of a heterojunction transfer carriers to the low-barrier side to equalize the Fermi levels. If the dopant atoms are separated from the heterojunction by a spacer layer, a process called modulation doping or selective doping, the carrier mobility may be enhanced because of the increased separation between carriers and ionized impurities. The amount of charge transferred in this way is controlled by the density, location, and binding energy of the impurities, by the band offset between the two sides of the heterojunction, and by any external voltages applied. Induced charge densities in heterojunctions are usually smaller than those possible in silicon MOS structures.

Charge can also be induced in a semiconductor by a charged layer of surface states or surface atoms, which is compensated by a space-charge layer in the semiconductor. Surface states, as controlled by ambient gas atmospheres, were being investigated by Brattain and Bardeen in the early 1950s (see ELECTRONIC STRUCTURE OF SURFACES). The physics of semiconductor surfaces, a forerunner of the physics of inversion layers and related two-dimensional electron systems, has been well described in the book by Many *et al.* (1965). In some materials, for example ZnO, it is possible to create charged surface states, and therefore a compensating space-charge layer, with more than 10^{14} charges per cm^2.

At the other extreme of charge density is the system of electrons on liquid helium, discussed in Sec. 6 below.

3. ELECTRONIC STRUCTURE

The wave functions of electronic states in a perfect crystal can be expressed in the Bloch form (see ELECTRONIC STRUCTURE OF SOLIDS)

$$\psi_{\mathbf{k}}(\mathbf{r})=e^{i\mathbf{k}\cdot\mathbf{r}}u_{\mathbf{k}}(\mathbf{r}), \qquad (1)$$

where **k** is the wave vector of the state and $u_{\mathbf{k}}(\mathbf{r})$ has the translational periodicity of the crystal lattice. In the effective-mass approximation, which underlies the discussion in this article, the periodic function $u(\mathbf{r})$ is often omitted in describing electronic states, and the electrons are considered to have an effective mass m^* that is usually different from the free-electron mass m_0. For some semiconductors, such as silicon, it is necessary to consider the anisotropy of the effective mass and the multivalley nature of the conduction band. The complications that arise from the degenerate valence-band structure are largely ignored in this article.

3.1 Electronic States

In the effective-mass approximation approach, it is often sufficient to describe electronic states by an envelope function that includes the effects of external potentials, which are presumed to vary slowly on an atomic scale, and of boundary conditions. In this approximation the potential variations on an atomic scale are considered only through their influence on the effective mass and the dielectric constant. Although one would normally expect this approximation to be valid when the potential is slowly varying on an atomic distance scale, it holds up surprisingly well even for quantum-well structures only a few atomic layers across, as shown by calculations that include the discrete atomic structure (see, for example, Gell *et al.*, 1987).

3.1.1 Two-Dimensional Systems. The wave function for an electronic state in a two-dimensional system in the presence of a confining potential $V(z)$ can be approximated as

$$\psi_{n,\mathbf{K}}(\mathbf{R},z)=e^{i\mathbf{K}\cdot\mathbf{R}}\zeta_n(z)u(\mathbf{r}), \qquad (2)$$

where $u(\mathbf{r})$ is the periodic part of the Bloch function of Eq. (1), taken at a point in the Brillouin zone representative of the states being described, the plane-wave factor describes free-carrier motion in the x-y plane, and the envelope function $\zeta_n(z)$ is the solution of the Schrödinger equation

$$-\frac{\hbar^2}{2}\frac{d}{dz}\frac{1}{m^*}\frac{d\zeta_n}{dz}+V(z)\zeta_n(z)=E_n\zeta_n(z), \qquad (3)$$

where $\hbar$ is the Planck constant divided by 2π, with the boundary condition that the wave function vanish at large values of $|z|$. Note that we use uppercase letters to represent vectors, or lengths of vectors, in two dimensions and lower case letters for three dimensions. Thus the vector $\mathbf{R}$ has coordinates (x,y) and the vector $\mathbf{r}$ has coordinates (x,y,z). We here consider a simple case with an isotropic effective mass independent of energy, but allow for the possibility that the effective mass may have a spatial variation associated with composition changes along the z direction. Multivalley effects and mass anisotropy effects arise in silicon inversion layers, for example, and are discussed in the paper by Stern and Howard (1967). More complicated situations can arise in heterostructures. In the discussion that follows we shall usually omit the factor $u(\mathbf{r})$ from the wave function, but it is essential in some cases, such as the calculation of the strength of optical transitions.

The energy levels of the system described by Eqs. (2) and (3) form series of continua, each of which has its origin at an eigenvalue E_n of Eq. (3), with energies

$$E=E_n+(\hbar^2K^2)/2m^*. \qquad (4)$$

Each of these two-dimensional continua arises out of states of the conduction band as modified by the z-dependent potential, and is called a subband. The corresponding continuum of levels in a superlattice, where the energy depends both on the wave vector in the plane and on the wave vector along the superlattice axis, has come to be called a miniband.

The density of states per unit energy and unit area in the nth two-dimensional subband is

$$\rho(E)=g_s\, g_v m_d/2\pi\hbar^2, \quad E>E_n \qquad (5)$$

and vanishes for $E<E_n$. We have introduced m_d, the density-of-states mass per valley for motion in the K_x-K_y plane; g_v, the valley degeneracy; and g_s, the spin degeneracy, which equals 2 unless a magnetic field is present to separate spin-up and spin-down levels. Note that for a two-dimensional system the density of states is independent of energy within each subband under the assumptions used here. The total density of states is a sum of such strips of constant density, each starting at the bottom of the corresponding subband. For electrons in GaAs the valley degeneracy g_v is 1, and for electrons in the lowest subband of an inversion layer on a {001} surface of silicon it is 2.

In two dimensions, unlike one and three dimensions, the integral of the density of states times the Fermi–Dirac occupation function can be evaluated analytically, and the density of electrons per unit area in the nth subband at temperature T is

$$N_n=(g_s\, g_v m_d k_B T/2\pi\hbar^2)$$
$$\times\ln\{1+\exp[(E_F-E_n)/k_BT]\}, \qquad (6)$$

where E_F is the Fermi energy and k_B is the Boltzmann constant. If the carrier density is large enough that $(E_F-E_n)>k_BT$, then the system is said to be degenerate and the Fermi level relative to the subband edge is approximately proportional to the carrier density if only one subband is occupied. If the carrier density is very small, the Fermi level lies below the bottom of the lowest subband and the system is said to be nondegenerate.

The energy levels of a two-dimensional system in a magnetic field (strictly, magnetic induction) B perpendicular to the plane of motion are the Landau levels $(i+\frac{1}{2})\hbar\omega_c$, where

$\omega_c = eB/m^*$ is the cyclotron radian frequency and i is an integer. Thus when a magnetic field is present perpendicular to the plane of a two-dimensional electron system, the constant density of states described in Eq. (5) is rearranged, and the levels form a series of peaks separated by the cyclotron energy. The number of states per unit area in each peak is eB/h, which must be multiplied by the spin and valley degeneracies if these are not resolved. If there were no scattering or disorder, the peaks would have zero width, but in a real system there is a finite width. There is good evidence that for high magnetic fields, the states in the tails of the Landau levels are localized and do not carry a current.

The conductance of a two-dimensional system in a magnetic field shows clear evidence of the equally spaced Landau levels expected from the simple arguments just described. When a gate voltage is applied to a metal–insulator–semiconductor system, the charge in the two-dimensional system is approximately linear in gate voltage. Thus as the gate voltage is increased in the presence of a magnetic field, a fixed amount of charge is required for each Landau level. This leads to a periodic dependence of conductance on magnetic field, as shown in Fig. 2 from the work by Fowler *et al.* (1966) that first clearly demonstrated, using a silicon MOS structure, the presence of two-dimensional electrons.

Electron–electron interactions have a substantial effect on the energy levels in metals and semiconductors (see Collective Phenomena in Solids). These effects are even more important in two-dimensional systems than in bulk systems, because they can be of the same magnitude as the energy-level spacings connected with spatial quantization. Early optical experiments on inversion layers showed that the measured spectrum of transitions between subbands cannot be reconciled with calculations in the Hartree approximation, which ignores the "hole" in the electron distribution that follows each electron dynamically. Other evidence for the importance of many-electron interactions comes from the effective mass and the g factor, as inferred from magnetotransport and magneto-optical measurements [see, for example, Ando *et al.* (1982) for an account of such experiments and related theory].

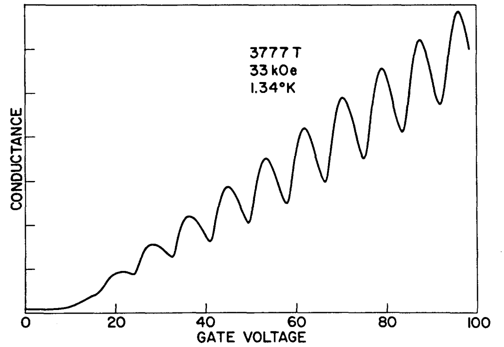

FIG. 2. Conductance of an inversion layer in a metal-oxide–silicon structure in a magnetic field vs applied gate voltage. The equally spaced oscillations, associated with the equally spaced Landau levels induced by the magnetic field, provided the first clear demonstration of a two-dimensional electron gas. [After Fowler *et al.* (1966).]

As in three dimensions, one can separate the many-electron effects into an exchange part, which reflects the energy gained by keeping electrons of like spin apart, and a correlation part, which includes all other effects (see Collective Phenomena in Solids). The exchange contribution to the energy is $-e^2k_F/3\pi^2\bar{\epsilon}$ in two dimensions, where $\bar{\epsilon}$ is the average permittivity of the media surrounding the electron plane, as compared to the value $-3e^2k_F/16\pi^2\epsilon$ found in three dimensions. Note that these values do not depend explicitly on the effective mass. Estimating the correlation effects requires elaborate calculations, for which the so-called plasmon-pole approximation to the dielectric response has been frequently used. Ando *et al.* (1982) and Czachor *et al.* (1982) give results on correlation effects in two-dimensional systems, with references to the earlier work.

The local-density formulation (see Collective Phenomena in Solids) can be used to approximate the many-electron effects in heterostructures, and adds an effective potential to the potential in the Schrödinger equation, Eq. (3). One complication in consideration of electron–electron interaction in inversion layers arises from the large difference of dielectric constants of Si and SiO_2. The resulting image potential modifies the effective interaction of two electrons near the Si–SiO_2 interface, as first treated by Ando (1976).

3.1.2 One-Dimensional Systems. The equations describing a dynamically one-dimensional case are similar to those given in the preceding section, except that the electrons are only free to move in one dimension, and the Schrödinger equation satisfied by the envelope function now involves two space dimensions. We only give here the density of states per unit energy and unit length for the one-dimensional case,

$$\rho(E)=(g_s\,g_v/2\pi)(2m_x/\hbar^2)^{1/2}(E-E_n)^{-1/2}, \tag{7}$$

with its divergence at the threshold. Here m_x is the effective mass for motion along the wire. The density of charges per unit length in the nth subband is

$$N_n=(g_s\,g_v k_B T/2\pi)(2m_x/\hbar^2)^{1/2} \times F_{-1/2}((E_F-E_n)/k_B T), \tag{8}$$

where

$$F_p(\eta)=\int_0^\infty \frac{x^p}{1+\exp(x-\eta)}\,dx \tag{9}$$

is the Fermi–Dirac integral of order p. In real systems, scattering processes will broaden the levels and remove the singularity at the bottom of each one-dimensional subband.

3.2 Dielectric Response

The self-consistent response of a two-dimensional free-electron system to a weak electric field of radian frequency ω and wave vector $\mathbf{Q}$ in the electron plane was obtained by Stern (1967) in the simplest approximation, often called the random-phase approximation, which ignores many aspects of electron–electron interaction (Ehrenreich and Cohen, 1959). The long-wavelength Fourier components of an applied static potential are screened by a factor $Q/(Q+Q_s)$, where the screening parameter is given by $Q_s=g_v m^* e^2/2\pi\bar{\epsilon}\hbar^2$ in a degenerate system and by $Q_s=e^2N/2\bar{\epsilon}k_B T$ in a nondegenerate system, where N is the two-dimensional carrier density. Note that the screening parameter is independent of carrier density in this long-wavelength limit in the degenerate case, reflecting the fact that the density of states of a two-dimensional electron gas is independent of energy within a subband. In three dimensions, the corresponding screening factor has the form $q^2/(q^2+q_s^2)$. The screened potential of a point charge falls off as $\exp(-q_s r)$ in a three-dimensional system, and falls off as R^{-3} for large values of R in two dimensions. Thus the screening in two dimensions is considerably weaker than in three dimensions, and the two-dimensional screening does not set a length scale in the same way as its counterpart in three dimensions. At low temperature and if level broadening is small, the potential also has oscillatory terms, the Friedel oscillations, which arise from the sharp drop in the screening of a two-dimensional electron gas at a wave vector equal to the diameter of the Fermi circle, the occupied region of wave-vector space.

The dynamical response of a two-dimensional electron gas leads to collective longitudinal modes, called plasma oscillations or plasmons, whose dispersion at small wave vectors is $\omega_p=(Ne^2Q/2\epsilon m^*)^{1/2}$, where N is the two-dimensional carrier density, first obtained by Ritchie in 1957, which has a square-root dependence on wave vector. This is considerably different from the three-dimensional result $\omega_p=(ne^2/\epsilon m^*)^{1/2}$, where n is the three-dimensional carrier density. The square-root dispersion of plasma oscillations in a two-dimensional system, which becomes quasilinear at small wave vectors if there are nearby gates or other metallic regions, has been verified experimentally both for electrons on liquid helium and for electrons in two-dimensional systems in semiconductors. This subject, including effects of magnetic fields, has been reviewed by Theis (1980).

Detailed studies of the dielectric response of the two-dimensional electron gas, with references to earlier work, are given by Czachor *et al.* (1982) and by Tanatar (1991). Studies for one-dimensional electron systems have been carried out by Friesen and Bergersen (1980) and others.

3.3 Bound States

Just as the hydrogen atom has proved to be a useful model system for discussing atomic spectra, its analog in bulk semiconductors has played a similar role. The energy levels of an electron bound to a center with a (positive) charge e in a semiconductor with permittivity ϵ and effective mass m^*, measured relative to the adjacent conduction-band edge, are

$$E_n=-m^*e^4/32\pi^2\epsilon^2\hbar^2n^2,\quad n=1,2,\dots, \tag{10}$$

in the hydrogenic approximation, whose validity improves for small effective mass and large dielectric constant. Corrections, sometimes called central-cell corrections, can change the energy significantly, particularly for the lowest states, whose wave functions are most localized. If mobile carriers are present, they will screen the attractive potential and reduce the binding energy. In three dimensions bound states arise only if the attractive potential is sufficiently strong. Thus for sufficiently high carrier densities, with correspondingly strong screening of the Coulomb potential, there are no bound states in three-dimensional systems.

In two dimensions the situation is quite different. The hydrogenic binding energy of an electron confined to a plane, in the presence of the attractive potential of a single (positive) charge e located in the plane is

$$E_n = -m^* e^4 / 8\pi^2 \bar{\epsilon}^2 \hbar^2 n^2, \quad n = 1,2,..., \qquad (11)$$

where $\bar{\epsilon}$ is the average permittivity of the media on the two sides of the plane in which the electron moves. If the dielectric constant is the same on both sides, the hydrogenic binding energy in two dimensions is four times as large as the bulk value. Screening effects will reduce the binding energy, as will a displacement of the attractive charge out of the plane in which the electrons move. In real two-dimensional systems, the electron wave function has a nonzero spatial extent perpendicular to the plane, and this also reduces the binding energy.

Another important result of the lower dimensionality is that there is no longer a threshold for appearance of a bound state. An arbitrarily weak attractive potential in a two-dimensional system can have a bound state, although the binding energy rapidly approaches zero and the spatial extent of the wave function becomes extremely large as the potential weakens.

Bound states in silicon inversion layers associated with sodium ions at the Si–SiO$_2$ interface have been seen in electrical measurements by Fowler and Hartstein (1980) and in optical measurements by Glaser *et al.* (1986) (see Interface Structures, Electronic Properties of; Si–SiO$_2$ Interface, Electronic Properties of). Detailed investigations of impurity levels in quantum wells have been made by a number of authors, for example, Reeder *et al.* (1988). For additional discussion, including theoretical aspects, see Heterostructures and Superlattices, Semiconductor.

Extensions of these results to dimensionality less than two are less simple in form, because the spatial extent of the wave function plays an increasingly important role. The general trends continue, however. Lower dimensionality leads to stronger binding.

4. TRANSPORT PROPERTIES

Although the general heading of transport properties includes heat transport and thermoelectricity, the discussion in this article is limited to electrical conduction. Many of the effects found in bulk systems are found in low-dimensional systems as well. For example, optical-phonon scattering is generally the dominant scattering mechanism at room temperature. There are two new elements that enter in low-dimensional systems: the states that carry current are now the constrained states of the particular structure, and the presence of interfaces may add new scattering mechanisms. Also, the size of the device in the direction of current flow may be comparable to the phase-breaking length or the mean free path, in which case the theory used to describe the transport differs from the conventional Boltzmann transport theory.

4.1 Boltzmann Transport

For systems that are large in the direction of current flow but small in one or two other directions, the effect of an electric field can be described as a perturbation on the occupation of current-carrying states, as given by the Boltzmann equation (see Electronic Transport in Solids), leading to a nonzero current flow. In some cases (for example, elastic scattering only) the Boltzmann equation can be solved explicitly and the scattering rate is given by an integration over all scattering events, weighted according to their influence on current flow. In other cases (for example, where optical-phonon scattering is important), more elaborate means for solving the Boltzmann equation must be used.

The low-temperature mobility of a two-dimensional electron gas is limited mainly by scattering from ionized impurities. In a silicon inversion layer, these are usually located near the Si–SiO$_2$ interface, and lead to peak mobilities of order 3×10^4 cm^2/V s. In a heterojunction or quantum well, the impurities may be purposely introduced to supply carriers, or may be residual impurities. In the highest-mobility heterolayers, it is the residual impurities that probably dominate the scattering. Because the cross section for Coulomb scattering decreases with increasing carrier velocity, the scattering rate in high-mobility samples decreases—and the mobility therefore increases—as the carrier density increases, because of the increase in the velocity of carriers at the Fermi surface.

Interface roughness is another scattering mechanism important at low temperatures. The roughness is usually modeled through the correlation of the excursion of the relevant interface from a plane. A Gaussian model,

$$\langle \delta z(\mathbf{R})\delta z(0)\rangle = \Delta^2 \exp(-R^2/\Lambda^2), \qquad (12)$$

where Δ and Λ are, respectively, the root mean square magnitude of the roughness and its lateral correlation length, was used at first, partly because of its simplicity. More recent work (Goodnick *et al.*, 1985) indicates that an exponential form for the roughness autocorrelation may be closer to experiment for silicon inversion layers. Interface roughness scattering becomes important in silicon inversion layers at high electron densities, and in quantum wells at small well widths. A discussion of low-temperature inversion-layer mobility that combines these mechanisms and analyzes the peak mobility versus carrier density has been given by Gold (1985).

Although the mobility at low temperatures in a degenerate electron system is expected to depend very little on temperature, since the velocity of the carriers involved in scattering processes is very close to the Fermi velocity, experiments by Cham and Wheeler (1980) and by Kawaguchi and Kawaji (1980) found an unexpectedly strong temperature dependence that could not be accounted for by known phonon-scattering mechanisms. Stern (1980) showed that the strong singularity at $2k_F$ of the wave-vector–dependent screening by a two-dimensional electron gas leads to a substantial temperature dependence even without phonon scattering. Detailed analytic expressions for the effect were given by Gold and Dolgopolov (1986).

Acoustic phonons scatter electrons both by deforming the lattice and perturbing the energy-band structure, called deformation-potential scattering, and—in polar materials—by creating electric fields, called piezoelectric scattering. At low temperatures the strength of these two scattering mechanisms is generally proportional to T. At higher temperatures, usually of order 100 K and above, optical-phonon scattering becomes important and generally increases rapidly with increasing temperature. Phonon-scattering mechanisms in semiconductor layers have been described in detail by Price (1981). Detailed analysis of high-temperature transport in low-dimensional systems is complex, both because the matrix elements for the scattering processes involve the wave functions of the confined states and because many subbands are occupied at elevated temperatures, requiring intersubband scattering processes to be treated. As the temperature increases and many subbands become occupied, the transport properties are expected to approach those of the bulk material.

An example of the temperature dependence of electron mobility in a high-quality Al$_{0.35}$Ga$_{0.65}$As/GaAs heterojunction, from the work of Pfeiffer *et al.* (1989), is shown in Fig. 3. Very high mobilities, of order 10^7 cm^2/V s, are achieved only at low temperatures and at very low current densities, and require samples with tight control over residual impurities. Figure 3 shows the great strides that have been made in improving electron mobility in GaAs-based heterojunctions.

If the electric field that induces the current is increased, the carrier temperature rises and the mobility drops. Non-Ohmic effects are seen in all two-dimensional systems as well as in three-dimensional systems, but the details depend on quantitative aspects of the scattering mechanisms and energy-level structure of the system.

When a current flows in a two-dimensional system with a magnetic field applied perpendicular to the electron plane, a current (or voltage, if current flow is blocked) develops at right angles to the direction of the current and the field. This is the Hall effect, well known in bulk systems (see ELECTRONIC TRANSPORT IN SOLIDS). The discovery (von Klitzing *et al.*, 1980) that at high magnetic fields the Hall conductance is accurately quantized in integer multiples of e^2/h, the famous quantum

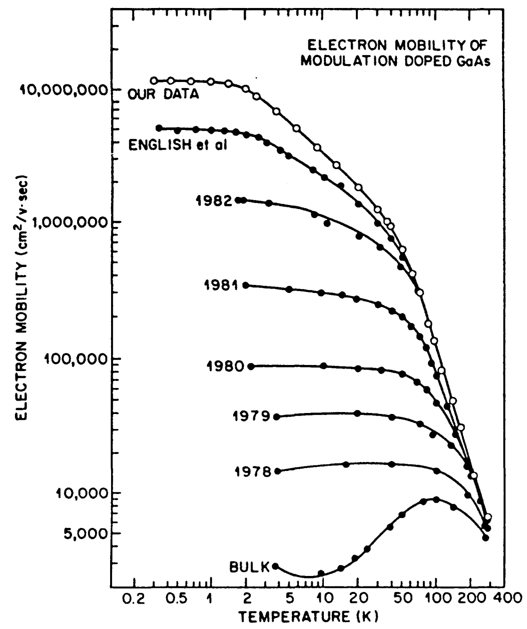

FIG. 3. Electron mobility in modulation-doped $Al_xGa_{1-x}As/GaAs$ heterojunctions, showing steady increases over the years. Note that all the mobilities approach the bulk value at 300 K. [After Pfeiffer *et al.* (1989).]

Hall effect, led to important theoretical and practical developments, which are described elsewhere (see QUANTUM HALL EFFECT, where the subsequent discovery of the fractional quantum Hall effect is also described), and to the award of the Nobel Prize in Physics to Klaus von Klitzing in 1985.

Microwave absorption between the Landau levels induced by a magnetic field B perpendicular to the plane of a two-dimensional electron gas, called cyclotron resonance, occurs at radian frequency eB/m^* if there are no impurities or defects. The experiments have a rich structure and an extensive literature. Work on cyclotron resonance in silicon inversion layers has been discussed by Ando *et al.* (1982). Richter *et al.* (1989) describe cyclotron resonance in doped heterostructures.

Sakaki (1980) suggested that the mobility in one-dimensional electron systems might be enhanced over corresponding values in two-dimensional systems because the only scattering that can limit the current is backscattering, in which the carrier direction reverses. Such events have a large momentum transfer, and this reduces the cross section for Coulomb scattering. There has been, as of this writing, no detailed confirmation of this idea. Measured mobilities for quantum wires are lower than those of the best two-dimensional structures. Quantum-mechanical corrections to a simple Boltzmann description of transport become stronger as the dimensionality is reduced, and may limit the applicability of ideas based on intuition developed for bulk transport.

Dimensionality has a strong influence on the transition between localized and delocalized states, in some ways similar to its influence on bound states. For dimensions above two, there is a threshold in the amount of disorder needed to localize states in a band. For one and, of course, for zero dimensions, all states are localized at absolute zero. In two dimensions, which represents a boundary between these two regimes, all states are weakly localized even in the limit of very weak disorder, but for sufficiently strong disorder states can be strongly (exponentially) localized. (See METAL–INSULATOR TRANSITIONS; ELECTRON STATES, LOCALIZED.)

4.2 Mesoscopic Systems

In two-dimensional systems, such as heterojunctions and inversion layers, it is possible to make samples in which one or more dimensions are small compared to the phase-breaking length, mentioned in Sec. 1. In this regime, sometimes called the mesoscopic regime, the assumptions underlying a Boltzmann transport picture are no longer valid (see MESOSCOPIC SYSTEMS). Phase coherence leads to interference effects not present at higher temperatures.

Among the phenomena that characterize the mesoscopic regime are fluctuations, often of order e^2/h, in the conductance of a sample as some physical parameter such as the voltage on a control gate, or the value of an applied magnetic field, is varied. Another effect seen in such samples is the Aharonov–Bohm effect, a periodic variation in the resistance of a ring as the magnetic flux through the ring changes by multiples of the flux quantum, h/e. A review of some of these effects has been given by Washburn and Webb (1986).

An approach to transport based on the transmission of a current past a scatterer or obstacle, originally proposed by Landauer in

1957, has been extended by him, Büttiker, and others to provide a valuable framework for considering transport in mesoscopic systems, with or without external magnetic fields present. The role of contacts as reservoirs in which equilibration takes place is an essential part of this picture. It is now recognized that simple concepts, such as the additivity of resistances of successive segments of a wire, can break down completely in sufficiently small structures. A recent discussion of transport in quantum wires has been given by Timp (1991).

4.3 Constrictions

The many methods of patterning samples, some of them described in Sec. 2, allow the fabrication of structures that cannot be described as quantum wires or dots. One such category, constrictions, has led to a number of dramatic experimental and theoretical discoveries. A constriction can be introduced by using electrostatic or other means to create a narrow neck separating two wider regions. This could take the form of a quantum wire, if the constriction is long compared to its width, or it could just be a saddle point separating two wider regions. van Wees *et al.* (1988) and Wharam *et al.* (1988) found that the conductance of a narrow constriction separating two quasi two-dimensional electron systems had a steplike structure as the voltage that controlled the size of the constriction was varied, and was approximately (within about 1%) quantized in multiples of $2e^2/h$, where the factor 2 arises from spin degeneracy.

The approximate quantization of conductance of constrictions is understood qualitatively. Far from the constriction, there are many current-carrying modes or channels. Near the constriction most of these modes are raised to such high energies that they lie well above the Fermi energy and cannot carry current past the constriction. For the few modes that can still pass a current, the transmission coefficient can be very close to unity if the constriction narrows and then widens gradually in the direction of current flow. That is expected to be the case for constrictions made electrostatically via patterned gates, because of fringing of the field lines between the gate and the layer where the electrons are located, and accounts for the experimental results. Constrictions with sharp corners would be expected to have additional structure in the dependence of conductance on gate voltage or another parameter controlling the width of the constriction. This subject has been well reviewed in the article on quantum transport in semiconductor nanostructures by Beenakker and van Houten (1991).

5. OPTICAL PROPERTIES

The changes in electronic structure associated with reduced dimensionality have significant effects on the optical properties in a one-electron picture. In addition, the effects of Coulomb interaction between the electron and hole that take part in an optical transition also enter in an important way. We saw, for example, that the binding energy of a charge attracted to an unscreened Coulomb potential increases by a factor of 4 on going from three to two dimensions. The combined effects of density of states and of Coulomb interaction serve to enhance the strength of optical transitions near the optical threshold. An important consequence is that the effects of low dimensionality on some optical properties can persist to room temperature, while the effects on transport properties generally are only seen at cryogenic temperatures. Thus some optical applications of low dimensionality have the advantage over electrical applications that low temperatures may not be required.

An early optical experiment on a two-dimensional system was the far-infrared intersubband absorption study of silicon accumulation layers by Kamgar *et al.* (1974). Because such transitions involve states within the same band of the underlying semiconductor, the optical matrix element between the Bloch function factors in the wave function is zero or very small. The optical matrix element in this case is proportional to $|\zeta_f^* \mathbf{E}\cdot\nabla\zeta_i|$, where ζ_i and ζ_f are the envelope wave functions of the initial and final states. Because the envelope functions depend only on the z coordinate, the matrix element will vanish in this simple example unless the electric field $\mathbf{E}$ of the incident light has a component polarized in the z direction. Light incident normal to the inversion layer is, therefore, not absorbed by this process. Kamgar and co-workers constructed a waveguide structure to funnel the light along the two-dimensional layer, but many other schemes for achieving the required polarization have been used. The experiments were in good agreement with theory after the effects of electron–electron interaction and so-called depolarization corrections were taken into account. See, for example, the discussion in Ando *et al.* (1982).

Parabolic potentials can be imposed on electronic motion in low-dimensional structures either by compositional grading, as in parabolic quantum wells, or as a natural consequence of electrostatic confinement in quantum wires and quantum dots. A remarkable property of electron motion in a parabolic potential is that many of the electron–electron interactions that perturb energy levels drop out in optical excitations of such a system (Brey *et al.*, 1989). That effect is exhibited in the far-infrared absorption of an array of quantum wires, studied by Hansen *et al.* (1987) and illustrated in Fig. 4. In these samples the density of a two-dimensional electron gas in a GaAs-based heterojunction is modulated by changing the voltage on a gate deposited over an insulator whose thickness varies laterally with a period of 500 nm. When a negative voltage is applied to the gate, charges induced in the GaAs by donors in the adjacent $Al_xGa_{1-x}As$ are depleted. For the upper range of gate voltages shown, the experiment measures the plasma resonance of a modulated two-dimensional electron gas, whose energy drops as the gate voltage becomes negative because the average density is decreasing. The clear break in the curve in Fig. 4 is associated with decoupling of the charge into adjacent quantum wires, whose effective width and effective charge density decrease as the gate voltage becomes more negative. The measured energy is identified as the harmonic oscillator energy of the bare potential in the wire at the given gate voltage, not as an energy difference of the one-dimensional subbands. This result is supported by separate magnetotransport measurements which show that the subband separations are considerably smaller than the measured optical transition energies.

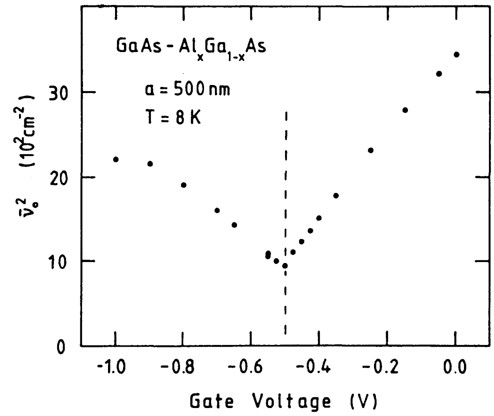

FIG. 4. Square of the resonant absorption wave number of an array of quantum wires induced in a selectively doped GaAs–$Al_xGa_{1-x}As$ heterostructure by electrostatic modulation of the carrier density using a metallic grating with a 500-nm period as a gate electrode. As the gate voltage is made more negative, the density of the two-dimensional electron gas in the GaAs is at first spatially modulated, with accompanying reduction of the average density, until at the most negative gate voltages the electrons are confined to an array of quantum wires. Note that 8 cm^{-1} corresponds to about 1 meV. [After Hansen *et al.* (1987).]

The cancellation of many-electron interactions in optical transitions also occurs when a magnetic field is present: the excitations observed are those of noninteracting electrons. In a quantum disk with a two-dimensional harmonic oscillator potential and a magnetic field perpendicular to the plane of the disk, the energy levels (first found by Fock in 1928) are

$$E=(2n+|l|+1)(E_L^2+E_O^2)^{1/2}+lE_L,$$
$$l=0,\pm1,\pm2,\ldots \qquad (13)$$

where E_O is the harmonic oscillator energy and $E_L=\hbar\omega_c/2$ is the Larmor energy. The energies of optical transitions, subject to the selection rule $\delta l=\pm1$, are given by

$$\delta E=(E_O^2+E_L^2)^{1/2}\pm E_L, \qquad (14)$$

as found by Sikorski and Merkt (1989).

Intersubband optical transitions can also be studied with inelastic light scattering. Here the polarizations of both the incident and the scattered photons enter, and one distinguishes between parallel polarizations, which are sensitive to collective effects, and crossed polarizations, which sense the one-electron states without such corrections. For a discussion of this powerful spectroscopic technique, including application to two-dimensional systems, see, for example, Abstreiter *et al.* (1984). See also RAMAN SCATTERING. Many light-scattering experiments to explore the effects of low dimensionality have been carried out in quantum wells and other heterostructures (see HETEROSTRUCTURES AND SUPERLATTICES, SEMICONDUCTOR).

Many aspects of reduced dimensionality are exhibited by the system of small particles in a glassy matrix [see, for example, Ekimov *et al.* (1989)]. In particular, excitonic effects exhibit considerable variety, depending on the relation of the particle size to the exciton radius or to the effective Bohr radii of electrons and holes. [The effective Bohr radius of a carrier with effective mass m^* in a medium with permittivity ϵ is $4\pi\epsilon\hbar^2/m^*e^2$. The exciton radius is given by the same expression, with the reduced mass $m_e^*m_h^*/(m_e^*+m_h^*)$ taking the place of the effective mass.] For particles smaller than the effective Bohr radius of both electrons and holes, the confinement effects begin to dominate the excitonic effects.

Semiconductor lasers have been optimized through the flexibility afforded by the various growth and fabrication methods available. Many kinds of structures have been made to confine the carriers, the photons, or both so as to reduce losses and threshold currents. Quantum wells— and more recently quantum wires and quantum dots—are widely used, and benefit from the enhancement effects mentioned earlier in this section (see LASERS, SEMICONDUCTOR).

Optical methods have been used to study the effects of reduced dimensionality on diluted magnetic semiconductors (see SEMICONDUCTORS, DILUTED MAGNETIC)—for example, by tailoring the wave-function confinement in the quantum well and thereby influencing the interaction between electrons and the magnetic atoms, which in some structures are located only in the barrier and not in the quantum well.

6. ELECTRONS ON CRYOGENIC SUBSTRATES

Electrons just outside the surface of liquid helium are attracted to the surface by the very weak image potential energy, $-e^2\delta/16\pi\epsilon_0 z$, where $\delta=(\epsilon_{He}-\epsilon_0)/(\epsilon_{He}+\epsilon_0)$. Here ϵ_{He} is the permittivity of liquid helium, ϵ_0 is the permittivity of free space, and z is the distance of the electron from the surface. The dielectric constant of liquid ^{4}He is $\epsilon_{He}/\epsilon_0=1.057$, and so the potential is rather weak. In most experiments, it is enhanced by an external electric field applied normal to the liquid–vapor interface. The resulting potential well leads to two-dimensional subbands with energy separations of order 1 meV. The density of electrons is limited to values below about 10^9 cm^{-2} by a hydrodynamic instability. At such low densities, the electrons are not degenerate, i.e., their energy distribution in equilibrium is described by Maxwell–Boltzmann statistics even at temperatures in the millikelvin range.

The mobility of electrons in such a system is limited by scattering from helium atoms in the vapor above the liquid helium—an effect that can be reduced by lowering the temperature and therefore the vapor pressure of the helium—and by scattering of electrons by surface excitations in the liquid, called ripplons. At very low temperatures, mobilities as high as 10^7 cm^2/V s have been achieved. Millimeter-wave absorption measurements give sharp spectral lines in good agreement with theoretical expectations provided allowance is made for the fact that the density of the helium changes from its value in the liquid to its value in the vapor over a distance of about 0.5 nm, leading to a gradual interface rather than the abrupt interface assumed in the conventional image potential as given above.

Although this system has no known applications, it has led to several beautiful experimental results. The first experimental confirmation of the predicted dispersion law of two-dimensional plasmons (see Sec. 3.2) was obtained for electrons on liquid helium. Even more dramatic, this system gave the first experimental example of an electron crystal, a structure in which the electrons form a regular lattice. Microwave measurements by Grimes and Adams in 1979 showed a series of features that could be identified as the modes of a hexagonal electron lattice [Grimes and Adams (1980)]. The melting temperature is proportional to the square root of the electron density, consistent with a Kosterlitz–Thouless (1973) melting mechanism involving the thermal excitation of dislocations in the electron lattice. The physical parameter in such a theory is the ratio of the average potential energy of interaction between electrons to the average kinetic energy. This ratio, $\Gamma=(\pi N)^{1/2}\times e^2/4\pi\epsilon_0 k_B T$, where N is the two-dimensional electron density, is found to be about 130 at the melting temperature. For a detailed account of the theory, see Nelson and Halperin (1979).

If, at some fixed and very low temperature, the electron density could be steadily increased, the electron gas would eventually become degenerate. A melting transition is again expected, but in this case the system would be an electron liquid, with no long-range order, at densities *above* the critical density, while at densities below the transition the electrons would form an ordered lattice to minimize their potential energy. This transition was predicted by Wigner in 1934 for three-dimensional systems, and the resulting crystal is called a Wigner crystal, but has eluded experimental observation. The two-dimensional density where such a transition would be expected to occur for electrons on liquid helium is of order 10^{12} cm $^{-2}$, three orders of magnitude higher than the stability limit mentioned above. A number of people have tried to achieve such densities by using cryogenic solids instead of liquids as substrates, or by using thin films of liquid helium on a substrate with higher dielectric constant. A considerable increase in density has been achieved [see, for example, Kajita (1988)] but not enough as yet to see the Wigner crystal in this system.

A magnetic field perpendicular to the electron plane can enhance the tendency to crystallize at low densities (see, for example, Lam and Girvin, 1984). Such a system, often also called a Wigner crystal but perhaps more properly called a magnetically induced electron crystal, has been investigated primarily in GaAs-based heterostructures. Impurity effects complicate the interpretation of experiments, and definitive confirmation of the presence of a magnetically induced electron crystal remains elusive.

An introduction to the physics of electrons on liquid helium is provided, for example, by the articles of Cole (1974) and Grimes (1978). Stan and Dahm (1989) have investigated the melting of the electron crystal through measurements of the temperature dependence of electron mobility and effective mass.

7. DEVICES AND APPLICATIONS

Semiconductor devices have been central to the massive growth of applications in information storage and processing and in communications. As miniaturization of these devices continues, they are coming closer to the regime where low dimensionality begins to play an important role, particularly if the big step to low-temperature operation is taken. It is therefore likely that some of the effects of reduced dimensionality, which have primarily been of research interest, will find increasing prominence in applications in coming years.

Devices that exhibit negative resistance as a result of tunneling through barriers that contain energy levels resonant with states in the contact regions have been widely investigated and are used as high-frequency oscillators. Reduced dimensionality plays a role in the physics of such devices. See RESONANCE TUNNELING for a discussion of this fascinating field.

Some of the properties of low-dimensional structures lend themselves to new kinds of devices. In the ballistic regime, for example, electronic structures are analogous to waveguides and lend themselves to manipulation in a coherent way, to influence the nature of modes, their transmission, and their direction. Many such devices have been proposed and investigated. Electrostatic focusing of electrons has been demonstrated by Spector *et al.* (1990) and Sivan *et al.* (1990). The possibility that the motion of individual electrons through small tunnel junctions can be correlated has been discussed by Likharev (1989), and a number of related ideas have been proposed and in some cases implemented. The high impedance and limited current-carrying capacity of small devices in the regime in which these novel effects occur will limit the range of applications that is possible. Landauer (1990) has emphasized conditions that devices for general-purpose computer logic should meet, and pointed out that many proposals do not meet these conditions.

The situation is somewhat different in the case of optical applications. Many of the effects associated with reduced dimensionality, such as enhanced binding energy and oscillator strength, persist to room temperature and therefore are quite promising for immediate application. Small semiconductor lasers are an example. Quantum wells have also been proposed as versatile infrared detectors, since the resonant energies can be varied over a wide range by appropriate design of the quantum-well dimensions and composition [see, for example, Goossen *et al.* (1988) and Levine *et al.* (1990)].

Optical nonlinearities in low-dimensional structures also lend themselves to device applications, such as bistability, mixing effects, modulation of amplitude or phase, switching, and beam deflection [see, for example, the articles in the book edited by Haug (1988)].

8. MODELING

Low-dimensional structures with simple shapes lend themselves to simple theoretical models such as the particle in a box (a flat potential bounded by infinitely high, steep walls) and the parabolic potential. Analytic results for some other structures, including quantum wires near and below threshold, have also been obtained [see, for example, Davies (1988)]. More complicated structures, such as electron waveguides with bends, generally cannot be treated analytically and are increasingly being studied with numerical methods. Some of the techniques are similar to those used for modeling semiconductor devices (see SEMICONDUCTOR DEVICE MODELING) or microwave devices. The models can be grouped into static models, which find the potential profiles and energy levels for a particular structure given the distribution of impurities and the voltages on electrodes, and dynamic models, which calculate the transmittance properties linking various modes of the system when a current is flowing. Examples of static calculations are the work of Laux and Stern (1986) and Kerkhoven *et al.* (1990), who solve the Schrödinger and Poisson equations self-consistently for a rather general two-dimensional semiconductor structure. An example of a dynamic calculation is the work of Baranger (1990), who finds the transmission coefficients of various modes in a semiconductor waveguide. Computational aspects of such calculations have been considered, for example, by Lent and Kirkner (1990).

Numerical methods are also required for calculations of conductance of low-dimensional structures in the high-electric-field, non-Ohmic regime. Such calculations are similar to those used for bulk semiconductors, invoking the drift-diffusion approximation or similar approximations based on moments of the Boltzmann equation, or using Monte Carlo methods to solve the Boltzmann equation itself [see for example, Jacoboni and Lugli (1989)]. Lower dimensionality, however, makes quantum corrections to Boltzmann transport increasingly important, and more powerful methods may be required. Fully quantum-mechanical treatments have not been as widely used as treatments based on the Boltzmann equation, except for the work on localization effects noted in Sec. 1 above.

9. SUMMARY

Low-dimensional structures have provided enormous scope for invention, both in physics and in potential applications. The field is about 25 years old, and some aspects are reasonably well developed and understood. The effects of reduced dimensionality on electrical and optical properties and on thermodynamic properties can be dramatic, and this has made the field exciting and productive. Technological and materials problems in fabricating ever smaller structures often limit the rate at which advances are made, but there is good reason to expect continued progress, with the ultimate limit on size set mainly by atomic dimensions. Many applications of low-dimensional structures have been proposed, and in many cases realized, and it is likely that use of such devices will increase in the next decade.

ACKNOWLEDGMENTS

I am indebted to John and Christine Davies for helpful comments.

GLOSSARY

Degenerate System: A system of carriers, governed by Fermi–Dirac statistics, at low temperatures. Apart from thermal broadening of order $k_B T$ near the Fermi energy, where k_B is the Boltzmann constant, all states from the band edge or subband edge to the Fermi level are occupied.

Fermi Wave Vector: The radius of the region in wave-vector space occupied by electrons at low temperatures; proportional to $n^{1/d}$, where n is the carrier density and d is the dimensionality.

Inversion Layer: A confined layer of carriers near the surface of a semiconductor, with carrier type opposite to that of the bulk.

Modulation Doping: Impurity placement in a heterostructure that minimizes scattering and maximizes mobility by introducing the impurities outside the region in which carriers are confined. Also called *selective doping.*

One-Dimensional System: A system in which carriers are free to move in one direction, but are constrained in the other two space dimensions. Sometimes called a *quantum wire.*

Quantum Dot: A structure in which carriers are confined in all three space dimensions. A *zero-dimensional* system.

Subband: A continuum of states in a two-dimensional system associated with quantization in one dimension and free electron motion in two dimensions, or the analogous continuum in a one-dimensional system.

INTRODUCTION

In a perfect elemental crystal, all atoms are identical and arranged periodically in space. This periodic arrangement constitutes perfect, long-range translational order. An immediate consequence of this perfect periodicity is that there are universal features in the electronic structure of crystals. The most important of these are energy bands separated by gaps, crystal momentum as a good quantum number, and the form of the states as plane waves modulated by the lattice periodicity. These universal features form the basis of Bloch's theory of electron states in a perfect periodic lattice. Although this basic theory of perfect crystals with noninteracting particles can only explain a few observable properties of solids, it provides the conceptual foundations for most of solid-state physics, if it is supplemented by a kinetic theory in which the electrons interact with one another and with imperfections of different types in the lattice.

Disordered materials lack the periodicity of the crystals. Accordingly, one might expect that all those universal features of crystalline materials dependent upon their translational symmetry disappear as well. However, it might be possible that there are also corresponding universal features in the electronic structure of disordered materials. If so, what are they?

The theory of noninteracting electrons in static disordered systems is well developed only in the case of low concentration of impurities. In this limit, multiple scattering from different impurities can be omitted and the problem can be reduced to that of a single impurity. Even under circumstances where some appropriate measure of the disorder cannot be considered weak, a very common situation in real materials with practical interest, we usually approximate the disordered system under study by an "effective" periodic one, a situation where Bloch's theory can be readily applied.

Anderson's classic paper "Absence of Diffusion in Certain Random Lattices" in 1958 treated the motion of an electron in a random potential, outside the framework of Bloch's theory. Anderson came to the conclusion that randomness, if strong enough, can trap the electron in a finite region of space. This is known as the *Anderson localization problem.* If the disorder is weak, the wave function

appears as a plane wave on a short length scale and, of course, it loses phase coherence—because of scattering by the random potential—on a long length scale. The distance over which the phase of the wave function deviates appreciably from that of the plane wave is called the mean free path. As the disorder is made stronger, additional changes in the nature of the wave function occur: amplitude fluctuations appear that become stronger and of larger extent as the randomness increases. Eventually, one (or a few) of the fluctuations may dominate and the corresponding eigenfunctions undergo a qualitative transformation, becoming *localized,* or *nonpropagating.* This means that their amplitude, $|\psi(\mathbf{r})|$, decays to zero as $|\mathbf{r}| \to \infty$ (usually by acquiring an exponential envelope). Physically, one expects states to become localized when the mean free path becomes comparable to the wavelength. The central question in the Anderson localization problem is precisely how the localized states evolve from extended states as the disorder increases. The study of Anderson localization for the last 30 years has led to new concepts such as wave-function localization, mobility edges, and fractal wave functions, and to a different way of describing materials. It also marked a significant departure from the philosophy (Bloch's theorem and perturbation theory) that had dominated solid-state physics. These new concepts and ideas have expanded into many fields beyond the electronic structure of matter. Research in the physics of disordered systems has seen a substantial growth in the last decade.

The approach taken here is to review the universal features of perfect and imperfect crystals, observing the effects of increasing disorder on the electronic structure. Then the nature of disordered materials is discussed and a simple model that illustrates the main characteristics of the electronic structure is presented. The focus is on the universal features of these models and their consequences for amorphous semiconductors. Simple arguments are given showing that continuous bands of extended states with tails of localized states associated with fluctuations within the disordered material can always be expected. The significance of the disorder-induced localization transition is discussed. A distinct energy exists, called the mobility edge, that separates regions of localized from regions of extended states. At the mobility-edge energy, the character of the wave functions changes abruptly, even though the eigenvalue spectrum is continuous. Exactly at the mobility edge, the electron states are fractal in nature. The question of the dimensionality dependence of the Anderson transition and the energy dependence of the tails of the density of states (Urbach tails) is reviewed. We present examples of the general theoretical results applied to binary alloys, quasiperiodic systems, and model systems with different types of disorder. Experimental evidence is also presented that supports the localization transition. Recently, the question of classical wave localization has received increased attention and the existence or not of gaps in classical wave systems is of central interest. In conclusion, we summarize the present state of the field and indicate the unsolved problems of immediate interest.

1. THE UNIVERSAL FEATURES OF ELECTRONIC STRUCTURES IN CRYSTALLINE AND DISORDERED SYSTEMS

The electronic structures of crystals, both perfect and imperfect, show universal features. Bloch's theorem for the crystalline system and the existence of energy bands separated by gaps are two typical examples. The basic model for disordered systems is first presented as a natural extrapolation of the modifications resulting as one moves from perfect crystals to imperfect crystals.

1.1 Perfect Crystals

We consider the motion of electrons in perfect crystals in the single-particle picture. The common characteristic of perfect crystals is their periodicity. An immediate consequence of this perfect periodicity is the Bloch-Floquet theorem stating that the one-electron wave function is a periodically modulated plane wave, i.e., it must be of the form

$$\psi_{nk}(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} U_{nk}(\mathbf{r}), \tag{1}$$

where the wave vector **k** is in the first Brillouin zone (see ELECTRON STRUCTURE OF SOLIDS or Ashcroft and Mermin, 1976). $U_{nk}(\mathbf{r})$ has the periodicity of the crystal structure and n is the band index. Thus, all the wave functions in the crystal are extended: the magnitude is the same in every unit cell of the crystal. Moreover, all states possess perfect phase coherence, i.e., long-range order in the phase. Given the phase of the wave function at one point, one can determine the phase at any other point in the crystal provided that one knows the wave vector **k**. The effects of the periodicity are much more severe for the density of states (DOS); the energy spectrum consists of continuous bands of allowed energy levels that may or may not overlap. In the latter case, forbidden regions, termed gaps, where no eigenenergies exist, appear. There are sharp band edges where the DOS shows square-root singularities in its dependence on energy. Within the bands there are also singularities in the DOS corresponding to various kinds of critical points in the dependence of E on **k**. As a result of these properties, an applied dc voltage will produce an ac or zero current, depending on whether or not the Fermi energy (i.e., the highest occupied energy) is inside a band. All of these features, and particularly the extended nature of the states, their perfect phase coherence, and the sharp band edges, are universal properties of the electronic structure of perfect crystals stemming from the periodicity of the lattice.

1.2 Single Localized Impurity in a Perfect Crystal

Let us consider a crystal containing a single, local imperfection such as an impurity. The problem can then be thought of as one of scattering by the imperfection, where the Bloch states of the perfect crystal play the role of the incident waves. If the local potential variation ΔV introduced by the impurity is weak, one can use the Born approximation to obtain the solution of the scattering problem. The result is that the states remain extended and retain their phase coherence. There are only minor changes in the local DOS and, in particular, the sharp band edges remain. As ΔV increases, a resonance structure develops in the DOS near the bottom of the lowest band for ΔV attractive, or near the top of this band for ΔV repulsive. Higher bands, because they are wider and with smaller gaps among them, require, in general, larger values of $|\Delta V|$ for resonances to appear. The amplitude of the states associated with the resonance is no longer spatially uniform: it is enhanced near the local imperfection, although it still extends throughout the crystal. Finally, when the strength of the potential change exceeds a certain critical value, in $d=3$, the resonance splits off from the band as a delta function in the band gap. It can be shown that the state corresponding to this delta function is bound to and consequentially localized around the impurity (for $d=1$ and $d=2$ there are always bound states independent of the strength of the potential change). Accordingly, both attractive and repulsive localized potential changes can bind an electron in a crystal, in contrast to the ordinary scattering problem where one cannot produce bound states out of repulsive potentials. The reason is that the energy spectrum in a crystal is composed of bands that possess both lower and upper bounds. A repulsive potential, if strong enough, can push a localized state above the upper bound of the continuum in the same way that an attractive potential can push a localized state below the lower bound of the continuum. These features are summarized in Fig. 1.

1.3 Imperfect Crystals

The next step is to consider what happens if we have a finite concentration of randomly distributed impurities of equal potential strength, e.g., when a crystalline semiconductor is doped with p-type impurities, which substitutionally replace host atoms. Here the disorder is due to the spatial distribution of the scatterers and is characterized by the concentration of the impurities and by the difference of the atomiclike levels between the impurity and the host atom. The disorder will affect the DOS as well as the wave functions. In general, the wave function can be written as

$$\psi(\mathbf{r})=A(\mathbf{r})e^{i\phi(\mathbf{r})}, \qquad (2)$$

where for a periodic system the amplitude $A(\mathbf{r})$ is a periodic function of $\mathbf{r}$ and the phase $\phi(\mathbf{r})$ exhibits perfect phase coherence and is given by $\phi(\mathbf{r})=\mathbf{k}\cdot\mathbf{r}$.

For a disordered system, both the phase and the amplitude of the wave function will be affected. When the disorder is weak, it is usually assumed that the amplitude is essentially unaffected, while phase incoherence appears:

$$\langle e^{i(\phi(r)-\phi(0))}\rangle \sim \exp[-|\mathbf{r}|/l], \qquad (3)$$

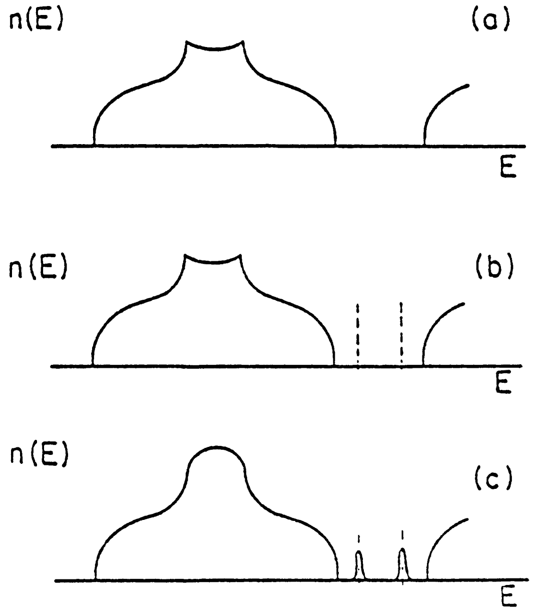

FIG. 1. Density of states *n*(*E*) as a function of energy *E* for (a) a perfect crystal, (b) a crystal containing only one localized imperfection, and (c) a crystal containing a low concentration of localized imperfections. In all three cases, there are continuous bands of energy levels separated by gaps with square-root singularities at the band edges. The square-root singularities associated with saddle points within the band in (a) and (b) are eliminated by scattering in (c). If the potential change ΔV introduced by the imperfection is strong enough in (b), localized levels split off from the bands (off the bottom for attractive ΔV or the top for repulsive), which broaden into bands in (c).

i.e., the memory of the value of the phase at a given point **r** is lost after the wave propagates a distance larger than or equal to a characteristic length called the phase-coherence length, which is of the same order of magnitude as the mean free path l. The scattering of the particle by the impurities implies a finite collision time τ. In general l depends on the eigenenergy E and the other quantum numbers characterizing the eigenfunction $\psi(r)$. Similarly τ depends on E and **k**. Through an appropriate fixed energy averaging [achieved by a Green's-function approach; see, e.g., Abrikosov *et al.* (1963), Chap. 39.2] one obtains $l(E)$ and $\tau(E)$. For weak disorder, $l(E)=v(E)\tau(E)$, where $v(E)$ is a properly averaged unperturbed velocity. If the disorder is strong, it will affect not only the phase but the amplitude as well. The wave functions exhibit strong amplitude fluctuations of variable spatial extent. It is possible, for even stronger disorder, that $A(\mathbf{r})\rightarrow 0$ as $|\mathbf{r}|\rightarrow\infty$ (usually in an exponential way). We will first discuss the effects of disorder on the DOS and then on the wave functions.

2. EFFECTS ON DENSITY OF STATES

As we have previously discussed for the case of the perfect crystal, the corresponding one-electron energies $E=E_n(\mathbf{k})$ fall into continuous bands of allowed levels usually separated by forbidden gaps. The energy $E_n(\mathbf{k})$ is a continuous function of **k** within each band and analytic except at certain high-symmetry points and lines of the Brillouin zone. There are well-defined band edges that correspond to the absolute minimum or maximum of E as a function of **k** for each band. The DOS has square-root singularities at these edges as shown in Fig. 1(a). Topological consideration shows that other critical points, saddle points, must occur within the band, also giving rise to square-root singularities in the DOS.

For the case of isolated impurities in an otherwise perfect crystal, the sharp band edges as well as the square-root singularities associated with saddle points within the band remain. The only new feature of the DOS is the introduction of impurity states in the gap that can broaden into bands if the concentration of the localized impurities becomes finite. These are called impurity bands and will be discussed later. The other effect that the finite concentration of impurities has on the DOS is the rounding off of the square-root singularities in the band. As the concentration of the localized impurities increases, one might question the entire band picture. However, there are some common experimental observations which suggest that the main features of the band picture must still be preserved. In particular, ordinary window glass, which is a disordered system, is transparent to visible light and, hence, must have a band gap of several eV, as otherwise the photons would be absorbed and the glass would appear opaque. The reason why the band picture is still valid is that short-range order is still present in disordered systems. This local order, under certain conditions, still gives rise to bands and gaps. However, the absence of long-range order has the effect of smearing the band edge into tails. We will study in Sec. 2 these tails, which are commonly called the Urbach tails. As will be discussed later, the electron states in the band tails are not the same as those within the band. The tail states are localized and, hence, electrons in those states have a very low mobility compared with those in the bands. As we will see from the discussion of the next section, the tail states are, in general, associated with local potential fluctuations.

2.1 Urbach Tails

It is well demonstrated experimentally (Cody, 1984) that the introduction of disorder causes tails to appear at the band edges in the DOS. In a systematic and thorough study, Urbach documented the existence of exponential tails in the optical adsorption of ionic crystals in 1953. Since Urbach, such exponential tails have been found in a wide range of materials, both in the optical absorption and in the DOS of individual bands (Cody, 1984). The rather general character of the exponential tails in the DOS suggests a quasiuniversal mechanism that bypasses the complexity of real materials. In the quest for uncovering such possible underlying quasiuniversality, the behavior of the DOS near the band edge can be easily understood from the following representation.

An electron moving in a disordered system can be described by a Hamiltonian of the form

$$H=H_0+H_1, \tag{4}$$

where H_0 is a nonrandom part that is assumed solvable and H_1 is random. In almost all cases, the operator $\langle H_1\rangle$, i.e., the average of H_1 over the randomness, is a constant which without loss of generality can be taken as zero. For a typical disordered system, H_0 allows us to obtain the unperturbed DOS [see Fig. 1(a)] $\rho_0(E)$ and the unperturbed Green's function $G_0(E)$; $G_0(E)$ can be expressed as an integral of $\rho_0(E')/(E-E')$. The random part H_1 in simple cases can be expressed in terms of some matrix elements ϵ_i, which are random variables possessing a probability distribution $p(\epsilon_i)$. To a first approximation, all we need to know from $p(\epsilon_i)$ is its variance w^2 and its form in the tail; in most cases, because of the many independent sources of disorder, one expects the distribution $p(\epsilon_i)$ to be Gaussian,

$$p(\epsilon_i)=\frac{1}{\sqrt{2\pi}w}\exp\left[-\frac{\epsilon_i^2}{2w^2}\right]. \tag{5}$$

Note also that lattice oscillations of not so low temperatures T produce fluctuating time-dependent local potentials with a Gaussian distribution and with an extent of atomic size. For not so low T and for fast processes, such as optical absorption, the phonon-induced fluctuations behave as static and, consequently, they give rise to another independent contribution of the form given by Eq. (5). The standard deviation (w_T) of this contribution can be obtained if the electron-phonon interaction is known; e.g., if a deformation potential coupling is assumed, i.e., if the phonon-induced electronic potential ϵ is given by

$$\epsilon=E_s\nabla\cdot\mathbf{u}, \tag{6}$$

where $\mathbf{u}$ is the lattice displacement and E_s is the so-called deformation potential, then w_T is given by

$$w_T^2=(E_s^2/B)U_L, \tag{7}$$

where B is the bulk modulus and U_L is the lattice vibration energy per unit volume due to longitudinal phonons only. For high T, $U_L\simeq k_BT/a^3$. Therefore, in the presence of both Gaussian static disorder and phonon-induced fluctuations, one obtains a local contribution of the form given by Eq. (5) with a total variance w^2 given by the sum of the static disorder variance w_S^2 and the thermal variance w_T^2,

$$w^2=w_S^2+w_T^2. \tag{8}$$

The above discussion supports the claim that the tails of the probability distribution of the local fluctuating potential exhibit, in general, a Gaussian form, which is characterized by a single parameter w^2. This parameter, together with the unperturbed DOS (and the unperturbed Green's function) near the band edges, constitute, to a first approximation, the basic inputs for calculating the main features of the electronic structure of disordered systems such as amorphous semiconductors.

The behavior of the DOS of a disordered system near the gap can be deduced from the unperturbed density of states $\rho_0(E)$ with the help of the coherent potential approximation (CPA) (Economou, 1983). The CPA is conceptually simple: the approximation consists in replacing the random matrix elements ϵ_i by appropriately chosen nonrandom complex effective matrix elements $\Sigma(E)$. The criterion that determines $\Sigma(E)$ is that the fluctuation around $\Sigma(E)$ produces no scattering on the average. This conceptually simple condition leads to a rather complicated set of equations involving $G_0(E)$, from which $\Sigma(E)$ are determined. In the weak-scattering case (w^2 small) the CPA reduces to second-order perturbation theory. It is worthwhile to note that the CPA becomes exact in the limit where the eigenstates are bound around a single, large, isolated potential fluctuation; the CPA is also very satisfactory for states extending over a large number of sites. It is only in the intermediate case where the eigenstates are trapped in a (random) cluster of a few sites that the CPA fails.

CPA (or second-order perturbation theory for small w^2) shows that the fluctuating local potential ϵ_i will produce an almost rigid shift of both the valence and the conduction bands towards the gap by amounts δE_v and δE_c, respectively, where

$$\delta E_v = |G_0(E_{v0})|w^2, \quad \delta E_c = |G_0(E_{c0})|w^2, \tag{9}$$

where $E_{v0}(E_{c0})$ is the unperturbed valence (conduction) band edge. Thus, the gap is reduced by an amount equal to $\delta E_g = \delta E_v + \delta E_c$.

In addition to the almost rigid shift of the DOS, both the valence and the conduction bands develop tails toward the gap (see Fig. 2). The tails in the DOS near the new band "edges" $E_v = E_{v0} + \delta E_v$ and $E_c = E_{c0} - \delta E_c$ are dominated by states trapped in some random clusters of atomic sites. These cluster-trapped states, under normal conditions, dominate the DOS over a very narrow range of energies. The deeper tails are usually dominated by single-site bound states. For a Gaussian probability distribution, the single-site bound states produce an exponential tail in the DOS, as observed experimentally:

$$\rho_0(E) \sim \exp[-|E|/E_0]. \tag{10}$$

Equation (10) is an immediate consequence of the fact that the binding energy E in a single potential well of depth ϵ is approximately a linear function of ϵ^2:

$$E \simeq c_1\epsilon^2 + b_2. \tag{11}$$

Equation (11) is valid over a considerable range of intermediate energies ϵ. Combining Eqs. (5) and (11), one obtains immediately Eq. (10) with $E_0 = 2c_1w^2$. This exponential behavior of the DOS could span over more than five orders of magnitude. Moreover, the calculated values of c_1 together with the estimates of w yield values of E_0 of the order of 50 meV or less, in good quantitative agreement with experiments on crystalline and amorphous semiconductors (Cody, 1984). Finally, much deeper into the tail one obtains, as one should, a gradual change of the behavior of the DOS that approaches the same functional form as the probability distribution for the disorder. This limiting behavior cannot be easily seen because it is very deep in the tail. Conditions that favor the observation of this limiting behavior are either the nearby presence of another band of similar atomic nature or the existence of large correlation lengths in the fluctuating potential responsible for the tails in the DOS.

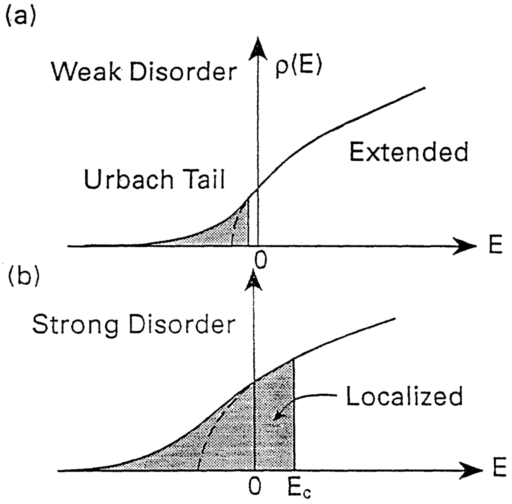

FIG. 2. (a) One-electron DOS in a random potential. For weak disorder, there is an Urbach tail of localized states below the positive-energy square-root continuum of extended states, which is shifted downward slightly by the disorder. (b) As the disorder is increased, the mobility edge eventually moves into the positive-energy regime.

The simple physical model discussed above gives clear physical insight into, and a good quantitative account of, the Urbach tail. Nevertheless, some of the assumptions of the model were untested; in particular, the correlation in the random potential was not considered explicitly. More sophisticated saddle-point (instanton) evaluation of the replica-functional-integral representation of the one-electron propagator and the Feynman path-integral formulation provide a careful treatment of DOS in a correlated Gaussian random potential (John *et al.,* 1988). The primary conclusion of this type of work is that the shape of Urbach tails in disordered materials provides a sensitive measure of the microscopic spatial autocorrelations in the random potential. The observed linear dependence of the logarithm of the tail DOS on the energy [see Eq. (10)] in a variety of materials suggests strong short-range order on the scale of the interatomic distance, but correlations that decay more rapidly than exponentially on longer length scales.

The electron–phonon (el-ph) interaction has been taken into account only in the static limit in all the evaluations described thus far. However, in slow processes such as photoluminescence, the dynamic effects of the el–ph interaction are important. These include inelastic scattering, phonon-induced hopping, and polaron formation. It is already known that disorder has a strong effect on polaron formation, and the effects of disorder are strongly affected by the dynamic aspects of the el-ph interaction. The problem is a very difficult one, and only recently have some results on the influence of lattice dynamics at nonzero temperature on band tailing been obtained (John *et al.,* 1988). The interplay between the dynamic aspects of the el-ph interaction and disorder must be addressed for slow processes. Similarly, for fast interband processes, the interplay between the electron–hole interaction and disorder must be addressed in the future.

3. CLASSICAL TRANSPORT

We know that at $T=0$, there exist neither excitations of lattice, vibrations (phonons) nor any inelastic processes. Therefore, in a perfect periodic lattice, no scattering occurs at all. This is a direct consequence of the Bloch-Floquet theorem. One is tempted to say that the collision time (mean free time) τ of the particles due to scattering of impurities, etc., is infinitely long ($\tau=\infty$) and that the mean free path $l = v_F\tau$ of the particles is also infinite ($l=\infty$); here v_F is the Fermi velocity. Actually a dc voltage will produce, in this idealized case, an ac current (or no current at all if no partially filled band exists).

In a lattice that is weakly disturbed by disorder, the situation is different. As we have discussed above, when the disorder is weak, it is usually assumed that the amplitude of the wave function is essentially unaffected, while phase incoherence appears. The scattering of the particles off the impurities implies a finite collision time τ and thereby a finite mean free path l. Then the conductivity, which is proportional to $|\int_V d^3r\psi_a^*(\mathbf{r})\hat{p}\psi_b(\mathbf{r})|^2$, becomes

$$\sigma_0 \sim \sum \left| \int_{V_l} d^3r\psi_a^*(\mathbf{r})\hat{p}\psi_b(\mathbf{r}) \right|, \tag{12}$$

where $V_l \sim l^d$, d is the dimensionality, and the summation is over all coherent regions, each of volume V_l. Mott and Davis (1979) show how one can obtain from Eq. (12) the usual formula for conductivity,

$$\sigma_0 = (e^2n/m)\tau = (e^2/p_F)nl, \tag{13}$$

where n is the electronic density, e and m are the charge and the mass of the particle, respectively, and $p_F = mv_F$ is the Fermi momentum. The quantity σ_0 is often called "Boltzmann conductivity," because Eq. (13) is also a direct consequence of the Boltzmann transport theory. In this theory, consecutive collisions of particles are assumed to be independent of each other, i.e., collisions are uncorrelated. This implies that multiple scattering of a particle from different scattering centers is not taken into account. Consequently, if such multiple scatterings become important, the basic assumption of the independence of scattering events breaks down and the validity of Eq. (13) is questionable. We will discuss in the next section what one does in this case.

4. INTERFERENCE EFFECTS

To investigate this fundamental point, we consider the diffusive behavior of a particle in a disordered system. Let the particle be in a position A at some initial time. Because of its diffusive motion, the particle will be in position B at some later time. In Feynman's formulation of quantum mechanics, the amplitude for the propagation of a particle between two points is given by the sum of classical amplitudes over all the paths connecting the two points. This is different from classical mechanics, in which one considers the most probable path only. For a free particle, the dominant trajectories have a typical width given by the de Broglie wavelength, $\lambda_{\mathrm{F}}=\hbar/mv_{\mathrm{F}}$. In the classical case ($\hbar=0$), these paths are arbitrarily sharp ($\lambda_{\mathrm{F}}=0$); in the quantum-mechanical case, however, one has that $\lambda_{\mathrm{F}} \simeq k_{\mathrm{F}}^{-1} \simeq a$, i.e., the trajectories have a finite diameter, which means that the cross section is $\lambda_{\mathrm{F}}^{d-1}$.

Now consider the propagation or transport of a particle from point A to point B. Since the transport from A to B may take place along different trajectories, there is a probability amplitude A_i connected to every path i. The total probability P of reaching point B from point A is then given by the square of the magnitude of the sum of all amplitudes, $P=|\Sigma_i A_i|^2=\Sigma_i|A_i|^2+\Sigma_{i\neq j}A_iA_j^*$. The first term describes separate noninterfering paths. This is the classical case, in which the cubes are infinitely sharp. On the other hand, the second term represents the contribution due to interference of the path amplitudes, which is a quantum-mechanical effect. In the Boltzmann theory, these interference terms were neglected. In most cases this is justified, since the trajectories have different lengths and the amplitudes A_i have different phases. On the average, this leads to destructive interference; hence, the quantum-mechanical interference is generally unimportant. In other words, the interference terms average to zero, and the addition of probabilities leads to the Boltzmann description or classical diffusion. This is no longer true, however, when one looks at closed loops—that is, when we consider the probability of returning to the starting point. In this case, starting point and ending point are identical, such that each (closed) path can be traversed in two opposite directions: forward and backward. The amplitudes for the forward and backward directions of the same path are equal; $A_{if}=A_{ib}=A_i$. For this case the quantum-mechanical probability for returning to the origin is given by $P_{\mathrm{QM}}=2\Sigma_i|A_i|^2+2\Sigma_i A_{if}A_{ib}^*=4\Sigma_i|A_i|^2$, while the classical return probability P_{cl} due to the neglect of the interference terms is given by $P_{\mathrm{cl}}=2\Sigma_i|A_i|^2$. Hence, we obtain $P_{\mathrm{QM}}=2P_{\mathrm{cl}}$. The probability for a quantum-mechanical particle to return to a starting point is seen to be twice that of a classical particle. One might argue that "quantum diffusion" is slower than classical diffusion because in the first case there exists a more effective backscattering effect. This enhanced probability of return decreases the diffusion constant and diminishes the conductivity.

To estimate the effect of the enhancement of backscattering on conductivity σ, we must consider the reduction $\delta\sigma$ of σ relative to the metallic conductivity σ_0, i.e., $\delta\sigma/\sigma_0$. Because of the expected decrease of σ, the sign of $\delta\sigma/\sigma_0$ will be negative. Furthermore, $\delta\sigma$ will be proportional to the percentage of different paths that will return to the starting point within the *inelastic* collision time, τ_{in}, after which coherence will be lost by inelastic processes. This is the same as the probability for a trajectory to intersect itself during the diffusion and for $\tau\ll\tau_{\mathrm{in}}$. In a d-dimensional tube with diameter λ_{F}, i.e., of cross section $\lambda_{\mathrm{F}}^{d-1}$, during a time interval dt, a particle moves a distance $ds=v_{\mathrm{F}}dt$; thus the corresponding volume element is given by $dV=v_{\mathrm{F}}dt\lambda_{\mathrm{F}}^{d-1}$. On the other hand, $V_{\mathrm{diff}}=(D_0t)^{d/2}$ is the d-dimensional volume into which the particle will diffuse after time t. Thus, the probability for the trajectory of the particle to intersect itself during diffusion is given by the ratio of these two volumes. We therefore have

$$P=\int_{\tau}^{\tau_{\mathrm{in}}}\frac{dV}{V_{\mathrm{diff}}}=v_{\mathrm{F}}\lambda_{\mathrm{F}}^{d-1}\int_{\tau}^{\tau_{\mathrm{in}}}\frac{dt}{(D_0t)^{d/2}}, \qquad (14)$$

where we have integrated over all times $\tau\ll\tau\ll\tau_{\mathrm{in}}$; τ is the microscopic time for single elastic collision (shorter times are not possible), while τ_{in} is the shortest inelastic time in the system. It determines the maximal time during which coherent interference of the forward-backward path amplitudes is possible. The conductivity σ_0 and the diffusion constant D_0 are related by the Einstein relation $\sigma_0=e^2N_{\mathrm{F}}D_0$, where N_{F} is the density of states at the Fermi surface. Because of $D_0\propto l$ and $\lambda_{\mathrm{F}}\propto\hbar$, one obtains, for $\tau\ll\tau_{\mathrm{in}}$, that

$$\frac{\delta\sigma}{\sigma_0}\simeq-\begin{cases}(\tau_{\mathrm{in}}/\tau)^{1/2} & d=1,\\ \ln(\tau_{\mathrm{in}}/\tau), & d=2,\\ (\tau_{\mathrm{in}}/\tau)^{-1/2}, & d=3.\end{cases} \qquad (15)$$

One can rewrite Eqs. (14) and (15) as a function of wave vectors q or lengths L instead of the different characteristic times τ and τ_{in}. Indeed, by defining $L_m=(D_0\tau)^{1/2}$, L_M

$= (D_0\tau_{\rm in})^{1/2}$, and $q=(D_0 t)^{-1/2}$, one obtains from Eq. (14)

$$P= \int_{1/L_M}^{1/L_m} \frac{q^{d-1}dq}{q^2} \sim -\frac{\delta\sigma}{\sigma_0}, \qquad (16)$$

where L_M is equal to the shortest of several upper cutoff lengths that may be present in the system, and L_m, the lower cutoff length, is believed to be very close to the mean free path l. Examples of upper cutoff lengths L_M, besides the geometrical dimension L, are the diffusion length during the inelastic relaxation time $\tau_{\rm in}$, $L_D=(D\tau_{\rm in})^{1/2}$; and the diffusion length during the time ω^{-1}, where ω is the frequency of an external ac field, $L_\omega=(D/\omega)^{1/2}$. The presence of an external magnetic field H introduces two characteristic lengths $L'_H=(D/\omega_0)^{1/2}$, where $\omega_0=eH/mc$ is the cyclotron frequency, and the cyclotron radius, $L_H=(\hbar c/eH)^{1/2}$. From Eq. (16), one finds that the contribution to the conductivity is (assuming that $L_m \ll L_M$)

$$\frac{\delta\sigma}{\sigma_0} \sim -\begin{cases} L_M/L_m, & d=1, \\ \ln(L_M/L_m), & d=2, \\ L_m/L_M, & d=3. \end{cases} \qquad (17)$$

Equation (17) is exactly equivalent to Eq. (15). For $d=1$ and $d=2$, Eq. (17) is very significant because these values show that the corrections to the conductivity do not disappear as the upper cutoff length L_M becomes very large. On the contrary, they increase with L_M until L_M becomes so large that $\sigma_0 \to 0$. Thus, a truly metallic behavior is not possible for $d \leqslant 2$. That is, of course, consistent with the statement that all eigenstates are localized for $d \leqslant 2$ (Abrahams *et al.*, 1979). However, in the presence of spin-orbit coupling, the above conclusions are modified drastically (Kramer and Schön, 1990). The nonmetallic nature of the conduction for $d \leqslant 2$ is usually masked by the fact that at high enough temperatures, L_D (and hence L_M) becomes quite short. It is clear from Eq. (17) that when $L_M \simeq L_m$, $\delta\sigma=0$.

For inelastic scattering as $T \to 0$, $\tau_{\rm in}^{-1}$ typically is proportional to T^p where the exponent p depends on which scattering, electron–phonon or electron–electron, is dominant in a given temperature range. By substituting in Eq. (15) that $\tau_{\rm in}^{-1} \sim T^p$, one obtains the following T dependence of the conductivity corrections:

$$\frac{\delta\sigma}{\sigma_0} \simeq -\begin{cases} T^{-p/2}, & d=1, \\ \ln(\hbar/\tau/k_{\rm B}T), & d=2 \\ T^{p/2}, & d=3. \end{cases} \qquad (18)$$

Thus, a ln$T$ correction is predicted for the conductivity of thin films. A decrease of the conductivity ($\delta\sigma<0$) is equivalent to an increase of the resistance ($\delta R>0$). The corresponding logarithmic T dependence of the resistance of very thin films ($d=2$) has been found in numerous experiments (Bergmann, 1984).

Finally, it should be stressed that the results obtained within the weak-localization theory and given by Eq. (18) have been derived with the assumption that a particular path and its time-reversed path are perfectly coherent. Such a "time-reversal invariance" is obeyed if there are no external magnetic fields and if the impurities are nonmagnetic.

However, the most dramatic effects of the weak-localization theory occur when a magnetic field is present, in which case the theory predicts a negative magnetoresistance, in contrast to the predictions of the Boltzmann theory. In standard transport theory, an applied external magnetic field perpendicular to the current tends to cause the carriers to drift in a direction transverse to both the current and the field, thus increasing the resistivity. Weak-localization theory, by contrast, predicts a decrease in the resistivity when a magnetic field is turned on. In the presence of a magnetic field, each path picks up an additional phase factor $\mathbf{A}\cdot\int d\mathbf{r}$, where the line integral is along the trajectory. Hence, a particular path and its time-reversed path (or conjugate) will pick up opposite phases in a magnetic field. When the paths return to the starting point, their phases will be different by $2\mathbf{A}\cdot\oint d\mathbf{r}$; that is, by twice the flux enclosed by the loop the closed path forms—and the constructive interference leading to the weak-localization effect will be destroyed. These ideas are related to the Aharonov-Bohm effect. Therefore, the resistivity will decrease when the phase difference becomes of order π. The typical area of a loop is $L_{\rm in}^2$, where $L_{\rm in} = (D_0\tau_{\rm in})^{1/2}$. This condition can be described as $HL_{\rm in}^2 \approx \phi_0$, where $\phi_0=hc/e$ is the flux quantum. Because at low T, $L_{\rm in}$ is much larger than the mean free path l, the external magnetic field H becomes very small, even as small as a few tens of Gauss, as has been seen experimentally in inversion layers of silicon MOSFET and thin metallic films (Bergmann, 1984; Lee and Ramakrishnan, 1985).

Another very important evidence of the same physics is the prediction of oscillations in the magnetoresistance of a sample shaped like a hollow cylinder. Provided that the walls of the cylinder are very thin and its perimeter is less than L_{in}, the phase difference between each path that encloses the cylinder and its conjugate path will be the same and equal to $2\phi/\phi_0$, which is the total magnetic flux through the cylinder. The resistance along the cylinder was predicted and confirmed experimentally by Sharvin and Sharvin (1981) to oscillate with increasing magnetic field with the period of the oscillation being $\phi_0/2$, which is the flux quantum corresponding to a charge $2e$.

We want to mention again that Eqs. (15)–(18) are based on the treatment of the backscattering effects, i.e., multiple scattering and the correlation between consecutive collisions. Thus they cannot be obtained within the Boltzmann transport theory. However, this interference effect argument enables us to understand the temperature dependence of the conductivity. One must rely on more sophisticated field theoretical techniques to calculate the precise prefactors in Eq. (18). Two simplified versions of such theories are the scaling theory of Anderson localization and the self-consistent theory of localization. As will be discussed later, these two approaches not only produce integrals of the type of Eqs. (14) and (16), but also give the precise prefactors in Eq. (18).

5. LOCALIZATION

The interference effects, which on a short length scale are responsible for the fluctuations in the amplitude of the eigenfunction and the resulting reduction of the conductivity, may in addition force the eigenfunction to decay to zero for very large distances as shown in Fig. 3 (Anderson, 1958). In other words, the multiple-scattering processes trap the particle in a finite region of space. This trapping, for an infinite system, implies absence of propagation and zero value for the conductivity and the diffusion coefficient. It turns out that for one-dimensional systems, all eigenstates are *localized* (which by definition means they are decaying to zero for large distances) no matter how weak the disorder is (some pathological exceptions do exist) (Mott and Twose, 1961; Economou, 1983). The decay is exponential and is characterized by the localization length L_c, which is defined through the logarithmic average of $|\psi(x)|$:

$$L_c^{-1} \equiv -\lim_{|x|\to\infty} (\langle \ln|\psi(x)|\rangle/|x|). \qquad (19)$$

Because the probability distribution of $|\psi(x)|$ has long tails, other averages of $|\psi(x)|$ would give different values of the decay length, e.g., $\langle|\psi(x)|\rangle \sim \exp(-|x|/2L_c)$. A localized eigenfunction is not necessarily centered around a single atomic site; it may be trapped around a cluster of sites, in which case the decay sets in as one moves out of it. As a result, the length L_c' beyond which the localization is visible equals $L_c + l_c$, where l_c is the linear dimension of the cluster. Usually, but not always, $l_c \ll L_c$, and $L_c' \approx L_c$.

It is widely believed, although no rigorous proof exists, that the critical dimensionality for the localization problem in the absence of magnetic scattering or external magnetic field is $d=2$. For $d<2$, any amount of disorder is enough to localize all the eigenstates (pathological exceptions exist); for $d>2$, a critical value of the disorder must be reached before an eigenstate becomes localized. For $d=2$, one distinguishes different universality classes (Kramer and Schön, 1990). The main class, characterized by time invariance and absence of spin-orbit coupling, is believed to have all eigenstates localized no matter how weak the disorder is as in the 1D case. In the presence of spin-orbit coupling or an external magnetic

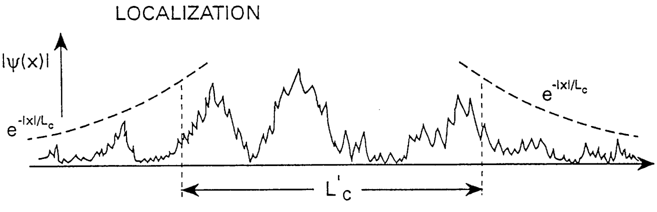

FIG. 3. Schematic plot of the amplitude of a one-dimensional eigenfunction. For large distances ($|x| \to \infty$) the eigenfunction decays on the average as $\exp(-|x|/L_c)$, where L_c is the localization length.

field, a critical value of the disorder is needed in order to localize all eigenstates, as in the 3D case.

The transition from localized (i.e., decaying) to extended (i.e., propagating) states depends on the parameters W_i ($i=1,2,\ldots$) that characterize the strength and the type of disorder and on the energy E of the eigenstate. In the $(E,\{W_i\})$ space, one can define a hypersurface separating the regions of localized from those of extended eigenstates, as shown schematically in Fig. 4 for a periodic system on which disorder is imposed. The critical energies at which the transition from localized to extended states takes place are termed *mobility edges*; their trajectory, as the $\{W_i\}$ vary, is shown schematically as a thick line in Fig. 4.

The localization problem in 1D systems has been studied extensively using various methods (Thouless, 1974; Economou, 1983). Exact analytical results and very accurate numerical data are available concerning the energy and disorder dependence of the localization length; the probability distribution of various quantities of interest, such as Green's functions; the relation between the localization length, the phase coherence length, and the DOS; etc. Of particular interest is the transmission coefficient, $|t|^2$, over a disordered segment of length L. The logarithmic average of $|t|^2$ behaves as $\exp(-2L/L_c)$ for $L/L_c \gg 1$, while other averages exhibit a different behavior (e.g., $\langle |t|^{-2}\rangle = \frac{1}{2}[1+\exp(4L/L_c)]$, while $\langle |t|^2\rangle = C_2(L_c/2L)^{3/2}\exp(-L/2L_c)$. This is due to the long tails in the probability distribution of $|t|^2$ due to very sharp resonances in $|t|^2$ vs E (where $|t|^2$ approaches almost unity). These resonances become exact localized eigenstates in the limit $L\rightarrow\infty$.

The interest in $|t|^2$ stems from its connection to the resistance R of the linear segment. Landauer (1957) has shown that

$$R=\frac{\pi\hbar}{e^2}\frac{1-|t|^2}{|t|^2}, \tag{20}$$

while Economou and Soukoulis (1981) on the basis of the Kubo formula obtained

$$R=\frac{\pi\hbar}{e^2}\frac{1}{|t|^2}. \tag{21}$$

The difference in the two expressions for R appears in the almost perfect conductor case ($L \ll L_c$), where the first expression becomes

$$R=\frac{\pi\hbar}{e^2}(e^{2L/L_c}-1)\approx\frac{\pi\hbar}{e^2}\frac{2L}{L_c}\ll\frac{\pi\hbar}{e^2}, \tag{22}$$

which is the classical result (taking into account that $L_c=4l$, where l is the mean free path), while the second tends to $\pi\hbar/e^2$. The reason for this difference is that the current-field relation is not local for ballistic transport, i.e., when $L \ll L_c$, and as a result, the resistance of the segment depends on how it is connected to the circuit and on what is happening outside the segment. A recent experiment (Timp *et al.*, 1989) in quantum lines has shown plateaus in the conductance at values equal to $e^2 n/\pi\hbar$ ($n=1,2,\ldots$) corresponding to

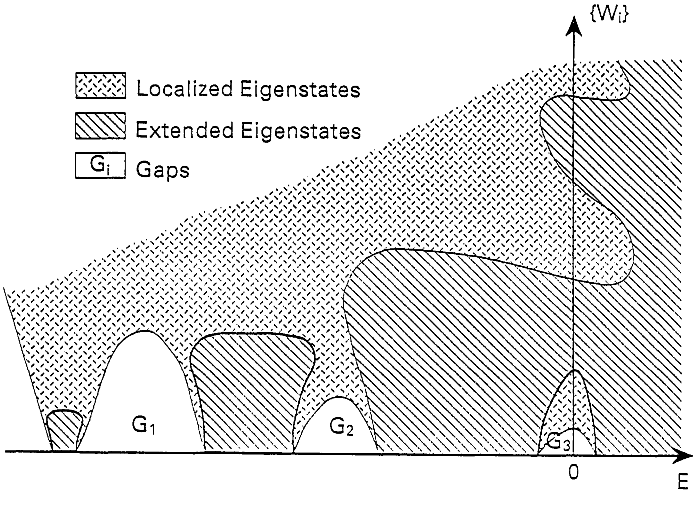

FIG. 4. The $(E,\{W_i\})$ space is separated into regions of no states (gaps), extended eigenstates, and localized eigenstates. The thin lines are the band-edge trajectories; the thick lines are the mobility-edge trajectories. The horizontal E axis ($\{W_i\}=0$) corresponds to a periodic system of alternating bands and gaps.

1,2,... one-dimensional channels reaching the saturation value $e^2/\pi\hbar$.

Quasi one-dimensional systems, of parallel-coupled $1D$ channels, have also been studied extensively because they correspond to the important and realistic cases of thin wires or quantum lines on semiconductor surfaces. Parallel-coupled $1D$ channels arranged on a plane so as to form a strip, or in space so as to form a wire of square cross section, allow reliable numerical studies of higher-dimensional systems; indeed, as the width of the strip Ma or the cross section of the wire M^2a^2 increases, the system approaches a $2D$ or $3D$ one (Kramer and Schön, 1990). It is worthwhile to mention also $1D$ quasiperiodic incommensurable systems [e.g., a simple tight-binding model with diagonal matrix elements $\epsilon_n=\epsilon_0\cos(\pi\sigma n)$ where σ is an irrational number] that exhibit a behavior intermediate between periodic and random systems (Sokoloff, 1985). In particular, the quasiperiodic $1D$ system allows either extended (when $\epsilon_0/V<2$) or localized eigenstates (when $\epsilon_0/V>2$), where V is the nearest-neighbor transfer-matrix element.

For higher-dimensional disordered systems, the localization problem is considerably more difficult and complex. Very few rigorous results exist. However, there is a plethora of theoretical approximate methods as well as some sophisticated numerical techniques.

The most systematic approach to the localization problem is based on its mapping into the sigma model (Wegner, 1976) and on subsequent use of field-theoretical techniques to establish a general scaling behavior. Through renormalization-group methods, one can obtain universal properties such as critical exponents for dimensionality d near 2. The perturbative expansion in powers of $d-2$ is then extrapolated to $d=3$.

Another approach, the so-called scaling one, starts with the observation that wave propagation in a simple tight-binding model must depend (besides the energy) on a single dimensionless parameter, namely the ratio $V/\delta\epsilon$ of the transfer-matrix element V to the level mismatch $\delta\epsilon$. The latter is proportional to the standard deviation of the probability distribution of each diagonal matrix element, ϵ_n. Next, one mentally divides the system into blocks (e.g., cubes) of ever-increasing linear dimension L. The question that arises is whether one can still define for each block two quantities $V(L)$ and $\delta\epsilon(L)$ such that the ratio $V(L)/\delta\epsilon(L)$ fully characterizes the localization properties of the system. Thouless (1974) argues that $\delta\epsilon(L)$ is essentially the level spacing, i.e., $\delta\epsilon(L)=\rho^{-1}L^{-d}$, where ρ is the DOS per unit volume, and $V(L)$ is the average change in the energy levels when the boundary condition in a block changes from periodic to antiperiodic. Furthermore, one can then show that $V(L)=\hbar/\tau'$, where τ' is the time it takes for a particle to diffuse from the center of the block to its boundary: $\tau'=(L/2)^2/D$, where D is the diffusion coefficient. Combining everything and using Einstein's relation $\sigma=2e^2\rho D$ (where σ is the conductivity), we obtain the assumed single dimensionless quantity, which fully characterizes the localization properties, as the dimensionless dc conductance $g=(\hbar/e^2)G$. The β function defined by

$$\beta\equiv\frac{d\ln g}{d\ln L}, \tag{23}$$

if positive (negative) for $L>L_0$, would imply that $G(L)\to\infty$ (zero) as $L\to\infty$, i.e., that the eigenstates are extended (localized). Abrahams *et al.* (1979) argued that β must necessarily be a function of g only (since there is a single parameter, namely g, which controls localization); furthermore, they assume that β is a monotonic function of g (an assumption that was proven wrong in the presence of spin-orbit coupling). This assumed monotonicity together with the limiting expressions $g\sim\exp(-2L/L_c)$ (when $g\to 0$) and $g\sim\sigma L^{d-2}$ (when $g\to\infty$) leads to a β vs $\ln g$ relation as shown in Fig. 5 for $d=1,2,3$. For $d=1,2$, β is always less than zero. Hence, for increasing L, g decreases, β becomes more negative, and thus we slide down toward strong localization as $L\to\infty$. In the 3D case, we distinguish two cases:

1. $g>g_c$ (g_c is roughly estimated to be 0.024). Then β is positive; g increases with increasing L, which leads to a further increase in β, and thus we move up the β curve toward extended states and classical transport behavior.
2. $g<g_c$. In this case β is negative and hence, with increasing L, we slide toward strong localization.

Another approach to the localization problem starts with the equation

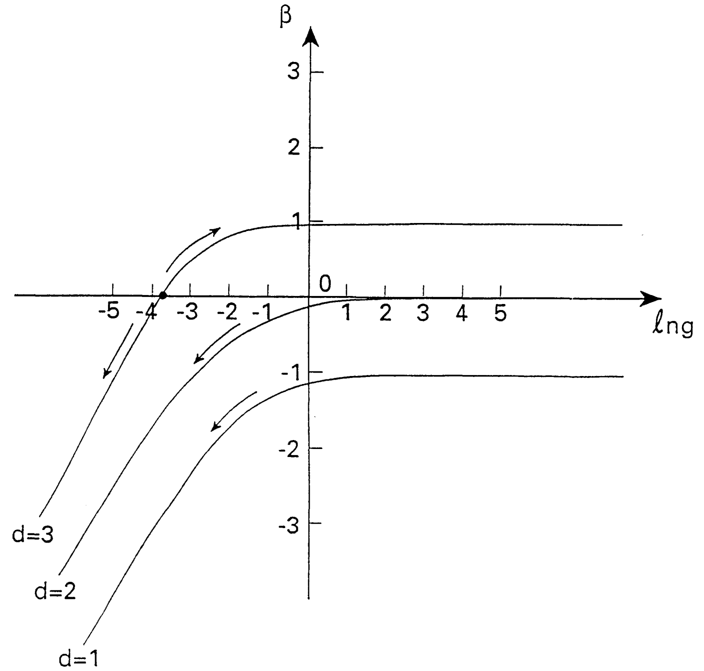

FIG. 5. The qualitative behavior of $\beta(g) = d\ln g/d\ln L$ for one, two, and three dimensions.

$$\delta\sigma \equiv \sigma - \sigma_0 = -\frac{e^2}{\pi\hbar}\frac{2}{(2\pi)^d}\int d^3q\,\frac{1}{q^2 - i\omega/D_0} \tag{24}$$

for the correction to the classical expression σ_0 for the conductivity, which, as the frequency $\omega \rightarrow 0$, reduces to Eq. (13). Equation (24) is valid for large g (near the classical regime) and is derived (Lee and Ramakrishnan, 1985) by summing up a subset of infinite terms in the perturbation expansion for σ (these terms correspond to the so-called maximally crossed diagrams). By replacing D_0 inside the integral by D, Eq. (24) can be reduced to a self-consistent one for the diffusion coefficient D. We have then

$$D(\omega) = D_0(\omega) - \frac{1}{(2\pi)^d \pi\hbar\rho}\int d^3q\,\frac{1}{q^2 - i[\omega/D(\omega)]}\,. \tag{25}$$

Note that in the localized regime $D(\omega) \rightarrow 0$ and the ratio $iD(\omega)/\omega \rightarrow L_c^2$ as $\omega \rightarrow 0$. Hence, Eq. (25) allows us to obtain the localization length (in the localized regime), the correction to the conductivity (in the extended regime), and the curve of β vs ln$g$ over the whole range.

Economou and Soukoulis (1983) and Economou *et al.* (1984) noticed that the structure of the maximally crossed diagrams and the form of Eq. (24) are mathematically identical to corresponding quantities in the simple problem of a particle being scattered or trapped by a local potential well. Thus, the localization problem (or at least the self-consistent approximation to it) can be mapped to that of a potential well (PW). The extent of the equivalent PW is proportional to the mean free path l, and its depth is proportional to $\sigma_0^{-1}l^d$. Thus the recipe for the potential-well analogy (PWA) is the following: For each particular energy and disorder, determine the mean free path l and the classical conductivity σ_0 (the best way is by use of the CPA). In terms of σ_0 and l, construct the equivalent potential well. If this PW sustains as a ground state a bound state with decay length L_c, then the eigenstates of the disordered system at this particular energy and disorder are localized with localization length L_c. If the PW has no bound states, but gives rise to a state with scattering length $|f| = \xi/\sqrt{2}$, then the eigenstates of the disordered system at this energy and disorder are extended but fluctuating up to a maximum length scale equal to ξ. (The $\sqrt{2}$ has been introduced in order that in the limit $E_r \rightarrow 0$ we have $E_r = \hbar^2/2m\xi^2$, where E_r is the resonance energy.) Furthermore, the bound or scattering eigenstate in the equivalent PW allows us to obtain the reduction of the conductivity σ_0

due to the weak or strong localization effects, i.e., to obtain $\sigma(L)$. Using the well-known results for the decay length of the lowest bound state in a PW of depth V_0 and radius R [$L_c \sim V_0^{-1}R^{-1}$ in 1D; $L_c \sim R\exp(\hbar^2/mV_0R^2)$in 2D; $L_c \sim RV_0/(V-V_0)$ for $V>V_0 = \pi^2\hbar^2/8mR^2$ in 3D], we obtain that all states are localized in 1D and 2D with $L_c \sim \sigma_0 \sim l$ and $L_c \sim l\exp[\pi^2 g_0]$, respectively. In 3D, localization appears only when $\sigma_0^{-1}l^{-1}$ exceeds a critical value, i.e., when $Sl^2 < C$ where S is the area of the surface of constant energy in k space and the universal constant C is estimated to be equal to 8.96; for isotropic systems $S=4\pi k^2$ and the condition for localization reduces to the well-known Ioffe-Regel condition

$$kl \leqslant (C/4\pi)^{1/2} \simeq 0.84. \tag{26}$$

In view of the fact that both L_c and ξ vary as $(V-V_0)^{-1}$ as $|V-V_0| \to 0$ for a PW, it follows that L_c and ξ blow up with a critical exponent equal to unity, i.e.,

$$\begin{aligned} L_c &= Al(C-Sl^2)^{-1}, \quad Sl^2 \to C^- \\ \xi &= Al(Sl^2-C)^{-1}, \quad Sl^2 \to C^+. \end{aligned} \tag{27}$$

The most reliable numerical technique (Economou, 1983; Kramer and Schön, 1990) for studying the localization problem calculates the longest localization length L_{CM} for a quasi one-dimensional system of coupled 1D channels arranged either in planar geometry (a strip of M channels for studying 2D systems) or in 3D geometry (a wire of $M \times M$ channels of square cross section in order to study 3D systems). In the numerical calculations, all lengths are measured in units of the lattice constant a; thus $Ma=M$ is the width of the strip and $M^2a^2=M^2$ is the cross-sectional area of the wire. It turns out that the quantity L_{CM}/M follows to a reasonable accuracy a single-parameter scaling law, i.e., the quantity L_{CM}/M is a function of only L_c/M or ξ/M if we are in the localized or the extended regime, respectively, where L_c and ξ are the localization and the correlation lengths, respectively, in the $M \to \infty$ limit. For two-dimensional disordered systems (with no spin-orbit coupling and no external magnetic field), there is a single branch in the curve of L_{CM}/M vs L_c/M. In most cases, for large yet numerically realizable M's, M/L_{CM} vs M becomes a straight line the slope of which determines L_c (which may be many orders of magnitude larger than M). For a three-dimensional disordered system and for $L_{\text{CM}}/M \lesssim 0.6$, there is the lower branch of the curve of L_{CM}/M vs. M, the behavior of which is similar to the one described above. For $L_{\text{CM}}/M \gtrsim 0.6$, there is an upper branch of the curve L_{CM}/M vs M corresponding to extended states, the behavior of which for large yet realizable M is $L_{\text{CM}} \approx M^2/\bar{\xi}$, where $\bar{\xi}$ is proportional to the correlation length ξ introduced earlier ($\bar{\xi} \simeq 4.82\xi$). The quantity ξ, which can be easily determined from the present numerical method, is very important because it is directly connected to the dc conductivity over the entire range of extended states up to the mobility edge (Economou *et al.*, 1985a) by the simple relation

$$\sigma = \frac{e^2}{\hbar}\left(\frac{a}{\xi} + \frac{b}{L}\right), \tag{28}$$

where L is the linear dimension of the system and a and b are numerical constants ($a \simeq 0.07 \pm 0.007$ and $b \simeq 0.05 \pm 0.03$).

It is worthwhile to point out that the probability distribution of the level spacing is different for localized states (for which there is little or no level repulsion) and for extended states (for which the level repulsion strongly reduces to zero the low end of the probability distribution). This observation allows another numerical approach to the localization problem (based on the level statistics) that has been used profitably in recent years (Kramer and Schön, 1990).

5.1 Explicit Results and Discussion

Explicit results for the strong-localization problem have been obtained mainly for simple tight-binding models (with a Hamiltonian of the form $\langle n|H|m\rangle = \epsilon_n\delta_{nm} + V[\delta_{n,m+1} + \delta_{n,m-1}]$, where $|n\rangle$ is an atomiclike orbital centered at the lattice site n) appropriate for describing isolated bands. The disorder has usually been introduced by assuming that the ϵ_n are independent (some correlated cases have also been studied) random variables, each with a probability distribution $p(\epsilon_n)$. Common choices for p are Gaussian, fully characterized by its standard deviation $\bar{\sigma}$; rectangular of total width W ($\bar{\sigma}$ in this case equals $W/\sqrt{12}$); and binary of the form $x\delta(\epsilon_n + \epsilon_0) + (1-x)\delta(\epsilon_n - \epsilon_0)$ characterized by two parameters x and ϵ_0. In Fig. 6, we show results

(Zdetsis *et al.,* 1985) for the mobility-edge trajectory, the exact band-edge trajectory (L), and the approximate band-edge trajectory (according to the CPA) in the upper half E-W plane for a simple tight-binding model with rectangular distribution for each ϵ_n.

The DOS between CPA and line L is extremely low. The solid line for the mobility-edge trajectory is based on a combination of the CPA (to obtain l and σ_0) and the PWA, while the triangular points are based on the numerical scaling method (the shaded area denotes the estimated errors of the latter). Figure 6 shows that when W exceeds a critical value W_c ($W_c \simeq 16.5$ V), the entire band consists of localized states only. This transition, where all regions of extended eigenstates in a given band disappear, is termed the Anderson transition. Anderson transition implies that the given band does not contribute at all to diffusion. In Fig. 7(a), we plot ξ and L_c vs E, i.e., as we move along the horizontal dotted line of Fig. 6; while in Fig. 7(b) we plot the same quantities versus W, i.e., as we move along the vertical line in Fig. 6. The agreement between the results of the two different methods is good (Zdetsis *et al.,* 1985). In Fig. 8, we plot the conductivity σ (together with the Born approximation result σ_{00} and the CPA result σ_0) vs W for the above-discussed model and for energy at the center of the band. Again, the agreement between the PWA and the numerical scaling method is good (Economou *et al.,* 1985a).

In Fig. 9, we show results for the binary alloy distribution (Soukoulis *et al.,* 1987; Soukoulis and Grest, 1991). For ϵ_0 larger than a critical value (which depends on x) a minority subband is split off the majority subband, creating a DOS gap (e.g., the segment ab in Fig. 9). The regions near all band edges consist of localized states; thus the mobility gap [i.e., the region where $\sigma(E)=0$ at $T=0$ K] is the segment $a'b'$, which is wider than the DOS gap. In the present case of a single band with binary distribution, increasing disorder creates first a gap which, with further increase, becomes wider and wider as shown in Fig. 9. However, usually disorder may create the opposite effect: its increase tends to make preexisting gaps narrower until they completely disappear. In this case, the mobility gaps initially become narrower and eventually either they may disappear (see, e.g., the G_3 region in Fig. 4) or they may be connected with other mobility gaps giving rise to a much wider region of localized states (e.g., the G_2 and G_1 regions in Fig. 4).

Besides the isolated bands described by tight-binding models, the simple continuum model,

$$H=p^2/2m^*+V(\mathbf{r}), \tag{29}$$

has been studied extensively. $V(\mathbf{r})$ is a Gaussian random function characterized by its autocorrelation function $\langle V(\mathbf{r})V(\mathbf{r}')\rangle-\langle V(\mathbf{r})\rangle \times\langle V(\mathbf{r})'\rangle$. The latter is assumed to possess a correlation length L_0 and a strength $\gamma=\bar{\sigma}^{\,2}L_0^d$,

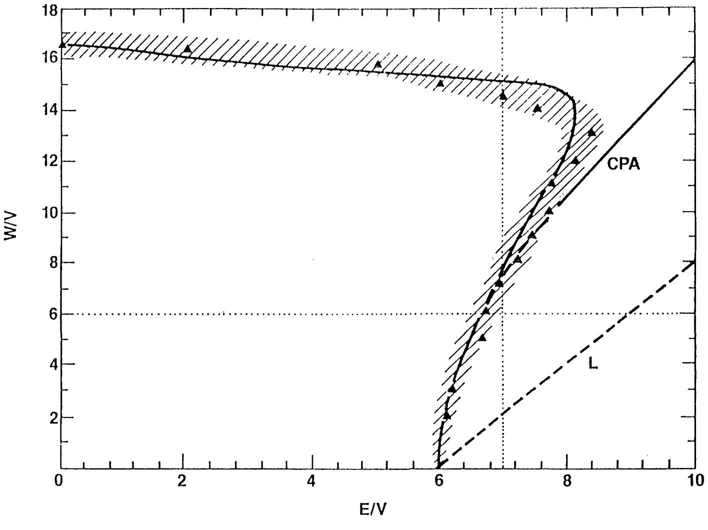

FIG. 6. Dependence of the mobility edge on the strength of the diagonal disorder W for the simple cubic lattice. Solid triangles are the numerical results. Thick solid line through the solid triangles is the prediction of the PWA with the CPA. The CPA band-edge trajectory is also indicated (solid line with the word CPA under it) together with the true (Lifshitz) band-edge trajectory (thin dashed line). The dotted straight lines indicate the independent variables for Fig. 7.

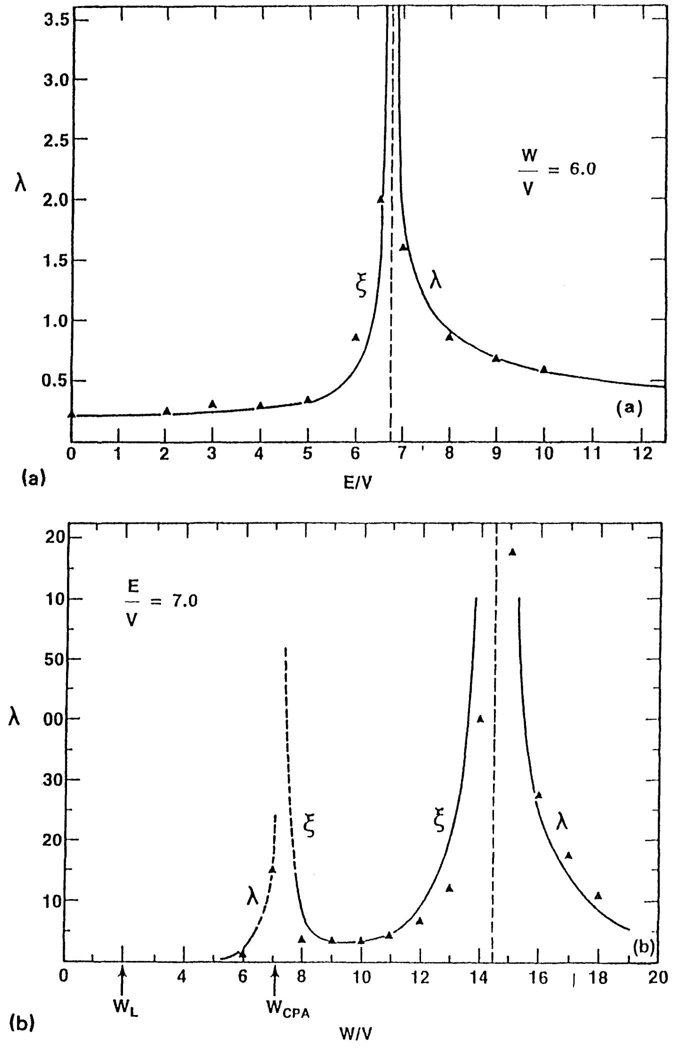

FIG. 7. (a) Localization length λ or correlation length ξ as a function of the energy E/V for a simple cubic lattice with disorder $W/V=6.0$. The solid line is the result of the PWA with the CPA, while the triangles are the numerical data. The CPA band edge is just above the critical energy, while the true band edge (Lifshitz limit) is at $E/V=9$. (b) Localization length λ or correlation length ξ versus the strength of the diagonal disorder W/V for a simple cubic lattice for energy $E/V=7.0$. The solid line is the PWA result and the triangles are the numerical data. The arrow indicates the position of the CPA band edge. The true band edge (Lifshitz limit) is lower at $W/V=2$. Near the lower critical point results have large uncertainties. All lengths are measured in units of the lattice constant a.

where $\bar{\sigma}^2$ is the variance of $V(\mathbf{r})$ and d is the dimensionality. Furthermore, most of the studies assume that the energy is close enough to the CPA band edge that the wavelength λ is much larger than L_0, and that the disorder $\bar{\sigma}$ is much smaller than $\hbar^2/|m^*|L_0^2$. These are very severe restrictions indeed, because many interesting structures appear when λ^{-1} and $\bar{\sigma}$ are comparable to or smaller than L_0^{-1} and $\hbar^2/|m^*|L_0^2$, respectively. Anyway, under the conditions $L_0 \ll \lambda$, $\lambda' \equiv (\hbar^2/|m^*|\bar{\sigma})^{1/2}$, the present model reduces essentially to the so-called white-noise model (WNM) for which several exact results exist (Thouless, 1974). It must be pointed out that the WNM (with some obvious modifications) can describe successfully a region around a CPA band edge, as long as both the energy difference from the CPA band edge and the disorder are much smaller than both the band gap and the bandwidth. Thus, for weak disorder, the region near a band edge exhibits a quasiuniversality as far as the DOS, the localization length L_c, the correlation length ξ, the mean free path l, and the conductivity σ are concerned (Economou *et al.*, 1985b).

In Fig. 10 we show results (Soukoulis *et al.*, 1989) for the mobility-edge trajectory (dashed line) obtained through an extension of the CPA-PWA method for a continuum model of nonoverlapping spheres of radius R embedded randomly within a uniform material and occupying 10% of its volume. The potential V is zero in the host material and $-\delta$ within the spheres. The unit of energy is taken as $\hbar^2/2m^*R^2$. The quasiuniversality region ends at

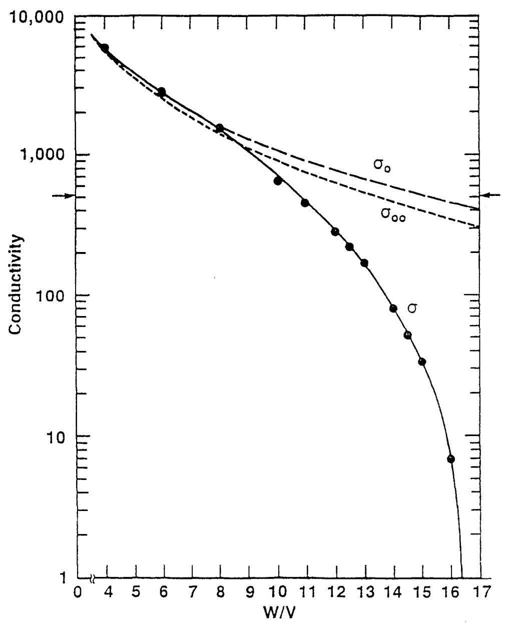

FIG. 8. Conductivity (in units of $10^{-4}\ e^2/\hbar a$), where a is the lattice spacing versus disorder for the center of the band of a simple cubic lattice. σ_{00} is the Born-approximation result, σ_0 is the CPA result; the solid line is based on Eq. (28), and the solid circles are based on the numerical results for ξ.

$\delta \approx 2$. For the interesting structure in the mobility-edge trajectory above $\delta \simeq 3$, both λ and λ' are comparable to or smaller than L_0, which in the present case equals $3.5R$. The solid line is the mobility-edge trajectory obtained through an extension of the numerical scaling method for a quasicontinuum model (consisting of $4\times4\times4$ lattice blocks of material A embedded in a host material B).

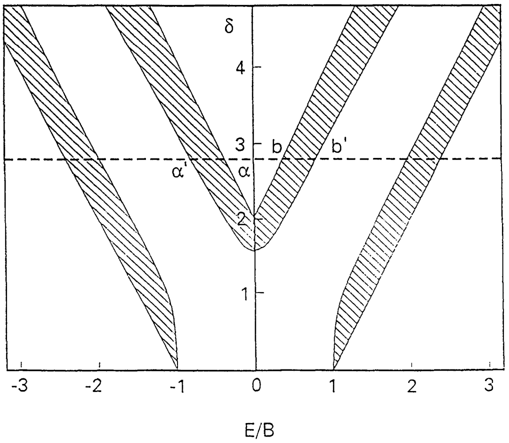

FIG. 9. Dependence of the mobility edge on the strength of the disorder $\delta = 2\epsilon_0/B$ for the binary alloy case for a particular x. B is half the bandwidth; shaded areas denote localized states.

5.2 Fractal Character of the Eigenstates

Explicit numerical results for the eigenstates in disordered d-dimensional systems ($d = 1,2,3$) show very wide fluctuations at various length scales. In a statistical sense, the eigenstates seem to be self-similar and, as a result, they can be characterized by various fractal dimensionalities (Schroeder, 1991), at least between a lower and an upper length limit. More explicitly, let a be an average interatomic distance (taken as the unit of length), N the total number of atoms in our system (so that $L \equiv N^{1/d}$ is its linear dimension), and $p_n \equiv \int |\psi(\mathbf{r})|^2 d^3r$ the probability of finding the electron in the immediate vicinity of atom n (the integral is over a volume a^3 around the atom n).

The various fractal dimensionalities D_q are defined as follows:

$$D_q = \lim_{L\to\infty} [\ln \Sigma_n p_n^q / (q-1) \ln(1/L)]. \qquad (30)$$

Of particular interest is D_2, since it is directly related with the so-called participation number $P \equiv (\Sigma_n p_n^2)^{-1}$, which is a measure of the number of sites over which the wave function is appreciable. Indeed, the above definition gives

$$P = cL^{D_2} = cN^{D_2/d}, \qquad (31)$$

where c is a constant. Equation (31) shows that P is *not* proportional to L^d, as expected for ordinary extended eigenstates, but grows with an exponent D_2 lower than the dimensionality of space. This reflects the self-similar nature of the states, which exhibit larger and larger regions where their values are almost zero. Numerical as well as field-theoretical results (Soukoulis and Economou, 1984) show that the above equation is obeyed with $D_2 \simeq 1.7 \pm 0.3$ (at the mobility edge) as long as $L_{\min} < L < L_{\max}$. The upper limiting length $L_{\max}$ equals L_c (in the localized regime) and ξ (in the extended regime), while it becomes infinite at the mobility edge. It is not clear what the lower limiting length is; possible candidates are the wavelength λ or the mean free path l (most probably λ).

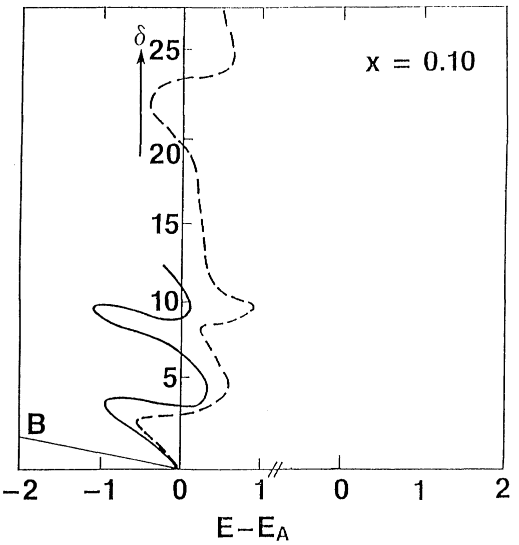

FIG. 10. Mobility-edge trajectory obtained from numerical results (solid line) and CPA results (dashed line) for the continuum binary case with $x=0.10$. The units of δ and $E-E_A$ are equal to $\hbar^2/2maR^2$ (see text).

Another interesting fractal dimension is $D_1=\lim_{L\to\infty}[\Sigma_n p_n \ln p_n/\ln(1/L)]$, which is related with the entropy measure $P_e \equiv \exp[-\Sigma p_n \ln p_n]$ of the number of sites over which the eigenfunction is appreciable,

$$P_e=c'L^{D_1}=c'N^{D_1/d}, \tag{32}$$

where c' is a constant.

It must be pointed out that the fractal exponent D_2 turns out to be the same as the so-called mass or density correlation fractal exponent D_m defined by the relation

$$\sum_{\substack{n,m \\ |\mathbf{n}-m|\leqslant r}} p_n p_m=c''r^{D_m}, \tag{33}$$

with $L_{\min} \leqslant r \leqslant L_{\max}$. The constant c'' can be obtained by setting $r=L$ (assuming, of course, that $L \leqslant L_{\max}$) in the above relation. We have then $1=c''L^{D_m}$ so that $c''=L^{-D_m}=N^{-D_m/d}$. Taking $r=L_{\min}$, we obtain $P{\sim}N^{D_m/d}$, assuming that

$$\sum_{|\mathbf{n}-\mathbf{m}|\leqslant L_{\min}} p_n p_m \sim \sum_n p_n^2.$$

Within numerical accuracy, it turns out that $D_m=D_2$. On the other hand, the various D_q are not the same, which, by definition, means that the eigenstates in disordered systems are *multifractal* objects in the range $\lambda \lesssim L \lesssim (L_c$ or $\xi)$, assuming, of course, that the parameters are such that $\lambda \ll (L_c$ or $\xi)$. An interesting physical application of the fractal exponent D_2 was proposed for the analysis of polaron formation near a mobility edge (Cohen *et al.,* 1983).

6. MOTT-HUBBARD INSULATORS: IMPURITY BANDS

The experimental investigation of the various consequences of strong localization, especially the metal–insulator transition, becomes complicated because other effects, such as thermal excitations, phonon-assisted hopping, and electron-phonon interactions, interfere. Among them probably the most important is the electron–electron (el-el) interaction because it, too, can induce a metal–insulator transition (Mott, 1974). The most pronounced effects of el-el interactions appear in narrow bands as in the case of disorder. Thus, a satisfactory theory must take into account simultaneously the effects of randomness and of el-el interactions. As in the case of disorder, the simplest system is an isolated band made up of a single atomiclike orbital per atom. Usually a further approximation is made that the Coulomb repulsion is appreciable only when the two interacting electrons are on the same site. Accordingly, an additional term is incorporated in the simple tight-binding Hamiltonian of the form

$$U \sum_i n_{i\downarrow}\, n_{i\uparrow}, \tag{34}$$

where U is the on-site Coulomb repulsion and $n_{i\uparrow}$ and $n_{i\downarrow}$ are the number operators at site i with spin up and spin down, respectively. The resulting Hamiltonian defines the so-called Hubbard model, which has been solved exactly for $d=1$. For the special, but important, case of one electron per atom (half-filled case), the Fermi level lies in the middle of a gap provided that U exceeds a critical value, U_c, of the order of half the bandwidth. Thus el-el interaction, at least in this particular case, induces a metal–insulator transition for a half-filled band. We remind the reader that even without the el-el interaction term (34), a metal–insulator transition appears when the disorder W exceeds the critical value W_c. The latter transition is termed Anderson M-I transition, while the former is known as a Mott(-Hubbard) M-I transition. The Hubbard model for a less than half-filled band has been studied extensively over the last 5 years because of its suspected connection with the magnetic and superconducting behavior of the high-T_c ceramic materials (Baskaran *et al.*, 1991).

A physical system that provides controlled conditions for studying the combined effects of both disorder and el-el interactions is the impurity band in a crystalline semiconductor. A substitutional impurity of valence $u=u_0 \pm 1$, where u_0 is the average valence of the host crystalline semiconductor, creates an impurity level just below the conduction band (if $u=u_0+1$) or just above the valence band (for $u=u_0-1$). As the concentration of impurities increases from zero, an impurity subband around the impurity level is formed. At a critical concentration, an insulator-to-metal transition takes place within the impurity subband. The phenomenon is further complicated by the nearby presence of the main band with which the impurity band eventually merges together completely. The on-site Coulomb repulsion is $U \simeq e^2/\epsilon a_B^*$, while the half-bandwidth $B \simeq U a_B^*/R = U a_B^*/n^{-1/3}$, where R^3 is the volume per impurity, $a_B^* = \hbar\epsilon/e^2 m^*$ is the effective Bohr radius, ϵ is the dielectric constant, and n is the concentration of impurities. The predicted critical concentration n_c for the I-M transition according to the Hubbard model is given by $U/B \simeq 1.2$, from which it follows that $a_B^* n_c^{-1/3}$ is constant (about 0.20). The experimental results for many combinations of impurities and host semiconductors are closely clustered around $a_B^* n_c^{-1/3} \simeq 0.26$. However, disorder, mainly due to big fluctuations in the distance between nearest neighbors, also predicts an I-M transition at $a_B^* n_c^{-1/3} \simeq 0.18$. Thus, it seems that both el-el and disorder simultaneously drive the I-M transition, pushing the critical value very close to the experimental one. By fine tuning the transition through pressure, the critical exponent for the conductivity was found to be close to 0.5, indicating that el-el interactions play a determining role at the critical point (disorder alone would give a critical exponent equal to unity).

7. CLASSICAL-WAVE LOCALIZATION

Acoustic waves in inhomogeneous (or composite) fluid materials having a constant mass density ρ_m obey a wave equation of the form

$$\nabla^2 p + [\omega^2/c(\mathbf{r})^2]p = 0, \tag{35}$$

where p is the pressure, $c^2(\mathbf{r}) = \lambda(\mathbf{r})/\rho_m$ is the sound velocity squared, and $\lambda(\mathbf{r})$ is the local bulk modulus. This equation is equivalent to Schrödinger's equation

$$\nabla^2\Psi + (2m/\hbar^2)[E - V(\mathbf{r})]\Psi = 0. \tag{36}$$

The motivation for studying classical-wave localization is twofold: on one hand, classical waves (acoustic, elastic, electromagnetic) are of interest in their own right from the point of view of basic physics as well as for possible applications. On the other hand, classical waves can easily be prepared free from self-interactions and from interactions with other degrees of freedom; their frequency can be fixed very accurately almost at will; and they are immune to complicating finite temperature effects. Thus, they present "clean" conditions for studying experimentally the localization problem. (Absorption could be a problem in some cases.) The main difficulty is that localization is inherently more difficult for classical waves than for electronic waves. To clarify this important point, we consider again a composite system consisting of nonoverlapping spheres of radius R embedded in a host material. For the electronic problem, the potential is taken as zero in the host and $-\delta$ inside each sphere. For the acoustic problem the sound velocity is c_0 in the host and c_i in each sphere ($c_0 > c_i$). By introducing the unit of energy $E_0 = \hbar^2/2mR^2$, we have the following correspondences between the acoustic and the electronic problem:

$$\begin{aligned} &R^2\omega^2/c_0^2 \leftrightarrow E/E_0, \\ &R^2\omega^2/c_i^2 \leftrightarrow (E+\delta)/E_0, \\ &c_0^2/c_i^2 \leftrightarrow (E+\delta)/E. \end{aligned} \tag{37}$$

Thus, for a constant ratio of velocities $c_0^2/c_i^2 = \mu^2 > 1$ and varying ω^2, we move in the equivalent electronic problem along the straight line

$$\delta = (\mu^2 - 1)E \tag{38}$$

in the δ vs E plane. For localized acoustic waves to appear, this straight line must cross the mobility-edge trajectory (see Fig. 10) so that the segments of $\delta=(\mu^2-1)E$ line that are in the localized regime give the frequency regions for which localization appears. As can be seen from Fig. 10, in order to have classical wave localization, it is necessary that

1. the mobility-edge trajectory cross to the right of the δ axis, which means that localized states must appear *above the highest value* of the random potential; and
2. the contrast $\mu=c_0/c_i$ must exceed a critical value.

The approximate theoretical and numerical results of Fig. 10 show that the first condition is satisfied, although under rather severe conditions (volume fraction for the spheres, x, in the range from roughly 5% to 40% and $\mu \gtrsim 1.6$).

In order to check the above approximate results and possibly to improve the localization conditions, it was suggested (John, 1988) to solve first the band structure of the problem resulting from placing the spheres in a periodic lattice. Attention was focused (Economou and Zdetsis, 1989) on finding out whether or not band gaps exist (we remind the reader that we are interested in band gaps above the maximum value of the periodic potential). If such gaps exist, it was argued that by gradually disordering the periodic system, localized states would appear in the gaps and eventually may fill the entire gap (John, 1988; Economou and Zdetsis, 1989).

The problem of the classical-wave band structure received increased attention when such periodic structures were fabricated (Yablonovitch and Gmitter, 1989) and were used to obtain experimentally the photonic band structure. It turned out (Ho *et al.*, 1990) that the vector character of the electromagnetic waves introduces significant differences from the scalar case. In addition, the band structures for acoustic (with mass density ρ_m being a periodic function as well) and elastic waves have been studied (Sigalas and Economou, 1992).

8. SUMMARY

In this article we have reviewed some of the recent developments in the theory of noninteracting electrons in disordered systems. Particular emphasis has been placed on the discussion of the universal features of the electronic density of states in disordered systems. An exponential behavior of the DOS is exhibited over many decades. The role of the disorder is, first, to shift the band edge by an amount proportional to w^2, which is given by second-order perturbation theory or by the CPA. Once the energies are measured relative to the CPA band edge, all the physical quantities of interest, including the DOS, are quasiuniversal, provided that the length and energy scaled relative to disorder-dependent units of energy and length are small. Next, the weak-interaction regime or the interference effects of the localization theory were presented. The interference between a closed Feynman path and its time-reversed path gives the unexpected result that $d=2$ is the marginal dimension for localization. Another dramatic effect of the weak localization in disordered electronic systems occurs when a magnetic field is applied, in which case the theory predicts a negative magnetoresistance. Then the scaling theory of localization, the self-consistent theory of localization, and the equivalence of localization in a random potential with the existence of a bound state in a potential well were briefly presented. The potential-well analogy (PWA) facilitates explicit calculations of the localization lengths, conductivities, mobility edges, etc., from quantities that can be obtained from mean-field theories, such as CPA. It was shown that the PWA coupled with the CPA is capable of producing results not only in qualitative but in quantitative agreement with an independent numerical approach. The advantage of the PWA-CPA approach over numerical approach is that it is analytical and gives results almost immediately, even for complicated quantities. The PWA method was applied to 3D systems by modeling the disorder using a Gaussian, a rectangular, and a binary distribution for the random site energies. The numerical results for the DOS exhibit the quasiuniversality expected from the analytical arguments (white noise model). However, the trajectory in the energy-disorder plane of the mobility edge depends on the type of the probability used. It is also discussed that the electronic wave functions in disordered systems are very complicated quantities. Explicit calculations have shown that the wave functions have strong amplitude fluctuations of various spatial extents. In particular, exactly at the mobility edge the wave functions can be characterized by fractal dimensionalities and in this sense they are fractal objects for all the length scales, while they are fractal-like for lengths up to the localization (correlation) length for localized (extended) states, respectively. Finally, a few remarks are given about the propagation of classical waves such as electromagnetic or sound waves in disordered media. What we learned about the wave nature of electrons in disordered systems should enhance our understanding of the propagation of classical waves in these systems or vice versa.

INTRODUCTION

A liquid is a random system, and quite a few investigations of it have been carried out over the past several decades. There are several different types of liquids, and they can be classified according to interparticle interactions. A liquid of rare gas atoms may be called *atomic liquid,* which is the simplest case. *Molecular liquids* are systems consisting of independent molecules, e.g., liquids of nonpolar molecules (normal liquid) and water (H_2O). Water molecules form a network of hydrogen bonds. *Liquid metals* are electron-gas systems in a positive charge background. The ionic distribution usually plays the role of a static random potential field, because the ionic motion is slower than the electron motion by a factor of a few tens or hundreds. Electrons in diluted systems are capable of undergoing a metal–nonmetal transition. Actually metal–nonmetal transitions have been observed in several liquid metals, sometimes near the critical point, as in cesium (Cs), and sometimes not, as in mercury (Hg). There are several varieties of liquid group-IV elements. Liquid germanium and silicon are metallic, and their structure is somewhere between a tetrahedrally bonded network and dense random packing of spheres. Recent optical and dc-conductivity experiments indicate that even liquid carbon is metallic. Liquid tellurium

digital Encyclopedia of Applied Physics

and selenium are kinds of molecular liquids, forming large molecules of spiral chain structures. *Molten salts* (liquid ionic compounds) are systems of practical importance, and the interaction between ions is of the long-range Coulomb type. Electron systems in a uniform positive background are themselves liquids of exotic character (*electron liquid*).

Here, we shall discuss the interplay of electronic structures and interatomic interaction in several different liquid systems. Very recently, an important new simultaneous simulation method for the electron and atomic structures has been developed by Car and Parrinello (1985); this is called the *first-principles molecular dynamics* method (or the Car–Parrinello method).

1. ATOMIC AND ELECTRON STRUCTURES OF LIQUIDS

Liquids are characterized by a certain atomic arrangement. The atomic environment is periodic in crystals but is aperiodic in liquids. A useful accessible characterization of the local atomic environments can be given in terms of the partial pair distribution function. The partial pair distribution function $g_{\alpha\beta}(\mathbf{R})$ or the density function $\rho_{\alpha\beta}(\mathbf{R})$ between α- and β-type atoms is defined by

$$\begin{aligned}\rho_{\alpha\beta}(\mathbf{R}) &= c_\beta\, \rho_0 g_{\alpha\beta}(\mathbf{R}) \\ &= \frac{1}{c_\alpha N}\left\langle \sum_{i,j} \delta(\mathbf{R}-\mathbf{R}_{i(\alpha)}+\mathbf{R}_{j(\beta)})\right\rangle_c \\ &\quad -\delta_{\alpha\beta}\delta(\mathbf{R}), \qquad (1)\end{aligned}$$

where $\langle ... \rangle_c$ means a configurational average of atomic positions or an average over different samples, $\mathbf{R}_{i(\alpha)}$ is the position of the ith α-type atom, N is the total number of atoms, c_α is the atomic concentration of α-type atoms, and ρ_0 is the density of atoms N/V (V is the volume of the system). The number of β-type atoms in a volume element d^3R at $\mathbf{R}$, when the α-type atom is located at the origin, is given by $c_\beta \rho_0 g_{\alpha\beta}(\mathbf{R})\, d^3R$. The asymptotic value of $g_{\alpha\beta}(\mathbf{R})$ is unity in the limit of $|\mathbf{R}| \to \infty$, which implies no long-range particle–particle correlation and homogeneity of the liquid.

The Faber–Ziman (FZ)-type partial structure factor is defined by

$$a_{\alpha\beta}(\mathbf{Q}) \equiv 1+\rho_0 \int [g_{\alpha\beta}(\mathbf{R})-1]e^{i\mathbf{Q}\cdot\mathbf{R}}\, d^3R, \qquad (2)$$

which is essentially the Fourier transform of the partial pair distribution function. This is directly related to the experimental scattering intensity $I(\mathbf{Q})$, which is the square of the Fourier transform of the scattering potential and is given by

$$\begin{aligned}I(\mathbf{Q}) = N^{-1}\Bigg\{ &\sum_{\alpha,\beta} c_\alpha c_\beta a_{\alpha\beta}(\mathbf{Q}) u_\alpha(\mathbf{Q})^* u_\beta(\mathbf{Q}) \\ &+ \sum_\alpha c_\alpha |\Delta u_\alpha(\mathbf{Q})|^2 \Bigg\} \quad (|\mathbf{Q}| \neq 0), \qquad (3)\end{aligned}$$

where $u_\alpha(\mathbf{Q})$ is the Fourier transform of the scattering potential $u_\alpha(\mathbf{r}-\mathbf{R}_{i(\alpha)})$ of an α-type atom at the position $\mathbf{R}_{i(\alpha)}$ and

$$\Delta u_\alpha(\mathbf{Q}) = u_\alpha(\mathbf{Q}) - \sum_\beta c_\beta u_\beta(\mathbf{Q}).$$

The scattering vector $\mathbf{Q}$ is measured by the scattering angle θ between incident and scattered wave vectors $\mathbf{k}$ and $\mathbf{k}'$ as $|\mathbf{Q}| = 2k \sin(\theta/2)$, $k = |\mathbf{k}| = |\mathbf{k}'|$, as shown in Fig. 1. Therefore, the Fourier transform of the scattering intensity $I(\mathbf{Q})$ can provide information on atomic arrangement. For monatomic liquids, the pair distribution function $g(\mathbf{R})$ and the FZ-type structure factor $a(\mathbf{Q})$ are defined as in Eqs. (1) and (2) with no specification of α and β, and $c=1$.

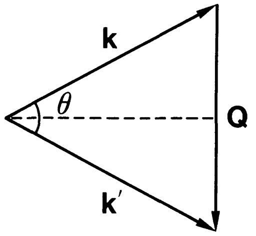

FIG. 1. The scattering vector **Q** and the scattering angle θ.

1.1 Electrons in Liquids

In periodic lattices, electronic states can be described by solutions $\psi_{\mathbf{k}}(\mathbf{r})$ of the one-electron Schrödinger equation

$$\{-(\hbar^2/2m)\nabla^2+v(\mathbf{r})\}\psi_{\mathbf{k}}(\mathbf{r})=E_{\mathbf{k}}\psi_{\mathbf{k}}(\mathbf{r}), \qquad (4)$$

where $\mathbf{r}$ is the position vector of the electron and $v(\mathbf{r})$ is a periodic potential. The Bloch theorem states that the wave functions $\psi_{\mathbf{k}}(\mathbf{r})$ are of the form

$$\psi_{\mathbf{k}}(\mathbf{r})=e^{i\mathbf{k}\cdot\mathbf{r}}u_{\mathbf{k}}(\mathbf{r}) \qquad (5)$$

and the functions $u_{\mathbf{k}}(\mathbf{r})$ are periodic with the periodicity of the lattice. The energy $E_{\mathbf{k}}$ is a function of the wave vector $\mathbf{k}$ or the electron momentum $\mathbf{p}=\hbar\mathbf{k}$. The relation between $E_{\mathbf{k}}$ and $\mathbf{k}$ determines the energy spectrum, the number of electron states with energies between E and $E+\Delta E$, and various physical properties. The periodic potential cannot be a scattering center of electrons, and excitations do not decay if there is no electron–electron interaction.

On the other hand, liquids are typical random aperiodic systems, and the Bloch theorem Eq. (5) does not apply. However, if the potential $v(\mathbf{r})$ is weak enough, we can start from the assumption that electrons can be described by the nearly-free-electron model and that the effect of random potential can be treated by perturbation theory. This is actually the case in alkali metals and alkaline earth metals.

In random systems, the momentum $\mathbf{p}=\hbar\mathbf{k}$ is not a good quantum number for the electronic states, but the $E_{\mathbf{k}}$–$\mathbf{k}$ relation can still be of great help in understanding electronic states. The electron transport phenomenon or the possibility of a metal–nonmetal transition is important in random systems.

1.2 Adiabatic Approximation

The electronic states are strongly influenced by the local geometry of atomic arrangement, and the electron wave function $\psi(\mathbf{r})$ is usually a function of the nuclear coordinates $(\mathbf{R}_1, \mathbf{R}_2, \ldots)$. In a crystal, the nuclear positions are fixed in a periodic lattice, and we can solve Eq. (4) in a static fixed lattice. Nuclei start to vibrate to elevated temperatures in a crystal. However, the electronic motion can be treated separately because the characteristic energies or frequencies of two different motions, electronic and nuclear, are different, by at least two orders of magnitude. The typical electron energy may be estimated as $E_0 \sim \hbar^2/ma_0^2$, where m is the electron mass and a_0 is the Bohr radius which may be taken as a typical value for the extent of the one-electron wave functions. On the other hand, if M denotes the mass of an ion, the nuclear or molecular translational (vibrational) and rotational energies are characterized by $E_t \sim (m/M)^{1/2}E_0$ and $E_r \sim \hbar^2/Ma_0^2 \sim (m/M)E_0$, respectively. Generally, $m/M \leqslant 10^{-3}$, and thus E_t and E_r are much smaller than E_0, by factors of 10^{-2} and 10^{-4}, respectively. Therefore, the effect of the nuclear kinetics on the electronic states is negligible, and the electron and nuclear motions can be treated separately. The total energy is, to a good approximation, a simple sum of energies of electron and nuclear motions. This approximation is called the *adiabatic approximation* or the *Born–Oppenheimer approximation.*

This is also the case in liquids. The characteristic time of atomic or nuclear motion in liquids is very similar to that of vibration or rotation of atoms or molecules in crystals. Electrons reach a stable state more rapidly during atomic motion. The electronic structure in a fixed aperiodic lattice can therefore be a good model of that in liquids, the aperiodic lattice being a kind of "snapshot" of changing atomic configuration in liquids.

1.3 Hard-Sphere and Multipole Interactions of Rare-Gas Atoms and Molecules

For rare-gas atoms, the electronic shell structure is closed, and the local electronic charge distribution around each nucleus is spherical. Therefore, if we neglect the effect of electronic excited states induced by interactions with nearby atoms, there are no higher multipole moments, and the interatomic potential should be of very short range. This interaction is given by the hard-sphere potential,

$$\phi(\mathbf{R}_i,\mathbf{R}_j)=\begin{cases}\infty, & \text{if } R\leqslant\sigma\,; \\ 0, & \text{if } R>\sigma,\end{cases} \qquad (6)$$

where $\mathbf{R}_i$ and $\mathbf{R}_j$ are atomic coordinates of the ith and jth atoms, $\mathbf{R}=\mathbf{R}_i-\mathbf{R}_j$, $R=|\mathbf{R}|$, and σ is the diameter of a hard sphere.

In the case of homopolar molecules without a dipole moment, such as oxygen molecules O_2, there can be a quadrupole–quadrupole interaction with a R^{-5} dependence. However, this term is usually averaged out by the rotational motion of the molecules and vanishes. On the other hand, when the electron charge distribution in one molecule is spherical, an interaction between an electron on one molecule and another electron on the other molecule has a R^{-3} dependence. Therefore, the second-order perturbation theory gives an effective intermolecular interaction with a R^{-6} dependence, which is the van der Waals interaction. The Lennard–Jones potential, an approximation for interatomic potential, is defined by the sum of the van der Waals potential plus a R^{-12}-dependent strong repulsive term and is usually written as

$$\phi(\mathbf{R}_i,\mathbf{R}_j)=\epsilon\{(\sigma/R)^{12}-2(\sigma/R)^{6}\}. \tag{7}$$

In more general cases, the interaction between two molecules at $\mathbf{R}_i$ and $\mathbf{R}_j$ can be given in series of 2^{α}-pole–2^{β}-pole interactions by

$$\phi(\mathbf{R}_i,\mathbf{R}_j)=\sum_{\alpha,\beta} C_{\alpha\beta}(\mathbf{R}/R)R^{-(\alpha+\beta+1)}, \tag{8}$$

where $C_{\alpha\beta}(\mathbf{R}/R)$ is a coefficient depending on α, β, and the configuration of two molecules relative to the intermolecular direction $\mathbf{R}/R$.

1.4 Electron Structure Calculations in Liquids

As already mentioned in Sec. 1.2, the characteristic energy of the electron motion, e.g., 1–10 eV, corresponds to about 10^4–10^5 K and is much higher than those of atomic or molecular motions, which are at most 10^3 K. Therefore, in most cases, atoms or molecules are essentially a source of a static random potential field. We now turn to the problem of surveying the electronic structures in a random array of atomic potentials. A very weak random potential field can be treated by perturbation theory. However, a nonperturbation method is required for a strong potential field.

1.4.1 Pseudopotential Theory. The one-electron Schrödinger equation is

$$\{-(\hbar^2/2m)\nabla^2+v(\mathbf{r})\}\psi(\mathbf{r})=E\psi(\mathbf{r}), \tag{9}$$

where $v(\mathbf{r})$ is a one-electron potential. (In Sec. 2.3, the one-electron Hamiltonian is derived from the many-body Hamiltonian.) We define a *pseudowave function* ϕ as

$$\phi(\mathbf{r})=\psi(\mathbf{r})-\sum_{c}\psi_c(\mathbf{r})\int d^3r'\ \psi_c^*(\mathbf{r}')\psi(\mathbf{r}'), \tag{10}$$

and a new nonlocal effective one-electron potential (*pseudopotential*) as

$$w(\mathbf{r},E)=v(\mathbf{r})+\sum_{c}(E-E_c)|\psi_c\rangle\langle\psi_c|. \tag{11}$$

Here $P_c=|\psi_c\rangle\langle\psi_c|$ is a projection operator onto a core state ψ_c, and the quantity $P_c\phi(\mathbf{r})$ is defined by

$$P_c\phi(\mathbf{r})=\psi_c(\mathbf{r})\int d^3r'\ \psi_c^*(\mathbf{r}')\phi(\mathbf{r}').$$

The summation in Eq. (11) extends over all core states ψ_c of energy E_c. Then, the Schrödinger equation for the pseudowave function ϕ is

$$\{-(\hbar^2/2m)\nabla^2+w(\mathbf{r},E)\}\phi(\mathbf{r})=E\phi(\mathbf{r}). \tag{12}$$

The pseudopotential $w(\mathbf{r},E)$ becomes shallower than $v(\mathbf{r})$ for valence orbitals of energy $E(>E_c)$, because the pseudowave function ϕ is orthogonalized to the core-electron wave functions ψ_c and is nodeless in the core region. This is the pseudopotential method (Heine, 1971). In alkali metals, alkaline earth metals, and the group-IV elements, except those in the first row in the periodic table, conduction or valence electrons are subject to weak pseudopotentials. If orbitals with a certain angular momentum quantum number l do not appear in a core-electron configuration, the pseudopotential $w(\mathbf{r},E)$ for valence orbitals with this angular momentum quantum number l cannot be appreciably shallower than $v(\mathbf{r})$. This is the reason why the free-electron model is not a good starting model for transition and rare-earth metals and the first-row elements. The spatial extent of the $4d$ wave functions of Y–Ag is wider than that of the $3d$ wave functions of Sc–Cu, and this fact means that potentials are shallower in $4d$ transition metals than in $3d$ transition metals. Conventionally, the pseudopotential has been constructed empirically so as to reproduce optical spectra of valence electrons. A method of nonempirical pseudopotentials has been proposed recently, and is called the *norm-conserving pseudopo-*

tential (Hamann *et al.*, 1979; Hamann, 1989). This method is now widely and successfully applied to solids and liquids.

1.4.2 Interatomic Potentials in Simple Metals and Semiconductors. The total energy per atom is given in the pseudopotential theory by the second-order perturbation theory as

$$\frac{E_0}{N}=\frac{1}{N}\sum_{|\mathbf{k}|<k_{\mathrm{F,spin}}} E(\mathbf{k})+\frac{1}{N}\sum_{i\neq j}\frac{1}{2}\frac{Z_iZ_je^2}{4\pi\epsilon_0R_{ij}},$$

$$\begin{aligned}E(\mathbf{k})&=\frac{\hbar^2k^2}{2m}+\sum_{\alpha}\langle\mathbf{k}|W_\alpha|\mathbf{k}\rangle+\sum_{\mathbf{q}\neq 0}\frac{\epsilon_0}{\epsilon(\mathbf{q})}\\&\quad\times\frac{\langle\mathbf{k}|W_\alpha|\mathbf{k}+\mathbf{q}\rangle\langle\mathbf{k}+\mathbf{q}|W_\beta|\mathbf{k}\rangle}{\hbar^2\{k^2-|\mathbf{k}+\mathbf{q}|^2\}/2m}\\&=E_{\mathrm{KE}}(\mathbf{k})+E_1(\mathbf{k})+E_2(\mathbf{k}),\end{aligned}\tag{13}$$

where

$$\langle\mathbf{k}|W_\alpha|\mathbf{k}+\mathbf{q}\rangle=\frac{1}{V}\int d^3r e^{-i\mathbf{k}\cdot\mathbf{r}}W_\alpha(\mathbf{r})e^{i(\mathbf{k}+\mathbf{q})\cdot\mathbf{r}},$$

$$W_\alpha(r)=\sum_i w_\alpha[\mathbf{r}-\mathbf{R}_{i(\alpha)}].$$

w_α is the pseudopotential of an α-type ion, Z_i is the valency of the ith ion, $-e$ is the electron charge, and ϵ_0 is the permittivity of vacuum. The function $\epsilon(\mathbf{q})/\epsilon_0$ is the relative dielectric constant due to electron screening. The second term in E_0/N is the ion–ion Coulomb energy. The first term of $E(\mathbf{k})$, $E_{\mathrm{KE}}(\mathbf{k})$, is the electron kinetic energy, and the second term $E_1(\mathbf{k})$ is the first-order band energy. The Fermi wave number k_{F} is defined by $k_{\mathrm{F}}=(3\pi^2n)^{1/3}$ with n the electron density. The summation on $\mathbf{k}$ can be replaced by an integral as

$$\frac{1}{N}\sum_{\mathbf{k}}E(\mathbf{k})\rightarrow\left(\frac{1}{2\pi}\right)^3\frac{V}{N}\int_{|\mathbf{k}|<k_{\mathrm{F}}}d^3kE(\mathbf{k}).$$

Using the static structure factor

$$S_\alpha(\mathbf{q})=N^{-1}\sum_{j(\alpha)}\exp(-i\mathbf{q}\cdot\mathbf{R}_j)$$

and the Fourier transform of the pseudopotential

$$w_\alpha(\mathbf{q})=\left(\frac{N}{V}\right)\int d^3r\exp(-i\mathbf{q}\cdot\mathbf{r})w_\alpha(\mathbf{r}),$$

we obtain

$$\langle\mathbf{k}|W_\alpha|\mathbf{k}+\mathbf{q}\rangle=S_\alpha(\mathbf{q})w_\alpha(\mathbf{q}).$$

By defining a function, including the spin degeneracy,

$$\begin{aligned}F_{\alpha\beta}(\mathbf{q})&=\frac{2V/N}{(2\pi)^3}\int_{|\mathbf{k}|<k_{\mathrm{F}}}\frac{\epsilon_0}{\epsilon(\mathbf{q})}\\&\quad\times\frac{w_\alpha(\mathbf{q})^*w_\beta(\mathbf{q})}{\hbar^2\{k^2-|\mathbf{k}+\mathbf{q}|^2\}/2m}d^3k,\end{aligned}\tag{14}$$

we can express the second-order band energy in terms of ion–ion pairs as

$$\begin{aligned}E_2&=\frac{1}{N}\sum_{|\mathbf{k}|<k_{\mathrm{F,spin}}}E_2(\mathbf{k})\\&=\sum_{\alpha,\beta}\sum_{\mathbf{q}\neq 0}S_\alpha(\mathbf{q})^*S_\beta(\mathbf{q})F_{\alpha\beta}(\mathbf{q})\\&=\frac{1}{2N}\sum_{i(\alpha)\neq j(\beta)}\phi_{\alpha\beta}(\mathbf{R}_{ij})\\&\quad+\sum_{\alpha}\frac{1}{N}\sum_{\mathbf{q}\neq 0}F_{\alpha\alpha}(\mathbf{q}),\end{aligned}\tag{15}$$

$$\phi_{\alpha\beta}(\mathbf{R}_{ij})=\frac{2}{N}\sum_{\mathbf{q}\neq 0}e^{i\mathbf{q}\cdot\mathbf{R}_{ij}}F_{\alpha\beta}(\mathbf{q}).$$

The first term of Eq. (15) determines the effective ion–ion two-body potential $\phi(\mathbf{R}_{ij})$. In Fig. 2, the Al–Al pair potential in face-centered cubic (fcc) aluminum is shown, which is presumably not much different from that in liquid Al. The distribution of near-neighbor

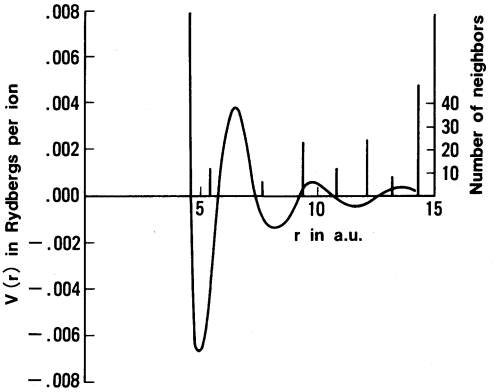

FIG. 2. The effective interaction between Al ions in the fcc structure (a continuous curve). The distribution of neighbor atoms in the fcc structure is shown as a function of distance by vertical lines. The distance is given in atomic units, i.e., 1 a.u.$=5.29\times 10^{-2}$ nm (Harrison, 1964).

atoms in fcc Al is shown as well. At large distances, the tail of the pair potential oscillates as

$$\phi(R_{ij}) \propto \frac{\cos(2k_F R_{ij})}{(2k_F R_{ij})^3}, \qquad (16)$$

and this oscillation, called the Friedel oscillation, is a consequence of oscillating screening charge density. Nearest-neighbor atoms sit at the first minimum of the pair potential and stabilize the total energy. The structure of solids and liquids may be determined so as to give the lowest total energy. Applications of the pseudopotential theory to atomic structures in liquids will be discussed in Sec. 3.1.

1.4.3 Green's-Function Theory. In a very weak potential field, we use perturbation theory and calculate the interatomic potential. In this case, plane waves can be good starting wave functions even in random systems. However, in systems with a strong potential field without translational symmetry, the plane-wave representation cannot be adopted, and a formalism of real-space representation is necessary.

We define the Green's function (or Green's-function operator) as

$$G=(E-H)^{-1}. \qquad (17)$$

Here, we write the Hamiltonian as $H=H_0+W$, where H_0 is the unperturbed part of the Hamiltonian; e.g., only the kinetic energy term. It should be noted that H and G are matrices. We assume, for simplicity, that there are no interactions between electrons. The random local potential in liquids is represented by W, i.e., $W_{ij}=w_i(\mathbf{r})\delta_{ij}$, where i denotes an individual atom. We assume, for convenience, that the zero of energy is the average potential $(1/V)\Sigma_i\int w_i(\mathbf{r})d^3r$. The spectral representation of the Green's function can be given, using the projection operator $|n\rangle\langle n|$ onto an eigenstate ψ_n of H, by

$$G=\sum_n \frac{|n\rangle\langle n|}{(E-E_n)},$$

where E_n is the eigenenergy of the state ψ_n. The Green's function can be expanded in terms of the unperturbed Green's function $G^0=(E-H_0)^{-1}$ as

$$G=G^0+G^0WG^0+G^0WG^0WG^0 +G^0WG^0WG^0WG^0+\cdots . \qquad (18)$$

The density of states $N(E)$ can be calculated in terms of Green's functions, including spin degeneracy 2, as

$$N(E)=-\frac{2}{V}\,\mathrm{Tr}\,\frac{1}{2\pi i}\lim_{\delta\to 0^+}\{G(E+i\delta) -G(E-i\delta)\}. \qquad (19)$$

The quantity $N(E)dE$ is the number of electronic states in an energy interval between E and $E+dE$. Hereafter, we assume that the system is monatomic and drop all indices α or β labeling the atom.

The self-energy can be defined in a perturbation series and calculated in a momentum representation, by the Fourier transformation, as

$$\Sigma(\mathbf{k},E)=\sum_{\mathbf{k}_1}\langle W(\mathbf{k}-\mathbf{k}_1)G^0(\mathbf{k}_1)W(\mathbf{k}_1-\mathbf{k})\rangle_c + \sum_{\mathbf{k}_1,\mathbf{k}_2}\langle W(\mathbf{k}-\mathbf{k}_1)G^0(\mathbf{k}_1)W(\mathbf{k}_1 -\mathbf{k}_2)G^0(\mathbf{k}_2)W(\mathbf{k}_2-\mathbf{k})\rangle_c+\cdots . \qquad (20)$$

The scattering potential $W(\mathbf{k})$ can be expressed as $W(\mathbf{k})=S(\mathbf{k})w(\mathbf{k})$, where

$$S(\mathbf{k})=N^{-1}\sum_j \exp(-i\mathbf{q}\cdot\mathbf{R}_j)$$

is the structure factor and $w(\mathbf{k})$ is the Fourier transform of $w_i(\mathbf{r})$. Using an experimentally observed quantity

$$a(\mathbf{k})=N\langle|S(\mathbf{k})|^2\rangle_c,$$

the second-order self-energy is derived as

$$\Sigma^{(2)}(\mathbf{k},E)=\frac{V/N}{(2\pi)^3}\int \frac{a(\mathbf{q})|w(\mathbf{q})|^2}{E-\epsilon_{\mathbf{k}+\mathbf{q}}}d^3q, \qquad (21)$$

where $\epsilon_{\mathbf{k}}$ is an eigenenergy of the unperturbed Hamiltonian H_0. If the energy E lies in a band region of $\epsilon_{\mathbf{k}}$, the integral in Eq. (21) gives both real and imaginary parts. The real part of the self-energy gives a shift of the electron energy. The imaginary part gives a broadening of the imaginary part of the Green's function or, in other words, the inverse of the imaginary part corresponds to the lifetime of an electron with a momentum $\hbar\mathbf{k}$. An electron with a momentum $\hbar\mathbf{k}$ is scattered to a state with $\hbar(\mathbf{k}+\mathbf{q})$ by the random potential field $W(\mathbf{q})$ and has a finite lifetime. The schematic energy dispersion and energy broadening of electrons in liquids are shown in Fig. 3. The shift of $E(\mathbf{k})$ has a positive sign for $k > K_p/2$ and a negative sign for $k < K_p/2$, where the wave vector K_p is a scattering vector of the strongest peak of the structure factor. Therefore, a pseudogap or dip appears in the electron density of states at an energy $E \simeq \epsilon_\mathbf{k}$ with $|\mathbf{k}| = K_p/2$. However, compared with the results obtained by a more sophisticated method, the second-order perturbation treatment Eq. (21) cannot give satisfactory results.

1.4.4 Effective-Medium Approximation. The best approximation of Eq. (18) to disordered systems on a periodic lattice is the *coherent-potential approximation* (CPA). The CPA has been widely and successfully applied to random systems on periodic lattices and extended to muffin-tin potential systems (Elliott *et al.*, 1974). We need an equivalent theory for liquids and amorphous systems. This is the *effective-medium approximation* (Roth, 1974). We consider the configurational average in the pair approximation, where the Green's function always appears together with a pair distribution function $g(\mathbf{R})$.

The single-site t matrix is defined, independent of site indices, by the equation

$$t = v + v\frac{1}{\rho_0}\int d^3R_1\, d^3R_2\, B(-\mathbf{R}_1)T(\mathbf{R}_1-\mathbf{R}_2), \tag{22}$$

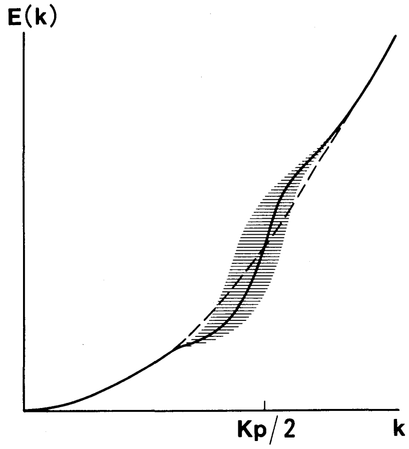

FIG. 3. Energy dispersion of electrons in liquids. The broadening of the Green's function is shown by hatching.

where v is the local scattering potential and $B(\mathbf{R})$ is the free Green's-function matrix defined by the matrix elements of $[E-(\hbar^2/2m)\Delta]^{-1}$. The single-site t matrix describes effects of repeated scattering of an electron at one site. The matrix $T(\mathbf{R})$, called the scattering path operator, describes the repeating scattering and hopping of electrons in a consistent way and should be determined by a self-consistent equation,

$$T(\mathbf{R}) = \rho_0 t\delta(\mathbf{R}) + \rho_0 t\int d^3R_1 \tilde{G}(\mathbf{R}-\mathbf{R}_1)T(\mathbf{R}_1). \tag{23}$$

Here, ρ_0 is the density of ions. The Green's function $\tilde{G}$ in the effective-medium approximation should obey the equation

$$\begin{aligned}\tilde{G}(\mathbf{R}-\mathbf{R})' &= B(\mathbf{R}-\mathbf{R}')g(\mathbf{R}-\mathbf{R}') + h(\mathbf{R}-\mathbf{R}')\\ &\times \int d^3R_1\, d^3R_2\, \tilde{G}(\mathbf{R}-\mathbf{R}_1)\\ &\times T(\mathbf{R}_1-\mathbf{R}_2)\tilde{G}(\mathbf{R}_2-\mathbf{R}'),\end{aligned} \tag{24}$$

where $h(\mathbf{R}) = g(\mathbf{R}) - 1$. These coupled equations should be solved self-consistently. The effective-medium approximation is the best approximation which consistently includes all possible single-site contributions. It has been extended to the muffin-tin potential systems and applied to liquid noble and transition metals. The electronic density of states in liquid Ni was calculated by Asano and Yonezawa (1980). The results is very close to that of solid fcc Ni, and shows that the short-range order persists in a liquid metal. (See Sec. 3.6.)

1.4.5 Recursion Method, LMTO-Recursion Method, and Supercell Method. The Green's function can be investigated by moment analysis of the spectral function, especially in cases in which the electron transfer is dominated by short-range hoppings. The *recursion method* (Haydock, 1980) is very practical for calculation of Green's functions. This method is closely related to the moment expansion method of the spectrum and the Lanczos method for matrix tridiagonalization. Let us try to calculate the diagonal element G_{00} of the Green's function of a tight-binding model, where the subscript 00 denotes the diagonal element with respect to an arbitrary state ϕ_0. We generate the whole set $\{\phi_n\}$ by the recursion relations, starting from ϕ_0,

$$b_1\phi_1 = H\phi_0 - a_0\phi_0$$
$$b_{n+1}\phi_{n+1} = H\phi_n - a_n\phi_n - b_n\phi_{n-1}. \qquad (25)$$

The coefficients a_n and b_n are determined so as to orthogonalize $H\phi_n$ (or ϕ_{n+1}) to the preceding functions ϕ_{n-1} and ϕ_n, and b_{n+1} is a coefficient which normalizes ϕ_{n+1} to unity. The resulting $\{\phi_0, \phi_1, \ldots, \phi_n, \ldots\}$ is an orthonormalized set. The matrix elements of the Hamiltonian are given by

$$\langle\phi_n|H|\phi_n\rangle = a_n,$$
$$\langle\phi_{n-1}|H|\phi_n\rangle = \langle\phi_n|H|\phi_{n-1}\rangle = b_n. \qquad (26)$$

No other states such as ϕ_{n-2} or ϕ_{n-3} appear in $H\phi_n$, and the Hamiltonian has been tridiagonalized on an orthonormalized basis set $\{\phi_0, \phi_1, \phi_2, \ldots\}$. Therefore, the diagonal element of the Green's function can be written as a continued fraction:

$$G_{00} = [(E-H)^{-1}]_{00} = \cfrac{1}{E - a_0 + \cfrac{|b_1|^2}{E - a_1 + \cfrac{|b_2|^2}{E - a_2 + \cfrac{|b_3|^2}{E - a_3 + \cdots}}}}. \qquad (27)$$

This method does not require translational periodicity. The recursion method was first applied to the tight-binding models.

The *linear muffin-tin orbital* (LMTO) method is one of the most efficient methods for the electronic band structure calculation, which can give high accuracy for energy eigenvalues and wave functions with minimal bases, i.e., one *s*-type, three *p*-type, and five *d*-type muffin-tin orbitals per atom (Andersen, 1975). The muffin-tin orbital is similar to an atomic orbital and is a solution to the Schrödinger equation in an atomic sphere at each atomic site and to the Laplace equation in an outer region where the potential is flat and the electron kinetic energy is small. By choosing localized envelope functions of each muffin-tin orbital so as to make them continuous at the boundary between two regions, we can reduce the effective Hamiltonian to a tight-binding form which we call the *first-principles tight-binding* method (Andersen and Jepsen, 1984). This method can be combined with the recursion method to give the *LMTO-recursion method*, which has been applied to amorphous and liquid systems (Fujiwara, 1984, Nowak *et al.*, 1991). Eigenvalues and eigenfunctions are very reliable even in liquid structures as well as in solids, but a structural model should be constructed by other simulation methods.

Recently, computational facilities have made great progress in terms of both computational speed and memory size. Hence, direct calculation of electronic structures in liquids can be achieved. For example, an efficient band-structure method can be applied to a system with a large unit cell containing several tens or hundreds of atoms. If we construct a cell with liquid structures of hundreds of atoms and impose a periodic boundary condition, the calculating procedure is just the same as that for crystalline solids. This is called the *supercell method* and has been applied to several liquid metals (Hafner and Jank, 1990, Hafner and Payne, 1990).

2. ELECTRON LIQUIDS

Electrons in metals form a highly degenerate liquid, subject to the Fermi–Dirac statistics, in a positive-charge background of ions. The effects of many-body correlation are quite important. The ground-state energy per electron is given in Rydberg units (1 Ry = 13.6058 eV = 2.1799×10^{-18} J), including the spin degeneracy 2, by

$$\frac{E_0}{N_e} = \frac{3}{5}\left(\frac{9\pi}{4}\right)^{2/3} \frac{1}{(r_s/a_0)^2} - \frac{3}{2}\left(\frac{3}{2\pi}\right)^{2/3} \frac{1}{r_s/a_0} + \epsilon_c, \quad \text{in Ry.} \qquad (28)$$

The parameter r_s is a mean interelectronic spacing defined by $r_s = (3/4\pi)^{1/3} n^{-1/3}$ with the electron density n, N_e is the total electron number, and a_0 is the Bohr radius (5.29×10^{-2} nm). Values of r_s/a_0 lie in normal metals between 2 and 6. The first and the second terms of Eq. (28) are the kinetic and exchange energies, respectively. The electron–electron Coulomb energy does not appear here because it exactly cancels the ion–ion and electron–ion interaction energies in a uniform system. The term ϵ_c is the remaining interaction energy, called a correlation energy, and it is a function of r_s as well. We can imagine that in the low-density region the electron liquid may crystallize, because stabilization by the exchange energy [the second term of Eq. (28)] overcomes the kinetic energy. This crystallization of the electron liquid is called *Wigner crystallization.* It is supposed that the first-order liquid–crystal phase transition occurs at about $r_s/a_0=14$–15. The correlation energy is quite important for understanding the ground-state properties in condensed phases.

2.1 Homogeneous Electron Liquids

In the interacting electron system, the N_e-electron Hamiltonian is the sum of the noninteracting part H_0 and the interaction part $H'(H=H_0+H')$. We can calculate the total energy of the ground state, using the adiabatic theorem,

$$\frac{E_0}{N_e}=\frac{E_0^{(0)}}{N_e}-\sum_{\mathbf{k}}\left\{\hbar\int_0^1\frac{d\lambda}{\lambda}\int_0^\infty\frac{d\omega}{2\pi}\,\mathrm{Im}\,\frac{\epsilon_0}{\epsilon_\lambda(\mathbf{k},\omega)}+n\frac{e^2}{4\pi\epsilon_0}\frac{2\pi}{k^2}\right\},\tag{29}$$

where $\epsilon_\lambda(\mathbf{k},\omega)/\epsilon_0$ is the dielectric function of the system $H_0+\lambda H'$. This equation gives the total energy of electrons in terms of the dielectric function.

The dielectric function $\epsilon(\mathbf{k},\omega)/\epsilon_0$ is related to $\chi(\mathbf{k},\omega)$, the density–density response function of electrons, by

$$\frac{\epsilon_0}{\epsilon(\mathbf{k},\omega)}=1+\frac{4\pi e^2}{4\pi\epsilon_0 k^2}\chi(\mathbf{k},\omega).\tag{30}$$

The density–density response function $\chi(\mathbf{k},\omega)$ can be precisely expressed as

$$\chi(\mathbf{k},\omega)=\sum_n\left|\left\langle n\left|\sum_i e^{i\mathbf{k}\cdot\mathbf{r}_i}\right|0\right\rangle\right|^2\times\left\{\frac{1}{\omega-\omega_{n0}+i\eta}-\frac{1}{\omega+\omega_{n0}+i\eta}\right\},\tag{31}$$

where $\omega_{n0}=\omega_n-\omega_0$, and $\langle n|\Sigma_i e^{i\mathbf{k}\cdot\mathbf{r}_i}|0\rangle$ denotes the matrix element of an electron density operator $\Sigma_i e^{i\mathbf{k}\cdot\mathbf{r}_i}$ between the N_e-electron ground state Ψ_0 with energy $\hbar\omega_0$ and the N_e-electron excited state Ψ_n with energy $\hbar\omega_n$. The infinitesimally small imaginary part $+i\eta$ $(\eta\to 0+)$ in the denominator is introduced for causality or the adiabatic switching of the external field.

2.2 Fermi Liquids

In case of noninteracting Fermi particle (fermion) systems, the total energy of the system can be expressed as

$$E=\sum_{\mathbf{p}} n_{\mathbf{p}}\frac{p^2}{2m},\tag{32}$$

where the occupation number of the fermions with momentum $\mathbf{p}$ is denoted by $n_{\mathbf{p}}$. When the fermion–fermion interaction is introduced adiabatically, the ground and excited states are still assumed to be specified by the particle occupation number $n_{\mathbf{p}}$. The occupation number of the ground state $n_{\mathbf{p}}^0$ is unity at energies below the chemical potential and vanishes at energies above. The excitation from the ground state can be characterized by the deviation of $n_{\mathbf{p}}$ from $n_{\mathbf{p}}^0$, i.e., $\delta n_{\mathbf{p}}=n_{\mathbf{p}}-n_{\mathbf{p}}^0$. The collision time of particles with density n and velocity v_{F} (the Fermi velocity) is approximately $\tau=n^{-1/3}/v_{\mathrm{F}}$ if all particles participate. However, because of the Fermi–Dirac statistics, the fraction of particles participating in collisions is Δ/E_{F}, where $\Delta\simeq k_{\mathrm{B}}T$ and E_{F} is the Fermi energy. Therefore, at finite temperatures T, the lifetime of excitations near E_{F} can be estimated as

$$\tau=\frac{n^{-1/3}}{v_{\mathrm{F}}}\left(\frac{E_{\mathrm{F}}}{\Delta}\right)^2\propto\frac{1}{T^2}.$$

As seen, the low-energy excitations are long lived at low temperatures, and they are called *quasiparticles.* At absolute zero temperature, the fermion occupation $n_{\mathbf{p}}$ is discontinuous at the Fermi energy.

The energy of the system is a functional of $n_{\mathbf{p}}$ and can be expanded as

$$E[n_{\mathbf{p}}]=E_0+\sum_{\mathbf{p}}\epsilon_{\mathbf{p}}\delta n_{\mathbf{p}}+\frac{1}{2}\sum_{\mathbf{p},\mathbf{p}'}f_{\mathbf{p}\mathbf{p}'}\delta n_{\mathbf{p}}\delta n_{\mathbf{p}'}+O(\delta n_{\mathbf{p}}^3),\tag{33}$$

where $E_0=\Sigma_{\mathbf{p}}n_{\mathbf{p}}^0p^2/2m$ is the ground-state energy and $\epsilon_{\mathbf{p}}$ and $f_{\mathbf{p}\mathbf{p}'}$ are the first and second derivatives of $E[n_{\mathbf{p}}]$ with respect to $\delta n_{\mathbf{p}}$. The excitation energy of a quasiparticle of momentum $\mathbf{p}$ can be written as

$$\tilde{\epsilon}_{\mathbf{p}}=\epsilon_{\mathbf{p}}+\sum_{\mathbf{p}'}f_{\mathbf{p}\mathbf{p}'}\delta n_{\mathbf{p}'}.\tag{34}$$

We assume that $\epsilon_{\mathbf{p}}$ and $f_{\mathbf{p}\mathbf{p}'}$ are continuous and that $f_{\mathbf{p}\mathbf{p}'}$ is of short range. The long-range interaction of the Coulomb term in the case of charged fermions (i.e., electrons) can be treated by adding to the free energy an average longitudinal polarization field with a momentum transfer **q** acting on a charge fluctuation,

$$\mathbf{E}_{\text{pol}} = -i\mathbf{q}\,\frac{4\pi(-e)}{4\pi\epsilon_0 q^2}\sum_{\mathbf{p}}\delta n_{\mathbf{p}}.$$

Our ground state at absolute zero temperature can now be redefined as the *vacuum* of the *quasiparticles* and *quasiholes*, i.e., absence of excitations. Equation (33) is the basic equation of the Fermi-liquid theory of Landau (see, e.g., Nozières and Pines, 1966). The short-range interaction $f_{\mathbf{pp}'}$ actually depends upon the spins, and we can define symmetric and antisymmetric parts as

$$\begin{aligned} f^s_{\mathbf{pp}'} &= \tfrac{1}{2}\,(f^{\uparrow\uparrow}_{\mathbf{pp}'} + f^{\uparrow\downarrow}_{\mathbf{pp}'}) \\ f^a_{\mathbf{pp}'} &= \tfrac{1}{2}\,(f^{\uparrow\uparrow}_{\mathbf{pp}'} - f^{\uparrow\downarrow}_{\mathbf{pp}'}), \end{aligned} \tag{35}$$

where $f^{\sigma\sigma'}_{\mathbf{pp}'}$ is the interaction between a fermion with momentum **p** and spin σ and a fermion with $\mathbf{p}'$ and σ'. These parts can be expanded in series of Legendre polynomials P_l as

$$f^{s(a)}_{\mathbf{pp}'} = \sum_{l=0}^{\infty} f^{s(a)}_l P_l(\cos\xi), \tag{36}$$

where ξ is the angle between **p** and $\mathbf{p}'$. The momenta **p** and $\mathbf{p}'$ are on the Fermi surface. It is, however, more convenient to define dimensionless parameters

$$F^{s(a)}_l = \nu(0) f^{s(a)}_l, \tag{37}$$

where $\nu(0)$ is the density of states at the Fermi energy, $\nu(0) = Vm^* p_{\mathrm{F}}(\pi^2\hbar^3)$. Macroscopic properties of the Fermi liquid can be characterized by these parameters:

$$\text{effective mass,}\quad m^* = m\left(1 + \frac{F^s_1}{3}\right); \tag{38a}$$

$$\text{compressibility,}\quad \kappa = \kappa^0\,\frac{m^*}{m}\,\frac{1}{1+F^s_0}; \tag{38b}$$

$$\text{spin susceptibility,}\quad \chi_P = \chi^0_P\,\frac{m^*}{m}\,\frac{1}{1+F^a_0}, \tag{38c}$$

where κ^0 and χ^0_P are the compressibility and susceptibility in the ideal noninteracting system.

2.3 Local-Density-Functional Theory

We shall now return to the general electron–ion systems. The total energy of the ground state is a unique functional of the electron density $n(\mathbf{r})$ (see COLLECTIVE PHENOMENA IN SOLIDS) and is extremum with respect to $n(\mathbf{r})$. The ground state energy of the electron–ion system, i.e., E_0 in Eq. (33), can be expressed as

$$\begin{aligned} E_0[n(\mathbf{r})] = {} & \int \nu(\mathbf{r}) n(\mathbf{r}) d^3r \\ & + \frac{1}{2}\frac{e^2}{4\pi\epsilon_0}\iint d^3r\, d^3r'\,\frac{n(\mathbf{r})n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} \\ & + G[n(\mathbf{r})], \\ G[n(\mathbf{r})] = {} & T_s[n(\mathbf{r})] + E_{xc}[n(\mathbf{r})], \end{aligned} \tag{39}$$

where $\nu(\mathbf{r})$ is the external potential including the Coulomb potential of the nuclei, the second term of $E_0[n]$ is the electrostatic interaction between electrons, $T_s[n]$ is the kinetic energy of the noninteracting system of the same density $n(\mathbf{r})$, and E_{xc} is the rest, called the exchange–correlation energy. We assume that the electron density $n(\mathbf{r})$ can be written as

$$n(\mathbf{r}) = \sum_i |\psi_i(\mathbf{r})|^2, \tag{40}$$

and that $\psi_i(\mathbf{r})$ is a one-electron wave function of the state i, and the summation encompasses all occupied one-electron states. The ground-state N_e-electron wave function can be given as the Slater determinant of $\{\psi_i\}$. Using the variational principle, we can show that the one-electron wave function $\psi_i(\mathbf{r})$ should obey the equation (the Kohn–Sham equation)

$$\left\{-\frac{\hbar^2}{2m}\nabla^2 + \nu(\mathbf{r}) + \frac{e^2}{4\pi\epsilon_0}\int d^3r'\,\frac{n(\mathbf{r})n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} + \frac{\delta E_{xc}[n]}{\delta n(\mathbf{r})}\right\}\psi_i(\mathbf{r}) = \epsilon_i\psi_i(\mathbf{r}). \tag{41}$$

The total energy is, of course, not a sum of the one-electron energies ϵ_i. The energy $-\epsilon_i\delta n$ corresponds to the energy cost for removing an infinitesimally small number δn of electrons of the state i.

Usually the exchange-correlation energy functional $E_{xc}[n]$ is approximated by the local quantity

$$E_{xc}[n(\mathbf{r})] = \int n(\mathbf{r})\epsilon_{xc}[n(\mathbf{r})]d^3r.$$

This is called the *local-density-functional theory* (Jones and Gunnarsson, 1989). The formulation has been generalized to the spin-polarized case and has been successfully applied to the ground-state properties of magnetic metals. Almost all electronic structure calculations in condensed matter are now based on the local-density-functional theory with great success in describing ground-state properties.

Although the density-functional theory is exact for the ground state, actual calculations are restricted by several approximations, in particular by the local approximation. Therefore, they still have several persistent and systematic errors, such as errors in the long-range tail of charge density from the surface, and incorrect prediction of metallic ground states of the transition-metal oxides and the undoped mother compounds of high-T_c cuprate superconductors. Several attempts have been made to improve or extend the local-density-functional theory in order to remove errors in the ground-state properties and to be able to predict excited-state properties such as the band gap in semiconductors and insulators, e.g., gradient expansion of the exchange correlation energy, the self-interaction correction, and many-body effects for the exchange-correlation potential.

2.4 Some Applications

2.4.1 Surfaces of Simple Metals. Several physical properties of metallic surfaces have been discussed using an electron liquid model. The ionic systems are treated as a semi-infinite positive-charge background. The exchange-correlation potential is important because in the vacuum region the electron density is very low ($r_s \rightarrow \infty$). The values of the work function and the surface energy increase with decreasing electron density in the bulk. The positive background model for solids fails in estimating the surface energy of systems with small r_s and even gives negative surface energies. However, when a model pseudopotential is assigned to each atomic position, positive and reasonable values of the surface energy can be predicted.

2.4.2 Two-Component Quantum Plasma. The theory of the one-component quantum liquid explained in Sec. 2.1 can be extended to a multicomponent quantum liquid and has been applied to problems such as screening charge around positrons in metals, electron-hole liquids, and liquid metals (Tosi *et al.*, 1974). The dielectric function Eq. (30) can be generalized as

$$\frac{\epsilon_0}{\epsilon(\mathbf{k},\omega)} = 1 + \sum_{i,j} \frac{4\pi e_i e_j}{4\pi\epsilon_0 k^2} \chi_{ij}(\mathbf{k},\omega), \tag{42}$$

where e_i is the electric charge of the ith component and $\chi_{ij}(\mathbf{k},\omega)$ is the i–j component of the density–density correlation function. In this system, there are two types of well-defined collective modes: density fluctuation of ions analogous to phonons in solids, and plasmons.

2.4.3 Two-Dimensional Electron Liquids: Quantum Hall Effect. The surface inversion layer or accumulation layer in semiconductors, and the interface between two semiconductors, are systems of typical two-dimensional electron liquids. The electron motion is quantized along the direction perpendicular to the two-dimensional layer. If we apply a magnetic field perpendicular to the two-dimensional layer, electron motion in the two-dimensional space can also be quantized. In this system, the Hall conductivity is quantized as

$$\sigma_{xy} = -n(e^2/h), \tag{43}$$

where n is an integer. This is a macroscopic appearance of quantum effects, called the quantum Hall effect, and it is now used as the standard of Hall resistance. This effect also provides an experimental method for determining the fine-structure constant $e^2/4\pi\epsilon_0\hbar c$.

Let us consider a ring or a disk with a spatial hole in the center and a magnetic field penetrating the hole (in the z direction). If the radius of an electron orbit on the disk is R, the quantization condition of the magnetic flux is

$$\pi R^2 B = m'\phi_0, \tag{44}$$

with a magnetic field B, a flux quantum $\phi_0 \equiv h/e$, and m' an integer. Generation of the Hall current is equivalent to adding another magnetic flux Φ which does not touch the metallic disk. The total magnetic flux is then given by

$$\pi R^2 B + \Phi = m''\phi_0, \tag{45}$$

where m'' is an integer, and this quantized magnetic flux appears in the phase factor of electron wave functions. If the flux Φ increases by a flux quantum ϕ_0, then R must decrease. This causes electrons to jump to an orbit with a smaller radius (along the x direction). The only change is, as a whole, that one electron moves effectively from the outer edge of the disk to the inner edge by a radial distance L. For measurement of the Hall resistance, an electric field E is applied along the radial direction (x direction) of the disk, and the resulting change of the energy is $\Delta\epsilon = eEL$. The net current along the tangential direction (y direction) can be written as

$$j_y = -\frac{1}{L}\frac{\Delta\epsilon}{\Delta\Phi} = -\frac{e^2 E}{h}, \tag{46}$$

and the Hall conductivity is $-e^2/h$. If the number of electrons shifting from one edge to the other is n, then the Hall conductivity is given by

$$\sigma_{xy} = -n(e^2/h). \tag{47}$$

This is the integral quantum Hall effect (Prange and Girvin, 1987).

So far, we have ignored the electron–electron interaction in the two-dimensional electron liquid. In a symmetric gauge where the vector potential is $\mathbf{A} = (y, -x)B/2$, the ground-state wave function of N_e electrons can be written, in a good approximation, as

$$\Psi(z_1, z_2, \ldots, z_{N_e}) \propto \prod_{j>i=1}^{N_e} (z_i - z_j)^m \times \exp\left(-\frac{1}{4}\right) \sum_{i=1}^{N_e} |z_i|^2). \tag{48}$$

Here, the electron coordinates are $z_j = x_j + iy_j$ in units of the orbital radius of the lowest Landau level $l_0 = \hbar/eB$, and m is an odd number because of the antisymmetric property of the wave function. This wave function produces a new liquid state, called the Laughlin state, with a lower energy than that of the Wigner crystal. The pair correlation function has an asymptotic behavior of the form r^{2m} for short distances, which is a more exclusive particle–particle correlation than that of the Wigner crystal. The power of a coordinate z_i in the first factor of the wave function (48) is $M = m(N_e - 1)$, and this means that the wave function (48) contains one-electron wave functions with angular momentum up to $\hbar M$. A one-electron state with angular momentum $\hbar l$ has $(l+1)$-fold degeneracy in the two-dimensional case. Therefore, this liquid state with a specific m is only possible for a specific occupancy of the Landau level, and its filling factor is $\nu = N_e/M = 1/m$ (m=odd number) when $N_e \to \infty$. Furthermore, the wave function (48) implies that the statistical behavior of the two-dimensional electron liquid is equivalent to that of the two-dimensional classical one-component plasma of charge m at the temperature $k_B T = m$. The liquid–solid transition of a two-dimensional one-component plasma has been investigated by Monte Carlo simulations, and the results indicate that the one-component plasma is a liquid when $2m < 140$ ($\nu > 1/70$) and a triangular solid when $2m > 140$ ($\nu < 1/70$). It has been shown that an excitation in the Laughlin state, a quasihole or quasiparticle, carries a fractional charge $\pm e/m$, and the Hall conductivity (the fractional quantum Hall effect) is given by

$$\sigma_{xy} = -\nu(e^2/h), \quad \nu = 1/m. \tag{49}$$

The finite density of quasiparticles and quasiholes ensures more complicated hierarchical excitation states stabilized at the electron filling factor ν;

$$\nu = \cfrac{1}{m + \cfrac{\alpha_1}{p_1 - \cfrac{\alpha_2}{(p_2 - \cdots)}}}$$

with $\alpha_i = \pm 1$, and p_i=even integers.

3. ELECTRON STRUCTURE OF LIQUID METALS AND SEMICONDUCTORS

One of the ideal structures of liquid metals is the dense random packing of spheres because of the nondirectional character of metallic cohesion. First, we will describe the structure of liquid metals and, then, several experimental and theoretical results will be presented and discussed.

3.1 Structure of Liquid Metals

The atom–atom interaction energy in liquid simple metals (*sp*-electron metals) is a sum of the two-body interactions, and the asymptotic behavior of the interatomic potential is given by Eq. (16). This is a characteristic result of the metallic behavior of electrons and weak potentials in simple metals, because the metallic bonding requires no specific directional ordering. The resulting structure of liquid metals is essentially dense random packing. The situation is very complicated in the transition metals and rare-earth metals, where the perturbation treatment for the total energy fails and multiatom interaction is quite important.

The fact is that, even in simple metals, the pair potentials show a wide variety. The pair potential is a function of the parameters $x = 2k_FR/2\pi$, $R_s = R_aZ^{-1/3}$, and R_c, where R, Z, R_a, and R_c are the interatomic distance, the valence, the atomic radius (characterizing the density), and the radius of the empty core of the pseudopotential, respectively. The parameter R_s is the electron density parameter denoted previously by r_s. The pair potential can be reduced to a factorized form

$$\Phi(R) = (Z^2/R_a)\Phi_{\mathrm{red}}(x), \qquad (50)$$

where $\Phi_{\mathrm{red}}(x)$ is shown in Fig. 4 (Hafner and Heine, 1983; Hafner, 1987). The oscillating behavior of the pair potential comes from the Friedel oscillation. The values of the phase and amplitude of the Friedel oscillations of the pair potential $\Phi_{\mathrm{red}}(x)$ are constant at a fixed R_c/R_s. The first-neighbor distance and further-neighbor configurations are determined by the position of the first minimum of the pair potential and by positions and depths of further deviations. The variation of $\Phi_{\mathrm{red}}(x)$ with R_c/R_s for a constant R_s shows a drastic change in the amplitude of the oscillation at $k_FR_c = \pi/4$ ($R_c/R_s = 0.4092$) and the damping of the oscillations accompanied by an increasing phase shift. [See Eq. (16).]

The structures of liquid metals can be classified in three different groups (Hafner, 1987). The first is the structure of I*a* and I*b* groups (Be, Mg, Al, and Pb). The structures show the following:

1. The first peaks of both the pair distribution function $g(R)$ and the static structure factor $S(Q)$ are symmetric.
2. The ratios of the positions of their second and first peaks are about $R_2/R_1 = 1.92$ and $Q_2/Q_1 = 1.86$.
3. The number of atoms n_1 in the first coordination shell is between 9.0 and 11.0.

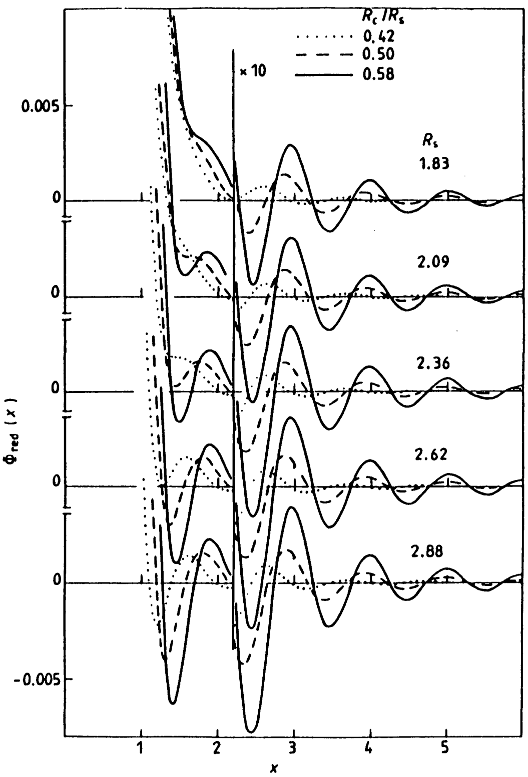

FIG. 4. Pair potential $\Phi_{\mathrm{red}}(x)$ as a function of R_c/R_s and R_s (Hafner and Heine, 1983).

These facts imply that the structure can be described by the dense random packing of hard spheres.

The second type is the group of Zn, Cd, Hg, and In, whose structures show

1. asymmetric peaks of $g(R)$ and $S(Q)$,
2. nonideal ratios of R_2/R_1 and Q_2/Q_1, and
3. metallic coordination number $n_1 \simeq 9$–11.

The last type is the structures of Ga, Si, Ge, and Sn, whose structures are greatly different from those of random packing of hard spheres and show

1. the first peak with shoulder in $S(Q)$ and with subsidiary minima in $g(R)$,
2. large deviations from the ideal values $R_2/R_1 \geqslant 2.0$ and Q_2/Q_1–2.0, and
3. low coordination number $n_1 \simeq 6.5$–7.

These three different classes can be explained by the pair potential and the systematic variation of the valency Z or R_s with a constant R_c/R_s.

3.2 Electron Spectroscopy in Liquid Metals

Electronic structures in liquid metals have been investigated quite accurately using synchrotron radiation in x-ray photoelectron spectroscopy (XPS) and ultraviolet photoelectron spectroscopy (UPS) experiments (Indlekofer *et al.*, 1990). In the photoelectron experiments, the photon energy is used to lift an electron from an occupied level to a vacuum level. The photoelectron intensity $I(E,\hbar\omega)$ is given approximately by

$$I(E,\hbar\omega) \propto (1/\omega^2) \sum_l N_l(E)\sigma_l(E,\hbar\omega), \qquad (51)$$

where E and $\hbar\omega$ are the energies of an electron and an incident photon, respectively, $N_l(E)$ is the electron partial density of states with the orbital angular momentum quantum number l, and $\sigma_l(E,\hbar\omega)$ is the partial photoionization cross section. Therefore, the intensity of photoelectrons does not give the exact density of states, but we can obtain information about it. The partial photoionization cross section depends rather sensitively on the incident photon energy and we can identify the orbital character of electrons in a given energy range by varying the photon energy. Comparison with crystals and amorphous systems provides much fundamental information on the cohesion of condensed matter. The problems of the photoelectron experiments in liquid metals may be summarized as follows:

1. The surface of a liquid metal is easily covered by oxides, and it is crucially important to obtain a clean surface.
2. The atomic composition of liquid metal alloys at a surface may be different from the bulk.
3. The vapor pressure at the melting point is, for many liquid metals, too high to be treated with the technique presently available.

A large amount of experimental data has been accumulated for monovalent metals (Li, Na) and polyvalent metals (Al, Ga, Ge, In, Sn, Hg, Tl, Pb, Bi) and their alloys (e.g., Indlekofer *et al.*, 1990). These experimental results can be summarized as follows:

1. The valence-band spectra of Li are in good agreement with a free-electron-like parabolic band, but the width (3.7 eV) is reduced significantly from the free-electron band (4.7 eV). The bandwidth of Na (3.2 eV) shows a minor reduction from the free-electron model.
2. The valence-band spectra of Al and Si show very simple free-electron-like *sp* bands. That of Ge, however, shows a small dip between *s* and *p* bands. The dip between *s* and *p* bands in Te is much enhanced and the two bands are almost separated. The spectra of these liquids show a sharp Fermi edge and are consistent with the transport properties. The calculated density of states (Hafner and Jank, 1990) will be discussed in the next section.
3. Solid Bi is a semimetal in the solid phase but a metal in the liquid phase. A band gap between 3*s* and 3*p* states is observed in Bi, Pb, and Tl, as shown in Fig. 5. The 6*s* band is located at 10, 8, and 5 eV below the Fermi energy, respectively. The 6*p* band in these liquids shows a small splitting of the peak,

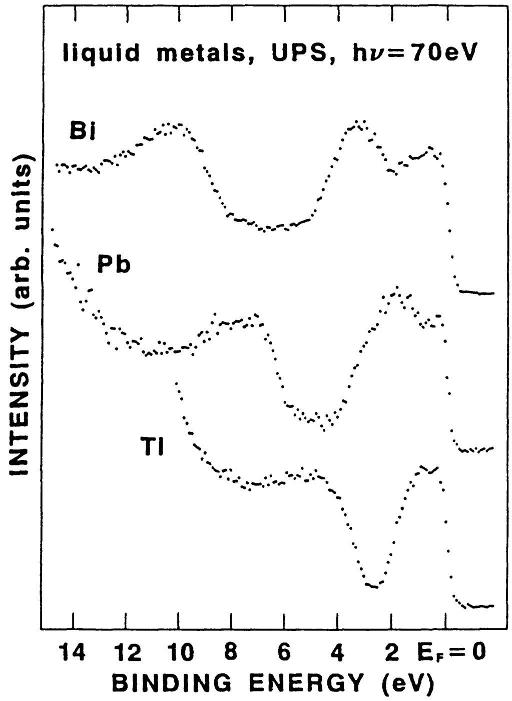

FIG. 5. Ultraviolet photoelectron spectra of liquid Bi, Pb, and Tl (Indlekofer *et al.*, 1990).

and this splitting is attributed to the spin–orbit interaction. The size of the band gap between the 3*s* and 3*p* bands and the depth of the 3*s* band change systematically.

4. The valence-band spectra of $Bi_{50}Ga_{50}$ are almost the same as those of pure Bi, while the valence-band spectra of $Bi_{50}Tl_{50}$ are different from those of both Bi and Tl. This is explained by the fact that the concentration of Bi atoms is much higher in the surface region in liquid BiGa alloys, while the atomic composition of $Bi_{50}Tl_{50}$ alloy scarcely changes in the surface region.

3.3 *sp*-Electron Metals

The systematic change in the electronic density of states for simple metals (*sp*-electron metals) has been investigated theoretically by Hafner and Jank (1990), using the LMTO-supercell method in a system of 50–70 atoms generated by the molecular-dynamics simulation. The agreement with experiments is fairly good. These results can be summarized as follows, and the calculated densities of states are shown in Fig. 6.

1. For Li and Be, a strong reduction of the occupied band and pronounced structure-induced minima in the density of states are found.
2. The densities of states of Na, Mg, Al, and Si are very close to those of the free-electron model.
3. In alkaline-earth metals, *s*-*d* hybridization and relativistic energy lowering of the *s* state induce strong deviation of the density of states from that of the free-electron models. The number of *d* electrons in liquid Ba is estimated to be 0.74/atom.
4. In the group-II*b* elements (Zn, Cd, Hg), the narrow *d*-band overlaps with the bottom of the broad *sp* band and the density of states at the Fermi energy is greatly reduced compared to the free-electron values.
5. In In and Tl, a deep minimum of the density of states appears 2–3 eV below the Fermi energy, highly analogous to the crystalline case. However, the electronic struc-

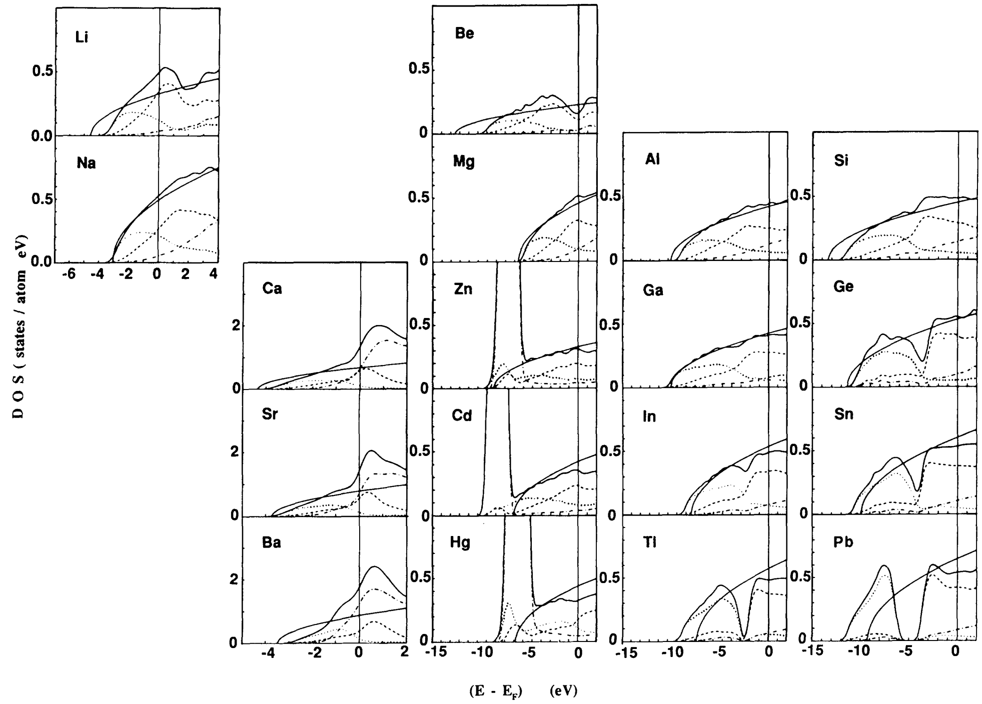

FIG. 6. Calculated density of states (DOS) in liquid *sp* metals and group-IV elements. Full curve, total density of states; dotted curve, *s* states; broken curve, *p* states; chain curve, *d* states; solid parabola, free-electron result. A vertical line shows the position of the Fermi energy. Energy origin is fixed at the Fermi energy (Hafner and Jank, 1990).

ture of Ga seems to be very different from the crystalline case whose density of states has a deep minimum at the Fermi energy.

3.4 Group-IV Elements: Si, Ge, Sn, and Pb

In the solid phase, Si and Ge are tetrahedrally bonded semiconductors with the diamond structure. The wave functions are sp^3 hybridized orbitals, and the band gap is attributed to the bonding–antibonding splitting of the hybridized orbitals. Tin has two solid phases: one is white tin (<13.2 °C) and the other is gray tin (>13.2 °C). Gray tin (α-Sn) has the diamond structure and is a zero-gap semimetal. White tin (β-Sn) has the tetragonal structure and is metallic. In heavier elements, the hybridization becomes weaker and the hybridization gap disappears. β-Sn shows a broad minimum between -4 and -7 eV below the Fermi energy which separates the 5*s* and 5*p* bands. The band gap appears between the 6*s* and 6*p* bands in Pb with the fcc structure.

Recent optical and dc-conductivity experiments show that even liquid carbon is metallic, and this is consistent with the very recent theoretical investigation of liquid carbon using first-principles molecular dynamics (Galli *et al.*, 1990). Liquid Si is metallic and has a free-electron-like density of states and no sp^3 hybridization. In liquid Ge and Sn, the *s-p* band separation leads to a broad minimum in the occupied density of states. In liquid Pb, the 6*s* and 6*p* bands are gap-separated at 4–5 eV below E_F. The structural deviation of Si and Ge from the ideal random packing is due to the Friedel oscillations of the pair potentials. In heavier elements (Sn, Pb), the separation of *s* and *p* states is enhanced by relativistic effects, and this leads to a strong damping of the Friedel oscillations as a result of smaller R_s. Therefore, the *s-p* separation stabilizes the close-packing structure. The calculated densities of states for these elements can be seen in Fig. 6.

3.5 Liquid Chalcogens: S, Se, and Te

The liquid chalcogens, sulfur, selenium, and tellurium, are other typical examples of liquid metals (Endo, 1985). The melting point of liquid sulfur is 113 °C. At the melting point, it is a molecular liquid with an eight-member molecular ring S_8 and is an insulator. A structural change occurs at 159 °C from the S_8 ring to a polymer chain with 10^6 atoms. At sufficiently high temperatures, it is a semiconductor. The polymerization leads to the appearance of a new optical band at 3.2 eV, which is assigned to the transition from a lone-pair band to a σ* band (antibonding band of σ orbitals).

Selenium has a chain structure at the melting point (217 °C) and behaves as a semiconductor, while at higher temperatures it is metallic. The valence–electron configuration is $4s^24p^4$. In the chain structure, two 4*p* electrons out of four occupy the σ bond connecting two Se atoms. The other two 4*p* electrons do not contribute to the bonding mechanism and form the lone-pair orbitals (LP) whose lobes extend perpendicular to the chain. The energy of two 4*s* electrons is much lower than that of the σ bond, and therefore the σ and the lone-pair orbitals are of almost pure 4*p* character. The schematic density of states is shown in Fig. 7. The bond angle of Se-Se-Se is about 90°, and the dihedral angle in the solid phase is 90°. The lone-pair orbital is almost perpendicular to the chain. Furthermore, the neighboring lone-pair orbitals are perpendicular to each other. These geometrical configurations are mainly determined by the repulsive interaction between the lone-pair orbitals. The lone-pair electrons essentially only contribute to the interaction between neighboring chains. The cohesive properties do not change very much at the melting point in Se. The liquid phase is characterized by fluctuation of the dihedral angle $\pm 90°$ of the spiral chain. In the high-temperature (~ 1200 °C) and high-pressure (~ 400 bar) region, liquid Se is in a metallic phase. In this region, the number of atoms per chain is reduced to 10, which has been observed by NMR experiments. At the same time, the density becomes ten times larger than that of the low-temperature semiconductor phase. The semiconductor–metal transition is also observed in the optical ab-

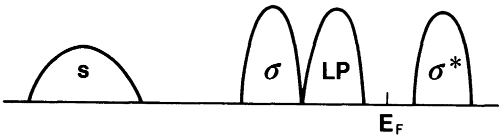

FIG. 7. Schematic energy spectra of liquid Se. LP stands for the lone-pair bands and σ* for the antibonding σ orbitals.

sorption spectrum. The absorption edge disappears, and the optical gap vanishes near the critical point.

Tellurium has a melting point at 450 °C, and the liquid phase is metallic with a coordination number of about 3. The resistivity is about 770 $\mu\Omega$ cm at 400 °C and about 360 $\mu\Omega$ cm at 800 °C. The threefold coordinated structure is an outcome of the shortened polymer chain and the interaction between the lone-pair electrons and the σ^* antibonding orbitals.

3.6 Liquid Transition Metals

The liquid transition metals are the extreme opposite of the *sp*-electron metals, and the nearly free-electron model does not work for them at all. A tight-binding model may, however, be applicable and could serve as a reasonable first-step approach. Fujiwara (1979) applied the tight-binding recursion method to liquid and amorphous transition metals Fe, Co, and Ni, using tight-binding parameters so determined as to reproduce the density of states obtained by standard band calculations in the crystalline cases. An apparent difference was found in the density-of-states curves of liquid and amorphous metals. In the amorphous transition metals, the densities of states have a double-peaked asymmetric shape, while those in liquids are single-peaked and asymmetric. These differences are attributed to the difference of the atomic density fluctuations and local environment. Asano and Yonezawa (1980) extended the effective-medium approximation to the Korringa–Kohn–Rostoker method. The density of states in liquid Ni, shown in Fig. 8, closely resembles that of fcc Ni and the result calculated by the tight-binding recursion method. This resemblance indicates the existence of a close-packed local environment in liquid structures similar to the fcc structure. Hafner and Jank (1990) presented the density of states of liquid transition metals Cr–Ni by the LMTO supercell method and reported the persistence of the double-peaked structure even in liquid systems.

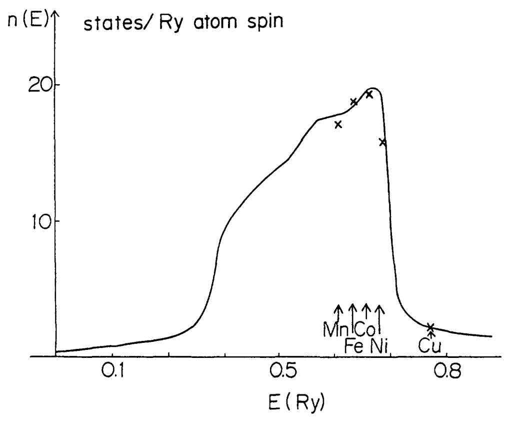

FIG. 8. Density of states of liquid Ni. Crosses denote the values estimated from susceptibility experiments. The Fermi energies of Ni, Co, Fe, Mn, and Cr are shown by arrows (Asano and Yonezawa, 1980).

3.7 Metal–Nonmetal Transition

A metal–nonmetal transition is observed in expanded Hg (higher density than the critical density) and in Cs (in the critical region). The metal–nonmetal transition in these systems is due to *s-p* band separation with changing coordination number, but not due to the scattering of electrons by the random potential.

3.7.1 Mercury. The resistivity of pure liquid Hg (density$=13.6$ g/cm^3) is about 100 $\mu\Omega$ cm (25 °C), and the corresponding mean free path is 0.7 nm. The conduction band of Hg originates from the 6*s* and 6*p* bands (see Fig. 6). Near the critical point, the density is very low; therefore the bandwidth becomes narrower because of the large separation between atoms, and the density of states at the Fermi energy $N(E_F)$ is reduced. At 9.0 g/cm^3 and 1440 °C, the resistivity is about 2500 $\mu\Omega$ cm. The system transforms to an insulating phase at a density about 1.6 times larger than the critical density d_c at the critical point ($d_c=5.7$ g/cm^3). The metal–nonmetal transition of Hg in the low-density region was confirmed by several experiments: thermoelectric power, Knight shift of NMR spectra, reflection spectra, thermal pressure coefficients, etc. These experiments show a change in the characteristics of interatomic interactions, accompanied by a drastic change in the transport properties. Yonezawa *et al.* (1977) presented the calculated density of states in expanded Hg and showed that there is a reduction in the density of states at E_F with decreasing atomic density and that a band gap opens up at some critical density around 2 to 4 g/cm^3, though this value is too low in comparison with the observed value. This metal–nonmetal transition is essentially due to the 6*s*-6*p* band separation in a diluted region.

3.7.2 Cesium. A metal–nonmetal transition is also observed in the monovalent metal Cs. The compressibility of heavier alkali metals is very large, and the density can be doubled by compression. In alkali metals, the temperature dependence of the transport properties can be well described by the nearly free-electron model in the region where the density is twice or much larger than the critical density. With increasing temperature, the density is reduced, and the resistivity increases gradually and finally reaches a value of two orders of magnitude larger. At the critical density $d_c = 0.41$ g/cm^3, the resistivity reaches a value of 3300 $\mu\Omega$ cm. The resistivity of Rb shows a behavior similar to that of Cs. The magnetic experimental data indicate that the susceptibility in the region $d > d_c$ can be explained by the Pauli-paramagnetic plus Landau-diamagnetic behavior enhanced by electron correlation effects and, on the other hand, that the susceptibility in the critical region follows the Curie law of localized spin. Therefore, electron–electron correlation effects may be important in the metal-nonmetal transition in Cs.

3.8 Electron Localization

Electron scattering by the random potentials in liquid metals leads to appreciable electrical resistivity and would therefore be expected to affect the electronic structures as well. The effect of the second-order energy shift and width may be included effectively in the self-energy, Eq. (20), by the self-consistent substitution of G for G^0, and the resulting formula is

$$\Sigma_{\mathrm{eff}}(\mathbf{k},E) = \frac{V/N}{(2\pi)^3} \int a(\mathbf{k}-\mathbf{q}) \times \frac{|w(\mathbf{k}-\mathbf{q})|}{E-\epsilon_{\mathbf{q}}-\Sigma_{\mathrm{eff}}(\mathbf{q},E)}\, d^3q. \tag{52}$$

This formula has been solved numerically, using pseudopotentials for Al, Li, Bi, etc. (Ballentine 1966; Chan and Ballentine, 1972). The density of states in these calculations was, more or less, similar to that of the free-electron model with a shallow dip at $k = K_p/2$. On the other hand, recent photoelectron experiments (Indlekofer *et al.*, 1990) show an almost free-electron-like *sp* band in Al and a separation of 6*s* and 6*p* bands in liquid Bi, but a depression of the density of states at $K_p/2$ was not observed. The supercell method was employed for calculating the electronic density of states in liquid Al and Bi, and the results can explain the experimentally observed spectra.

When electrons are scattered by several scattering centers, do wave functions of the electrons still extend over the whole system or do they localize at some specific center? The possibility of localization of the electronic wave function in a random potential field was first pointed out by Anderson in 1958 (Abraham *et al.*, 1979) and is now called Anderson localization (see ELECTRON STATES, LOCALIZED). Anderson localization is essentially due to the interference between a plane wave with wave vector **k** and the backscattered wave with wave vector −**k**. We might say that the electrons in liquids localize as a result of the randomness of the atomic configuration and that the transport in liquid metals occurs through the overlap of electron wave functions localized at each center, i.e., a density-fluctuation–assisted hopping process. However, this is very unlikely because normal metallic electron transport has been observed in amorphous metals whose atomic structure is believed to be just the quenched version of the liquid phase. The dimensionality is quite important in Anderson localization. In three-dimensional metals, even though there might be some localized states, the states at the Fermi energy are usually not localized. Furthermore, in amorphous metals at very low temperatures, phenomena premonitory to localization can be experimentally observed (Cochrane and Strom-Olsen, 1984).

4. FIRST-PRINCIPLES MOLECULAR DYNAMICAL SIMULATION

Computer simulations are a very important means of investigating the static and dynamical structure of liquids. The dynamics of atoms and molecules may be studied by solving the equations of motion. This is called the molecular dynamics method. After storing all data of atomic motions, we can observe or calculate several physical quantities of the model system. Conventional molecular dynamical simulation is based upon empirical interatomic potentials. Electron motions follow the atomic motions very faithfully, and with changing local atomic configurations, the electron wave functions are changed accordingly. It takes a great deal of computational time and effort to simulate atomic dynamics and dynamical effects on the electron wave functions by conventional methods.

Very recently, a new method was developed by Car and Parrinello (1985), wherein the electronic and atomic motions are simultaneously simulated. Usually we calculate the electronic structure in a fixed configuration of the ionic positions $\{\mathbf{R}_n\}$, and the electron charge density $n(\mathbf{r};\{\mathbf{R}_n\})$ is evaluated for this configuration. The new idea treats the electron density $n(\mathbf{r})$ and atomic configuration $\{\mathbf{R}_n\}$ as independent variables so as to find an extremum of the total energy in the extended configurational space $(n(\mathbf{r}),\{\mathbf{R}_n\})$, or more specifically $(\{\psi_i(\mathbf{r})\}, \{\mathbf{R}_n\})$, where $\psi_i(\mathbf{r})$ is the electronic wave function of the state *i*. The basic quantity is the local density functional $E_{\mathrm{LDF}}(\{\psi_i\}, \{\mathbf{R}_n\}, \{\alpha_\nu\})$, which includes the electron kinetic energy and electron–electron, electron–ion, and ion–ion interactions. The parameters α_ν are external constraints imposed on the system such as the volume of the system, symmetry, the thermostat leading the system to a canonical distribution, and so on. The second step of the new idea is the introduction of the Lagrangian

$$L=\sum_i \frac{1}{2}\mu \int d^3r|\dot{\psi}_i|^2+\sum_n \frac{1}{2}M_n|\dot{\mathbf{R}}_n|^2 + \sum_\nu \frac{1}{2}\mu_\nu\dot{\alpha}_\nu^2-E_{\mathrm{LDF}}(\{\psi_i\},\{\mathbf{R}_n\},\{\alpha_\nu\}), \quad (53)$$

with the orthogonalization condition $\int d^3r\psi_i^*\psi_j=\delta_{ij}$. The dot denotes time derivative, M_n is the ion mass, and μ and μ_ν are arbitrary parameters. The first and third terms are fictitious kinetic energies of the electrons and the external constraints. Note that the actual electron kinetic energy is included in the term E_{LDF}. The equations of motion can be derived from the Lagrangian as

$$\mu\ddot{\psi}_i(\mathbf{r},t)=-\frac{\delta E_{\mathrm{LDF}}}{\delta\psi_i^*(\mathbf{r},t)}+\sum_k \Lambda_{ik}\psi_k(\mathbf{r},t),$$

$$M_n\ddot{\mathbf{R}}_n=-\nabla_{\mathbf{R}_n}E_{\mathrm{LDF}},$$

$$\mu_\nu\ddot{\alpha}_\nu=-\frac{\delta E_{\mathrm{LDF}}}{\delta\alpha_\nu}. \quad (54)$$

The Lagrange multipliers Λ_{ik} are introduced because of the orthogonality condition for electron wave functions. The equation of the ionic motion is physical if the electron wave functions are on the Born–Oppenheimer surface, which can be specified by $\min_{(\{\psi_i\}, \{\alpha_\nu\})}E_{\mathrm{LDF}}(\{\psi_i\},\{\mathbf{R}_n\},\{\alpha_\nu\})$. The equations for the other variables $\{\psi_i\}$ and $\{\alpha_\nu\}$ are fictitious. If we successfully reach an equilibrium state for the electronic configuration, $\ddot{\psi}_i=0$, then the wave functions should satisfy the Kohn–Sham equation and be on the Born–Oppenheimer surface. The values of the parameters $\{\mu\}$ and $\{\mu_\nu\}$ should be chosen so that an equation of motion follows a trajectory not far from the Born–Oppenheimer surface.

The (norm-conserving) pseudopotential formalism is usually adopted, because the plane-wave base is very convenient for actual calculations. If we use a local basis set of electron wave functions and the centers of electron wave functions are chosen to coincide with the centers of moving atoms, additional variational forces acting on atoms and electron wave functions appear and create very serious difficulties. Furthermore, the transferability (i.e., transferable to the same ion in different local environments) of the norm-conserving pseudopotential is very desirable for treating a system with fluctuating local environments.

Up to now, several atomic liquids, C, Si, Ge, As, Al, and liquid GaAs have been investigated by this method. A standard supercomputer allows a unit cell size of about 50 atoms with periodic boundary conditions and an energy cutoff of about 10 Ry for the plane-wave expansion. As an example, we summarize the results for liquid Si (Stich *et al.*, 1989). These results show excellent agreement with the observed structure factor. The velocity autocorrelation function shows a bump at a frequency of ~40 meV, which is very close to the optical vibrational frequency of crystalline Si at temperatures just below the melting point. This may imply a persistence of solidlike atomic arrangement in the liquid state. The

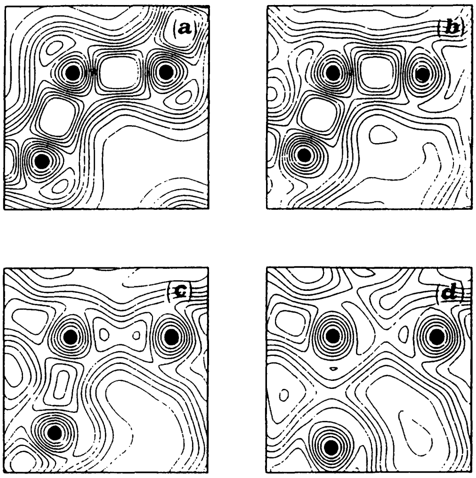

FIG. 9. Valence-charge contours of liquid Si. Black circles are Si atoms. (a) Crystalline Si in the (110) plane, (b)–(d) evolution of charge density in liquid Si at time intervals of ~0.02 ps (Stich *et al.*, 1989).

contour plot of the charge density (Fig. 9) also shows the local valence-bond character remaining in the liquid phase within a period of ~0.02 ps. For larger periods, some bonds start to break and reform. The electronic density of states in the liquid state indicates metallic behavior, and the conductivity calculated by the Kubo formula is estimated to be 0.0175 $(\mu\Omega\ \text{cm})^{-1}$, in good agreement with experimental results.

5. ELECTRON AND ATOMIC STRUCTURE OF WATER

Water is a very unique substance whose properties are determined by hydrogen bonds and their network. The melting and boiling temperatures are much higher than those of many other molecular liquids of similar molecular weight. The heat of evaporation and the heat capacity are very large.

We should also point out that the behavior of nonelectrolyte solutions such as Ar, methane (CH_4), and other nonpolar molecules with C–H base in water is anomalous. The solubility of these molecules is very low because of the hydrophobic bases C–H. The hydrophobic solute molecules have a tendency to come together and attract each other in order to reduce the area touching water molecules. This effective interaction between hydrophobic bases is called a *hydrophobic interaction* or a *solvent-separated hydrophobic pair interaction.* The ordered network of hydrogen bonds is broken in solutions, and the entropy increases. Therefore, the hydrophobic bond is stabilized at higher temperatures. Sometimes, water molecules form a more rigid hydrogen-bonded network (called an *iceberg* model) around a guest molecule (Ar, CH_4) with decreasing entropy. This is called *hydrophobic hydration.*

To understand these interesting properties of water and hydrogen bonds, we must first understand the structure of water molecules and their interactions. The distance between oxygen and hydrogen atoms in a water molecule is 0.09572 nm and the bond angle is 104.52°. The oxygen 2*s* and 2*p* orbitals form sp^3 hybridized orbitals $\phi_O(t_1)$–$\phi_O(t_4)$ as follows:

$$\phi_O(t_i)=\frac{1}{\sqrt{3+v^2}}\{v\phi_O(2s)\pm\phi_O(2p_x)\pm\phi_O(2p_y)\pm\phi_O(2p_z)\}, \tag{55}$$

where $\phi_O(2s)$ and $\phi_O(2p_x)$ are the oxygen 2*s* and $2p_x$ orbitals and v is a mixing parameter [Fig. 10(a)]. Two electrons from two hydrogen atoms and two electrons of the oxygen atom occupy one of the bonding orbitals

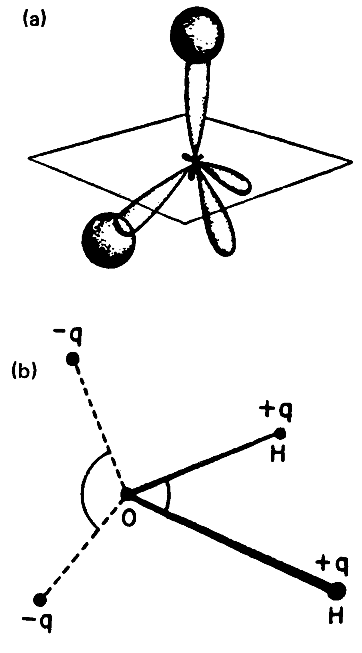

FIG. 10. (a) Extent of sp^3 orbitals of a water molecule; (b) a model structure of a water molecule.

formed by the hydrogen 1*s* orbital and either t_1 or t_2 hybridized orbitals:

$$\psi_1 = \lambda\phi_{H1}(1s) + \mu\phi_O(t_1),$$
$$\psi_2 = \lambda\phi_{H2}(1s) + \mu\phi_O(t_2), \tag{56}$$

where $\phi_{H1}(1s)$ is the 1*s* orbital of hydrogen atom 1. The remaining four valence electrons of the oxygen atom occupy the unbonded t_3 and t_4 orbitals. The bond angle 104.52° can be explained by appropriate values of the mixing parameters ν, λ, and μ and the Coulomb repulsion between electrons.

The symmetrical tetrad of point charges has been adopted as a model structure of the water molecule, based on the above bonding and unbonded orbitals, and this model ensures the existence of the tetrahedrally directed hydrogen bonds. One of the model pair potentials for water molecules is based on a rigid four-point-charge model proposed by Stillinger and Rahman (1974). The geometry involved is shown in Fig. 10(b). The positive charges $+q$ are partially shielded protons, and two negative point charges $-q$ are positioned 0.08 nm away from the oxygen ion. A vector connecting the two negative charges is perpendicular to the H-O-H plane. The water-water interaction consists of the 12-6 Lennard–Jones potential between oxygen atoms and Coulomb interactions of 16 pairs of positive and negative point charges $\pm q$.

Carravetta and Clementi (1984) calculated the electronic structure of water dimers in various geometrical configurations, considering the electron correlation effects, and constructed a revised pair potential. Each water molecule represents two positive charges $+q$ for the protons and one negative charge $-2q$ for the unbonding electrons of the oxygen ion on the bisection lines of the H-O-H bond angle. The new pair potential consists of Coulomb interactions of nine pairs of charges and numerically determined exponential terms between atoms. The correlation effect included by the configuration interaction accounts for about -4×10^3 J mol^{-1} of the total dimerization energy of about $(1.8\text{–}2.3)\times10^4$ J mol^{-1}. The correlation energy has a shallow minimum at the oxygen–oxygen distance of 0.37–0.42 nm. The potential minimum is obtained at the oxygen–oxygen distance of about 0.29 nm.

Several calculations of polymerized water molecules show that the structure of $(H_2O)_n$ is more stable for larger *n*. The pair distribution functions calculated by molecular dynamical simulation are in satisfactory agreement with experimental results, and the calculated short-range structure of water, in regard to the number of near-neighbor molecules ($\simeq$4.4) and the maximum peak position ($\simeq$0.45 nm), is quite similar to that of hexagonal ice.

The molecular dynamical simulation can also give the equation of state. A simulation by Stillinger and Rahman (1974) reproduced the density maximum at 27 °C (experimentally 1.0 g/cm^3 at 4 °C). The calculated velocity correlation function shows a structure of molecular vibrations and implies a persistence of the polymerized structure of a hydrogen-bonded network for a period of the order of 10^{-12} s. It was also suggested that the extent of the hydrogen-bonded network is limited to fewer than eight molecules.

The calculated average interaction energy was reported to be $(-3.9\pm0.02)\times10^4$ J mol^{-1} by Carravetta and Clementi (1984) and, adding the kinetic energy of molecular rotation and translation $3RT$, a total energy of -3.21×10^4 J mol^{-1} was obtained. This is in good agreement with the experimental value of -3.39×10^4 J mol^{-1}. The oxygen–oxygen radial distribution function is in good agreement with the experimental ones.

GLOSSARY

Anderson Localization: Localization due to randomness by means of quantum interference between a wave with wave vector **k** and a backscatter wave with wave vector −**k**.

Born–Oppenheimer Surface: A surface specifying the ground-state configuration and its energy as a function of the *N*-atom configuration $\{\mathbf{R}_n\}$.

Configuration Interaction: Interaction between several electron configurations, which stabilizes a system more than a state specified by a single electron configuration.

Dense Random Packing of Hard Spheres: A structure of densely packed hard spheres, which contains no internal holes large enough to accommodate another sphere and has only weak correlations between positions of spheres with intersphere distances more than five diameters.

Free-Electron Model: A model of free electrons, which is applicable to simple metals, i.e., no external potentials and no electron-electron interactions. A *nearly-free electron model,* starting from the free-electron model, can describe both periodic and aperiodic systems with weak potentials.

Friedel Oscillation: Oscillating electron density around a charged particle in condensed matter, which is due to screening of the charged particle and Pauli's exclusion principle for electrons.

Korringa–Kohn–Rostoker Method: One of the methods of band structure calculations, invented by Korringa, Kohn, and Rostoker and based on a Green's-function formalism of the Schrödinger equation in solids (Ziman, 1971).

Linear Muffin-Tin Orbital Method: A theoretical method for calculating the electronic structure in solids (Andersen, 1975) using energy-linearized partial waves

$$\psi_{\mathbf{R}l}(\mathbf{r}) = \phi_{\mathbf{R}l\nu}(\mathbf{r}) + (E - E_\nu)\dot{\phi}_{\mathbf{R}l\nu}(\mathbf{r}),$$

where $\phi_{\mathbf{R}l\nu}$ is a solution to the radial Schrödinger equation in each spherical potential region of an appropriately chosen energy E_ν and $\dot{\phi}_{\mathbf{R}l\nu}$ is its energy derivative.

Molecular Dynamics: A simulation method for the dynamics of atoms and molecules, obtained by computerized solution of the equations of motion.

Muffin-Tin Potential: Potentials in condensed matter, spherically symmetric inside nonoverlapping spheres at each ion and constant between the spheres.

NMR: Nuclear magnetic resonance, whose resonance frequency gives information about the local magnetic field and relaxation of spin motion to an equilibrium state.

Pair Distribution Function: A distribution function characterizing the atomic arrangement around one atom. Its Fourier transform can be measured by scattering intensity.

Quasiparticle: Low-energy excitation of fermion systems near the Fermi energy, which has a long life-time and behaves as an almost independent particle.

Slater Determinant: A many-electron wave function of the form of an $N_e \times N_e$ determinant:

$$\Psi(\{\mathbf{r}_i\}) = (N_e!)^{-1/2} \times \begin{vmatrix} \phi_a(\mathbf{r}_1) & \phi_a(\mathbf{r}_2) & \cdots & \phi_a(\mathbf{r}_N) \\ \phi_b(\mathbf{r}_1) & \phi_b(\mathbf{r}_2) & \cdots & \phi_b(\mathbf{r}_N) \\ \phi_c(\mathbf{r}_1) & \phi_c(\mathbf{r}_2) & \cdots & \phi_c(\mathbf{r}_N) \\ \cdots & \cdots & \cdots & \cdots \end{vmatrix},$$

which satisfies Pauli's exclusion principle.

***sp*-Electron Metals:** Metals whose valence electrons are of *s* or *p* type, with electron wave functions well approximated by plane waves.

Structure Factor: The Fourier transform of the atomic density function in the bulk.

Tight-Binding Model: A model for the electronic structure of materials, which can be described by localized atomic wave functions and short-range electron hopping between pairs of atoms. This model is an extreme opposite of the nearly free-electron model.

INTRODUCTION

The quantum-mechanical description of electron states in solids has been a goal that has occupied the physics community since the advent of quantum theory. The purpose of this article is to present an overview of the modern theoretical techniques that serve as the basis for such descriptions. The determination of the electron structure of materials is a topic of

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

great importance in condensed-matter physics. In this context, the term *electron structure* refers to the distribution of electrons in space, momentum, and energy (Moruzzi *et al.*, 1978). The field is very broad and highly developed and continues to grow rapidly. Consequently, our presentation is inevitably incomplete, and the interested reader is advised to consult the many excellent references on this subject matter.

Within the one-electron band approximation, the problem of calculating the energy levels and eigenfunctions of electron states in a solid essentially reduces to solving the Schrödinger equation associated with a periodic crystal potential. Consequently, the vast majority of basic theoretical tools necessary to perform such a task were introduced in the 1930s and the 1940s soon after the development of quantum theory. In fact, most of the theoretical methods outlined in this article were formulated before the middle of the century: Bloch proposed the tight-binding method in 1928, the concept of orthogonalized plane waves was formulated by Herring in 1940, the cellular method was introduced by Wigner and Seitz in 1933, the utilization of augmented plane waves was suggested by Slater in 1937, and Green's-function methods were originated by Korringa in 1937. Initial calculations of band structure were performed on the simplest high-symmetry systems and established a proof of principle. However, the advent of high-speed digital computers in the mid-1950s propelled the field of band theory to new levels by allowing workers to perform calculations with large enough basis sets to predict features of the band structure of realistic materials: The first calculation (correctly) predicting the existence of an indirect energy band gap in silicon appeared in the literature in 1954 and was performed with the orthogonalized-plane-wave method (Herman, 1954). Over the following decades, the appearance in the solid-state physics literature of numerous applications of band-structure methods clearly indicates that, to this day, the band-structure problem remains a very timely, exciting, and challenging subfield of condensed-matter theory.

Original applications of band-structure methods relied on empirical developments in which Hamiltonian matrix elements were adjusted to reproduce experimentally observed features of the energy band structures. In most cases, early band-structure calculations did not embody a self-consistency procedure, i.e., the crystal potential was not recalculated, and the effects of electronic rearrangements (screening) arising when isolated atoms are brought together to form the solid were not incorporated. However, with the formulation of density-functional theory in the mid-1960s and the accelerating developments in computer architecture, self-consistent first-principles electron-structure (band structure and total energy) calculations emerged in the early 1970s and are routinely performed nowadays.

Up until the mid-1980s, self-consistent first-principles electron-structure calculations were possible for systems containing at most a few tens of atoms. Moreover, only static configurations of atoms were considered (at zero temperature), and the modeling of highly complex materials (disordered phases, liquids, etc.) was prohibitively expensive. However, recent theoretical developments have led to the formulation of a unified combination of first-principles methods and concepts extracted from molecular-dynamics simulations. This new formulation constitutes one of the latest advances in the field of electron-structure theory and is based on a unified treatment of the electron-structure problem by coupling the local electron structure (bonding, localization, etc.) with the atomic motions at finite temperature. Such *ab initio* molecular-dynamics descriptions allow the determination of the thermodynamical properties of a system from first-principles evaluations of microscopic quantities. By allowing finite-temperature treatment of complex condensed-matter systems, the advantages introduced by these first-principles molecular-dynamics methods will bridge the gap between electron-structure theory and materials science.

The article is organized as follows: In Sec. 1, the language of group theory is introduced for the purpose of presenting theorems that are of central importance in the theory of the electronic structure of solids. The general form of an electron state in a periodic crystal potential is deduced on the basis of symmetry considerations alone. Fundamental properties of the crystal wave functions and of their associated energy eigenvalue spectrum are presented. Important elementary concepts such as energy bands, band gap, band occupation, Fermi level, and density of states are indicated. In Sec. 2, we present the elements of band theory by describing the various theoretical methods used to calculate the energy eigenvalue spectrum and eigenfunctions of electron states in a solid. For presentation purposes, these methods are divided into two approaches: fixed-basis-set and scattering methods. While this classification is certainly not unique and each electronic-structure technique is a method in its own right, it provides a natural distinction between the different classes of methods. Modern first-principles total-energy methods based on density-functional theory are presented in Sec. 3. This theory provides the basis for most first-principles calculations in the area of solid-state physics. We present results of total-energy density-functional calculations to illustrate its predictive power and to compare different implementations of this theory. Finally, in Sec. 4 we describe recent theoretical developments that go beyond static, zero-temperature electron-structure calculations by combining first-principles electron-structure descriptions with approaches and algorithms utilized in molecular-dynamics simulations.

1. PROPERTIES OF ELECTRON STATES IN CRYSTALLINE SOLIDS

1.1 Introduction

The self-consistent calculation of the energy eigenvalues and eigenfunctions of electron states in solids is essentially a many-body problem that can only be solved exactly with the use of many-body stochastic methods. Such methods are outside the scope of this article. Approximations are universally made to reduce this problem to a tractable endeavor and to obtain approximate solutions. However, the symmetry properties of the full many-body Hamiltonian can be used to derive the resulting symmetry properties of the *exact* solutions, even though these solutions are unknown. Group theory (*q.v.*) is the mathematical apparatus that affords such derivations.

The one-electron crystal Hamiltonian we will discuss in this article is of the form

$$H \equiv H(\mathbf{x}) = \frac{-\hbar^2}{2m}\nabla^2 + V(\mathbf{x}), \qquad (1)$$

where $\hbar = 6.5822 \times 10^{-16}$ eV s is Planck's constant and $m = 9.1095 \times 10^{-28}$ g is the free-electron mass. The justification for using the one-electron Hamiltonian H will be presented in the next section. The crystal potential $V(\mathbf{x})$ is invariant under all the symmetry operations that leave the crystal invariant. We assume that the crystal potential $V(\mathbf{x})$ is constructed from a linear superposition of atomic potentials such as shown in Fig. 1, where both the free-atom potentials and the total potential are indicated. The crystal potential is atomiclike in the region near the ions and flattens out in the interstitial regions between the ions.

The purpose of the present section is to indicate how essential results can be derived from the group-theoretical analysis of the crystal Hamiltonian. The language introduced here will serve as the basis for the next section, which describes actual methods of solution. The discussion that follows is necessarily incomplete, and the interested reader is advised to consult standard texts on the applications of group-theoretical methods to quantum mechanics (Tinkham, 1964; Heine, 1960; Hamermesh, 1962). In the next section we justify the utilization of the one-electron Hamiltonian of Eq. (1), and present methods of solutions of Schrödinger's equation associated with the crystal Hamiltonian H.

1.2 Crystal Symmetry: Space Groups

The elements of symmetry relevant to the study of electronic states in crystalline solids include rotations, translations, and reflections. The ensemble of such symmetry oper-

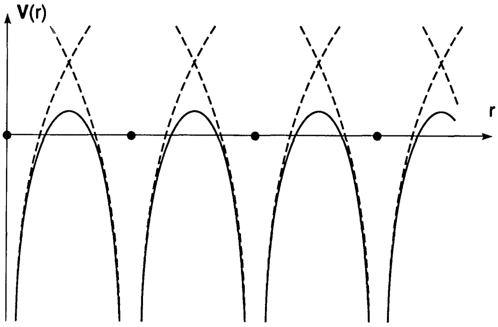

FIG. 1. Schematic representation of the crystal potential plotted along a line of ions (solid circles) in the solid. The crystal potential (solid line) is constructed from the individual ion potential (dashed line).

ations are called *space groups* (see CRYSTALLOGRAPHY). We describe below the essential features of space groups that allow us to derive the form of the crystal eigenfunctions. Such derivations can be found in standard solid-state physics texts (Callaway, 1974; Kittel, 1963; Ashcroft and Mermin, 1976).

An operation of symmetry with respect to the Hamiltonian operator $H(\mathbf{x})$ is defined as a linear transformation of the coordinates

$$\mathbf{x}'=\alpha\mathbf{x}+\mathbf{t}, \tag{2}$$

which leaves the Hamiltonian invariant,

$$H(\mathbf{x}')=H(\alpha\mathbf{x}+\mathbf{t})=H(\mathbf{x}). \tag{3}$$

In Eq. (2), α is a real 3×3 orthogonal (real unitary) matrix representing a (proper or improper) rotation and $\mathbf{t}$ is a translation vector. The symbol $\{\alpha|\mathbf{t}\}$ is used to denote an operator of the space group consisting of a rotation α and a translation $\mathbf{t}$. The unit operator is $\{\epsilon|\mathbf{0}\}$, where ϵ is a unit matrix.

We will not discuss in this article the very important subject of irreducible-representation theory (Tinkham, 1964; Heine, 1960). The basis of representation theory is the representation of a group in terms of matrices. This theory links group theory and quantum mechanics by introducing the concept of basis functions: The wave functions of a quantum system form basis functions for irreducible representations of the group of Schrödinger's equation, i.e., the group of operators which commute with the Hamiltonian, $H(\mathbf{x})$. Essentially, irreducible representation matrices indicate how basis functions transform among themselves under the operations of a group. Irreducible-representation theory can be used to classify the solutions of the Hamiltonian and is of central importance in the determination of the symmetry properties of the electronic states of the crystal: essential degeneracies, selection rules, etc.

The operator representing a pure lattice translation by $\mathbf{R}_j$ is denoted by $\{\epsilon|\mathbf{R}_j\}$, where the index j labels a particular lattice-translation vector. The set of lattice translations forms a group called the *lattice-translation group*. The lattice-translation group is Abelian, i.e., its members commute with each other. The commutativity property of the lattice-translation group implies that the irreducible representations of the lattice-translation group are one dimensional (Tinkham, 1964).

We formally define a space group as a group of operators of the form $\{\alpha|\mathbf{t}\}$ that contains an invariant subgroup of pure translations whose operators are of the form $\{\epsilon|\mathbf{R}_j\}$. In three dimensions, there are 230 possible space groups.

A space group is called symmorphic if the translation part $\mathbf{t}$ of all of the space-group operators $\{\alpha|\mathbf{t}\}$ can be written in the form

$$\mathbf{t}=n_1\mathbf{a}_1+n_2\mathbf{a}_2+n_3\mathbf{a}_3, \quad n_i=\text{integers} \tag{4}$$

where the vectors $\mathbf{a}_1,\mathbf{a}_2,\mathbf{a}_3$ are noncoplanar lattice-translation vectors defining the space lattice. For a symmorphic space group, the set of operators $\{\alpha|\mathbf{0}\}$ that does not involve any translation forms a subgroup of the space group known as the *point group*. Therefore, we can symbolically write the following association:

$$\text{crystal space group} \rightarrow \text{lattice-translation group}+\text{point group}.$$

1.3 Direct and Reciprocal Space: Bravais Lattices and Brillouin Zones

A three-dimensional *Bravais lattice* consists of all points with position vectors $\mathbf{R}_j$ of the form of Eq. (4):

$$\mathbf{R}_j=n_1\mathbf{a}_1+n_2\mathbf{a}_2+n_3\mathbf{a}_3, \quad n_i=\text{integers} \tag{5}$$

where the vectors $\mathbf{a}_i$ are any three vectors not all in the same plane (Ashcroft and Mermin, 1976). The label j identifies a particular set of integers n_1,n_2,n_3. The vectors $\mathbf{a}_i (i=1,2,3)$ are called *primitive-lattice vectors*. The Bravais lattice specifies the periodic array in which the repeated units (atoms, groups of atoms, molecules, etc.) of the crystal are arranged and describes only the geometry of the underlying periodic structure. There are 14 different Bravais lattices in three dimensions. The 14 possible three-dimensional Bravais lattices are listed in Table 1. The Bravais lattices are classified into seven crystallographic systems corresponding to seven types of unit cell: triclinic, monoclinic, orthorhombic, tetragonal, cubic, trigonal, and hexagonal. The second column in Table 1 indicates the number of lattices per system. The third column indicates the axial and angular relations that describe the different cells.

When the lattice-translation vectors $\mathbf{a}_i$ $(i=1,2,3)$ are such that they define a unit cell

Table 1. Fourteen possible three-dimensional Bravais lattices. The Bravais lattices are classified into seven crystallographic systems corresponding to seven types of unit cell: triclinic, monoclinic, orthorhombic, tetragonal, cubic, trigonal, and hexagonal. The second column indicates the number of lattices per system. The third column defines the axial and angular relations that describe the different cells where α is the angle between $\mathbf{a}_2$ and $\mathbf{a}_3$, β is the angle between $\mathbf{a}_3$ and $\mathbf{a}_1$, and γ is the angle between $\mathbf{a}_1$ and $\mathbf{a}_2$.

System	Number of lattices	Restrictions on axes and angles
Triclinic	1	$a_1 \neq a_2 \neq a_3$ $\alpha \neq \beta \neq \gamma$
Monoclinic	2	$a_1 \neq a_2 \neq a_3$ $\alpha = \gamma = 90° \neq \beta$
Orthorhombic	4	$a_1 \neq a_2 \neq a_3$ $\alpha = \beta = \gamma = 90°$
Tetragonal	2	$a_1 = a_2 \neq a_3$ $\alpha = \beta = \gamma = 90°$
Cubic	3	$a_1 = a_2 = a_3$ $\alpha = \beta = \gamma = 90°$
Trigonal	1	$a_1 = a_2 = a_3$ $\alpha = \beta = \gamma < 120°, \neq 90°$
Hexagonal	1	$a_1 = a_2 \neq a_3$ $\alpha = \beta = 90°, \gamma = 120°$

containing exactly one lattice point, the cell is a *minimum-volume cell* and is called a *primitive cell.* A primitive cell is called a *Wigner–Seitz primitive cell* if it has the full symmetry of the Bravais lattice. A primitive cell, when translated through all the vectors $\mathbf{R}_j$ in a Bravais lattice, fills all space without overlapping. The volume of a Bravais lattice primitive cell is

$$\Omega_{\mathbf{x}} = |\mathbf{a}_1 \cdot (\mathbf{a}_2 \times \mathbf{a}_3)|. \tag{6a}$$

Since, by definition, a primitive cell contains a single lattice point, the volume of a primitive cell is

$$\Omega_{\mathbf{x}} = V/N, \tag{6b}$$

where V is the total volume of the crystal and N is the total number of primitive cells (or lattice points) in the crystal.

From the lattice-translation vectors $\mathbf{a}_i$ ($i = 1,2,3$) we define a set of *primitive reciprocal-lattice vectors,*

$$\mathbf{b}_1 = 2\pi \frac{\mathbf{a}_2 \times \mathbf{a}_3}{\mathbf{a}_1 \cdot (\mathbf{a}_2 \times \mathbf{a}_3)}, \tag{7a}$$

$$\mathbf{b}_2 = 2\pi \frac{\mathbf{a}_3 \times \mathbf{a}_1}{\mathbf{a}_1 \cdot (\mathbf{a}_2 \times \mathbf{a}_3)}, \tag{7b}$$

$$\mathbf{b}_3 = 2\pi \frac{\mathbf{a}_1 \times \mathbf{a}_2}{\mathbf{a}_1 \cdot (\mathbf{a}_2 \times \mathbf{a}_3)}. \tag{7c}$$

It can be verified that

$$\mathbf{a}_i \cdot \mathbf{b}_j = 2\pi\delta_{ij}, \tag{7d}$$

where δ_{ij} is the Kronecker delta defined as

$$\delta_{ij} \equiv \begin{cases} 0 & \text{if } i \neq j \\ 1 & \text{if } i = j. \end{cases} \tag{7e}$$

The volume of a reciprocal-lattice primitive cell is

$$\Omega_{\mathbf{k}} = \mathbf{b}_1 \cdot (\mathbf{b}_2 \times \mathbf{b}_3) = \frac{(2\pi)^3}{\Omega_{\mathbf{x}}}, \tag{8}$$

where $\Omega_{\mathbf{x}}$ is the volume of the Bravais-lattice primitive cell given by Eq. (6a).

It is convenient to define a set of *reciprocal-lattice vectors* $\mathbf{G}_i$ such that

$$\exp(i\mathbf{G}_i \cdot \mathbf{R}_j) = 1, \tag{9a}$$

and having solutions

$$\mathbf{G}_i = m_1\mathbf{b}_1 + m_2\mathbf{b}_2 + m_3\mathbf{b}_3, \quad m_j = \text{integers} \tag{9b}$$

where the label i identifies a particular set of integers m_1, m_2, m_3. The set of reciprocal-lattice vectors $\mathbf{G}_i$ generates a Bravais lattice in $\mathbf{k}$ space, just as the set of lattice translation vectors $\mathbf{R}_j$ generates the Bravais lattice of the crystal in $\mathbf{x}$ space. A Wigner–Seitz primitive cell in reciprocal space defined by the $\mathbf{b}_j$ ($j = 1,2,3$) is called the *first Brillouin zone.*

1.3.1 Example: Face-Centered-Cubic Lattice.

We illustrate the above definitions by considering the Bravais lattice and the reciprocal lattice associated with the face-centered-cubic lattice. The face-centered-cubic lattice is shown in Fig. 2(a) (Kittel, 1986) where the filled spheres indicate the lattice points defining the face-centered-cubic lattice and not the atomic coordinates. The symmetric set of primitive lattice-translation vectors for the face-centered-cubic lattice shown in Fig. 2(a) is

$$\mathbf{a}_1=\tfrac{1}{2}a(\hat{\mathbf{y}}+\hat{\mathbf{z}}), \tag{10a}$$

$$\mathbf{a}_2=\tfrac{1}{2}a(\hat{\mathbf{z}}+\hat{\mathbf{x}}), \tag{10b}$$

$$\mathbf{a}_3=\tfrac{1}{2}a(\hat{\mathbf{x}}+\hat{\mathbf{y}}), \tag{10c}$$

where a is the length of the cube edge. The primitive-lattice vectors $\mathbf{a}_1$, $\mathbf{a}_2$, $\mathbf{a}_3$ connect the lattice point at the origin with lattice points at the face centers. The volume of the face-centered-cubic primitive cell is

$$\Omega_x=|\mathbf{a}_1\cdot(\mathbf{a}_2\times\mathbf{a}_3)|=\frac{a^3}{4}\,. \tag{11}$$

Since the primitive cell contains only one lattice point, the number of lattice points per volume is $4/a^3$ in the face-centered-cubic Bravais lattice. The primitive lattice-translation vectors of the lattice reciprocal to the face-centered-cubic lattice are found by using the construction of Eqs. (7):

$$\mathbf{b}_1=(2\pi/a)(-\hat{\mathbf{x}}+\hat{\mathbf{y}}+\hat{\mathbf{z}}), \tag{12a}$$

$$\mathbf{b}_2=(2\pi/a)(\hat{\mathbf{x}}-\hat{\mathbf{y}}+\hat{\mathbf{z}}), \tag{12b}$$

$$\mathbf{b}_3=(2\pi/a)(\hat{\mathbf{x}}+\hat{\mathbf{y}}-\hat{\mathbf{z}}). \tag{12c}$$

The first Brillouin zone of the face-centered-cubic lattice is the truncated octahedron confined by the planes normal to the reciprocal-lattice vectors,

$$\mathbf{G}=(2\pi/a)(\pm\hat{\mathbf{x}}\pm\hat{\mathbf{y}}\pm\hat{\mathbf{z}}), \tag{13}$$

at their midpoints. The corners of the octahedron are cut by the planes that are the perpendicular bisectors of six other reciprocal-lattice vectors,

$$\mathbf{G}=(2\pi/a)(\pm 2\hat{\mathbf{x}}),$$

$$\mathbf{G}=(2\pi/a)(\pm 2\hat{\mathbf{y}}), \tag{14}$$

$$\mathbf{G}=(2\pi/a)(\pm 2\hat{\mathbf{z}}).$$

The first Brillouin zone of the face-centered-cubic lattice is shown in Fig. 2(b) (Kittel, 1986).

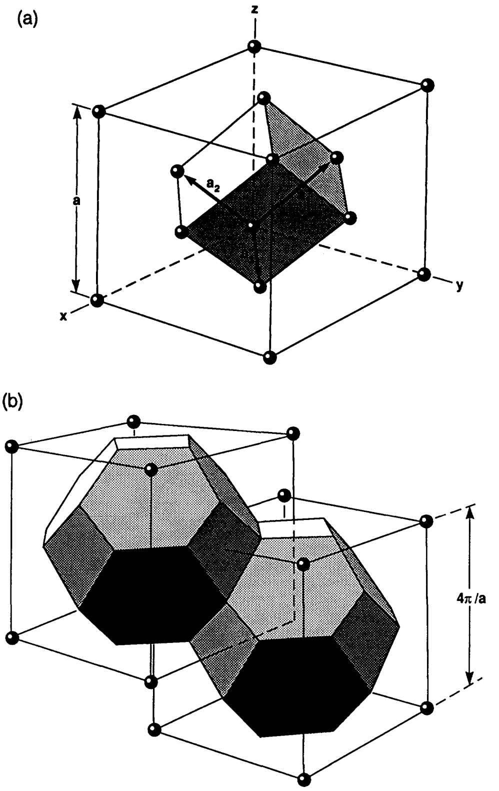

FIG. 2. (a) Primitive basis vectors of the face-centered-cubic lattice. The primitive lattice vectors $\mathbf{a}_1$, $\mathbf{a}_2$, $\mathbf{a}_3$ connect the lattice point at the origin with lattice points at the face centers. The filled spheres indicate the lattice points defining the face-centered-cubic lattice and not atomic coordinates. (b) Brillouin zones of the face-centered-cubic lattice. Two Brillouin zones are shown. (Reproduced with permission from Kittel, 1986, pp. 42 and 43.)

1.3.2 Relation with X-Ray Diffraction by a Crystal.

We now indicate the direct relationship between the construction of the reciprocal space, particularly as described by Eq. (9a), and the condition for constructive interference deduced from the formulation of x-ray diffraction by a crystal (Ashcroft and Mermin, 1976). The condition for constructive interference derived below is closely related to the problem of the scattering of electron at the Brillouin-zone boundary by a weak periodic potential treated in the next section.

When x-ray radiation is scattered from a crystalline solid, intense peaks (known as *Bragg peaks*) are observed for certain sharply defined wavelengths and incident directions. Our purpose is to determine the relationship between the atomic coordinates in the solid and the properties of the incoming x-ray radiation (energy and direction of propagation) giving rise to constructive interference. To determine the condition for constructive interference, we first consider two scatterers separated by a displacement vector **d**. The incoming x ray is incident from very far away and is characterized by a wavelength λ and a wave vector $\mathbf{k}=2\pi\hat{\mathbf{n}}/\lambda$, where $\hat{\mathbf{n}}$ defines the incident direction of propagation. The elastically scattered radiation is observed along the direction $\hat{\mathbf{n}}'$ and is characterized by the same wavelength λ and a wave vector $\mathbf{k}'=2\pi\hat{\mathbf{n}}'/\lambda$. A schematic representation of the geometry is indicated in Fig. 3 and reveals that the path difference between the rays scattered by each of the two ions is

$$d(\cos\theta+\cos\theta')=\mathbf{d}\cdot(\hat{\mathbf{n}}-\hat{\mathbf{n}}'). \tag{15}$$

The condition for constructive interference is that this path difference equals an integral number of wavelengths:

$$\mathbf{d}\cdot(\hat{\mathbf{n}}-\hat{\mathbf{n}}')=m\lambda, \tag{16}$$

where m is an integer. The condition of constructive interference for the wave vectors **k** (incident) and **k**′ (scattered) is found from Eq. (16) by multiplying both sides by $2\pi/\lambda$,

$$\mathbf{d}\cdot(\mathbf{k}-\mathbf{k}')=2\pi m, \tag{17}$$

for integral values of m.

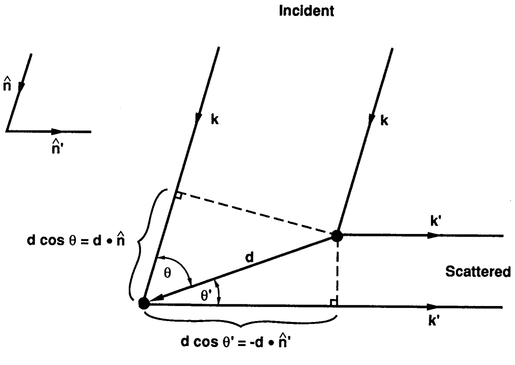

FIG. 3. Geometrical construction indicating that the path difference between incident (**k**) and scattered (**k**′) radiation is given by $d(\cos\theta+\cos\theta')=\mathbf{d}\cdot(\hat{\mathbf{n}}-\hat{\mathbf{n}}')$. (Reproduced with permission from Ashcroft and Mermin, 1976, p. 98.)

We now extend the condition for constructive interference, Eq. (17), to an array of scatterers located at the sites of a Bravais lattice. Since the displacment vectors between the scatterers are simply the Bravais-lattice vectors $\mathbf{R}_j$, the condition that all scattered rays interfere constructively is that the condition Eq. (17) holds simultaneously for all displacement vectors $\mathbf{d} = \mathbf{R}_j$, i.e.,

$$\mathbf{R}_j\cdot(\mathbf{k}-\mathbf{k}')=2\pi m, \tag{18}$$

for integral values of m and all Bravais-lattice vectors $\mathbf{R}_j$. Equation (18) can also be written as

$$\exp[i(\mathbf{k}'-\mathbf{k})\cdot\mathbf{R}_j]=1, \tag{19}$$

for all Bravais-lattice vectors $\mathbf{R}_j$. This relation [Eq. (19)] is called the von Laue condition. A comparison between this condition and the definition of the reciprocal lattice, Eq. (9a), reveals that constructive interference will occur provided that the change of wave vector upon scattering is a reciprocal- lattice vector, $\mathbf{k}-\mathbf{k}'=\mathbf{G}$.

It is somewhat more convenient to use an alternative form of the von Laue condition entirely in terms of the incident wave vector **k**. This is done by noting that the reciprocal lattice is a Bravais lattice and, consequently, if $\mathbf{k}'-\mathbf{k}$ is a reciprocal-lattice vector, so is $\mathbf{k}-\mathbf{k}'=\mathbf{G}$. The condition that the wave vectors **k** and **k**′ have the same magnitude (elastic scattering) is

$$|\mathbf{k}|=|\mathbf{k}'|=|\mathbf{k}-\mathbf{G}|. \tag{20a}$$

Squaring both sides of Eq. (20a) yields,

$$\mathbf{k}\cdot\hat{\mathbf{G}}=\tfrac{1}{2}G, \tag{20b}$$

where $\hat{\mathbf{G}}=\mathbf{G}/G$. Thus an incident wave vector **k** will satisfy the condition for constructive interference if the component of **k** along the reciprocal-lattice vector **G** is half the length of **G** [Eq. (20b)] or, equivalently, if the tip of the vector **k** lies in a plane that is the perpendicular bisector of a line joining the origin of the reciprocal space to a reciprocal-lattice point **G**. Such planes in **k** space are called *Bragg planes*. A realization of this condition is indicated in Fig. 4.

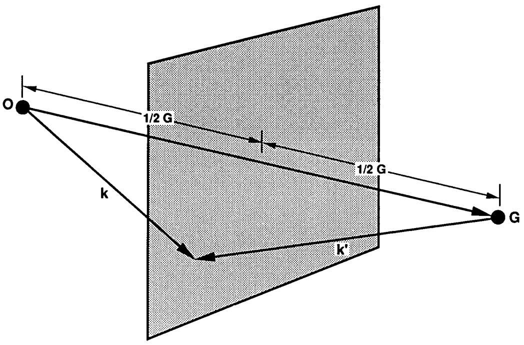

FIG. 4. Schematic representation of the von Laue condition for constructive interference. The conditions $\mathbf{k}-\mathbf{k}'=\mathbf{G}$ and $|\mathbf{k}|=|\mathbf{k}'|$ are simultaneously satisfied when the tip of **k** is equidistant from the origin *O* and the tip of the reciprocal-lattice vector **G**. The wave vector **k** therefore lies in the plane bisecting the line joining the origin *O* and the tip of **G**. Expressed in terms of the incident wave vector **k**, constructive interference occurs when the component of the incident wave vector **k** along the reciprocal-lattice vector **G** is half the length of **G**, or $\mathbf{k}\cdot\hat{\mathbf{G}}=\frac{1}{2}G$. (Reproduced with permission from Ashcroft and Mermin, 1976, p. 99.)

1.4 Form of Electron Solutions in Crystalline Solids: Bloch States

We now provide a derivation of Bloch's theorem, which is a result of central importance in the theory of solids. This result can be obtained by considering irreducible representations of the translation group. Under a pure translation of the form $\{\epsilon|\mathbf{R}_j\}$, the electron wave functions in a crystal must transform according to the irreducible representations of the lattice-translation group. As indicated in Sec. 1.2, the lattice-translation group is Abelian and, consequently, its irreducible representations are one dimensional (Tinkham, 1964). We show below that the one-dimensional irreducible representation of the lattice-translation group are labeled by a wave vector **k**, which classifies the Bloch solutions of the crystal Hamiltonian.

1.4.1 Proof of Bloch's Theorem. The central approximation in the one-electron band approximation is that the state of a solid can be specified by calculating the wave function of each individual electron. Although in principle only the full many-electron wave function is well defined, the one-electron description is a very useful concept. We assume that these one-electron wave functions are solutions of an effective (unspecified) Hamiltonian *H*, which commutes with all the operators $\{\alpha|\mathbf{t}\}$ of the space group (Callaway, 1974),

$$[H,\{\alpha|\mathbf{t}\}]=0, \tag{21}$$

where the commutator of two operators *A* and *B* is defined as $[A,B]\equiv AB-BA$. We define the translation operator

$$T(\mathbf{R}_j)\equiv\{\epsilon|-\mathbf{R}_j\}, \tag{22}$$

and define its action on a wavefunction $\psi(\mathbf{x})$ as

$$T(\mathbf{R}_j)\psi(\mathbf{x})=\psi(\mathbf{x}+\mathbf{R}_j). \tag{23}$$

The operators $T(\mathbf{R}_j)$ commute with each other,

$$[T(\mathbf{R}_j),T(\mathbf{R}_i)]=0, \tag{24a}$$

and with the Hamiltonian *H*,

$$[T(\mathbf{R}_j),H]=0. \tag{24b}$$

As a result, the one-electron wave functions $\psi(\mathbf{x})$ can be chosen to be simultaneously eigenfunctions of the Hamiltonian *H* and of the translation operator $T(\mathbf{R}_j)$ (Sakurai, 1985):

$$T(\mathbf{R}_j)\psi(\mathbf{x})=\psi(\mathbf{x}+\mathbf{R}_j)=\lambda(\mathbf{R}_j)\psi(\mathbf{x}), \tag{25a}$$

$$H\psi(\mathbf{x})=\epsilon_j\psi(\mathbf{x}), \tag{25b}$$

where $\lambda(\mathbf{R}_j)$ is the eigenvalue associated with the translation operator $T(\mathbf{R}_j)$ and ϵ_j is the energy eigenvalue associated with the Hamiltonian *H*. The eigenvalue $\lambda(\mathbf{R}_j)$ describes the action of $T(\mathbf{R}_j)$ on $\psi(\mathbf{x})$ and must be a complex number with unity modulus if we require the (one-dimensional) representation to be unitary, i.e., that the norm of $\psi(\mathbf{x})$ remains invariant under the action of $T(\mathbf{R}_j)$ (Callaway, 1974).

The form of the eigenvalue $\lambda(\mathbf{R}_j)$ can be derived by noting that the successive action of $T(\mathbf{R}_j)$ and $T(\mathbf{R}_i)$ corresponds to a single translation $T(\mathbf{R}_i+\mathbf{R}_j)$,

$$\begin{aligned}T(\mathbf{R}_i)T(\mathbf{R}_j)\psi(\mathbf{x})&=\psi(\mathbf{x}+\mathbf{R}_j+\mathbf{R}_i)\\&=\lambda(\mathbf{R}_j)\lambda(\mathbf{R}_i)\psi(\mathbf{x})\\&=\lambda(\mathbf{R}_j+\mathbf{R}_i)\psi(\mathbf{x}).\end{aligned} \tag{26}$$

It follows that

$$\lambda(\mathbf{R}_j)\lambda(\mathbf{R}_i)=\lambda(\mathbf{R}_j+\mathbf{R}_i). \tag{27}$$

The lattice-translation vector $\mathbf{R}_j$ is of the form of Eq. (5),

$$\mathbf{R}_j=n_1\mathbf{a}_1+n_2\mathbf{a}_2+n_3\mathbf{a}_3,\quad n_i=\text{integers} \tag{28}$$

where the vectors $\mathbf{a}_i$ ($i=1,2,3$) are primitive lattice-translation vectors. The complex eigenvalue $\lambda(\mathbf{R}_j)$ has unit modulus and can be taken to be of the form

$$\lambda(\mathbf{a}_i)=\exp(2\pi i x_i), \quad i=1,2,3. \tag{29}$$

We show below that the numbers x_i are related to a wave vector **k** used to classify the (one-dimensional) irreducible representations of the translation group.

Using the multiplication rule Eq. (27) resulting from successive applications of the translation operator $T(\mathbf{R}_j)$, we deduce

$$\begin{aligned}\lambda(\mathbf{R}_j)&=\lambda(n_1\mathbf{a}_1+n_2\mathbf{a}_2+n_3\mathbf{a}_3)\\&=\lambda(\mathbf{a}_1)^{n_1}\lambda(\mathbf{a}_2)^{n_2}\lambda(\mathbf{a}_3)^{n_3},\end{aligned} \tag{30a}$$

which can be written in the form indicated by Eq. (29),

$$\lambda(\mathbf{R}_j)=\exp(i\mathbf{k}\cdot\mathbf{R}_j), \tag{30b}$$

where **k** is an arbitrary wave vector that is the same for each translation. The eigenvalue $\lambda(\mathbf{R}_j)$ appearing in Eq. (30b) can be written in terms of the reciprocal-lattice primitive vectors $\mathbf{b}_j$ ($j=1,2,3$) as

$$\mathbf{k}=x_1\mathbf{b}_1+x_2\mathbf{b}_2+x_3\mathbf{b}_3, \tag{31}$$

by using the orthonormality relations $\mathbf{a}_i\cdot\mathbf{b}_j = 2\pi\delta_{ij}$. The coefficients x_i specify the allowed values of **k** and are determined by imposing suitable boundary conditions.

The wave vector **k** appearing in Eq. (30b) labels the wave function of an electron in a crystal, which we write as $\psi(\mathbf{k},\mathbf{x})$ and call a *Bloch function*. The energy eigenvalue corresponding to the crystal state $\psi(\mathbf{k},\mathbf{x})$ associated with **k** is denoted by $\epsilon(\mathbf{k})$. Combining Eqs. (25a) and (30b) leads to the formulation of Bloch's theorem:

$$T(\mathbf{R}_j)\psi(\mathbf{k},\mathbf{x})=\psi(\mathbf{k},\mathbf{x}+\mathbf{R}_j)=\exp(i\mathbf{k}\cdot\mathbf{R}_j)\psi(\mathbf{k},\mathbf{x}). \tag{32}$$

In the language of group theory, we say that the wave vector **k** labels the one-dimensional irreducible representations $\exp(i\mathbf{k}\cdot\mathbf{R}_j)$ of the translation group, or

$$\{\epsilon|-\mathbf{R}_j\} \text{ is represented by } \exp(i\mathbf{k}\cdot\mathbf{R}_j). \tag{33}$$

Equation (32) indicates the form of a Bloch state in a crystal and is the central result of this section. The form of Eq. (32) implies that the charge density remains unchanged by a lattice translation $\mathbf{R}_j$, i.e.,

$$|\psi(\mathbf{k},\mathbf{x}+\mathbf{R}_j)|^2=|\psi(\mathbf{k},\mathbf{x})|^2. \tag{34}$$

It is convenient to write the Bloch functions $\psi(\mathbf{k},\mathbf{x})$ as a product of phase factor $\exp(i\mathbf{k}\cdot\mathbf{x})$ and a *cell-periodic function* $u(\mathbf{k},\mathbf{x})$ defined as

$$\psi(\mathbf{k},\mathbf{x})=\exp(i\mathbf{k}\cdot\mathbf{x})u(\mathbf{k},\mathbf{x}), \tag{35a}$$

where the cell-periodic function $u(\mathbf{k},\mathbf{x})$ has the periodicity of the lattice,

$$u(\mathbf{k},\mathbf{x}+\mathbf{R}_j)=u(\mathbf{k},\mathbf{x}). \tag{35b}$$

1.4.2 Allowed Values of k: Periodic Boundary Conditions. We now impose boundary conditions on the wave functions $\psi(\mathbf{k},\mathbf{x})$ to determine the possible values of the wave vector **k** of the form given by Eq. (31). The possible values of **k** are determined by the application of *periodic boundary conditions.*

The lattice translation vector $\mathbf{R}_j$ is of the form of Eq. (5),

$$\mathbf{R}_j=n_1\mathbf{a}_1+n_2\mathbf{a}_2+n_3\mathbf{a}_3, \quad n_i=0,\ldots,N_i, \tag{36}$$

where we assume that the crystal has finite dimensions $N_1\mathbf{a}_1$, $N_2\mathbf{a}_2$, $N_3\mathbf{a}_3$. The integers N_i are large but finite. The total number of primitive cells in the crystal is $N=N_1N_2N_3$. The application of periodic boundary conditions requires that

$$\begin{aligned}&T(N_i\mathbf{a}_i)\psi(\mathbf{k},\mathbf{x})\\&\quad\equiv\psi(\mathbf{k},\mathbf{x}+N_i\mathbf{a}_i)\\&\quad=\psi(\mathbf{k},\mathbf{x}), \quad i=1,2,3.\end{aligned} \tag{37}$$

By application of Bloch's theorem, we deduce

$$\begin{aligned}&\psi(\mathbf{k},\mathbf{x}+N_i\mathbf{a}_i)\\&\quad=\exp[i\mathbf{k}\cdot(N_i\mathbf{a}_i)]\psi(\mathbf{k},\mathbf{x}), \quad i=1,2,3\end{aligned} \tag{38a}$$

which requires that

$$\exp[i\mathbf{k}\cdot(N_i\mathbf{a}_i)]=1, \quad i=1,2,3. \tag{38b}$$

If **k** has the form of Eq. (31), we must have

$$\exp[2\pi i(x_iN_i)]=1, \quad i=1,2,3, \tag{38c}$$

or

$$x_i=m_i/N_i, \quad m_i=0,\ldots,N_i. \tag{38d}$$

It follows that the possible values of **k** allowed by the periodic boundary conditions are of the form

$$\mathbf{k}=\frac{m_1}{N_1}\mathbf{b}_1+\frac{m_2}{N_2}\mathbf{b}_2+\frac{m_3}{N_3}\mathbf{b}_3, \quad m_i=0,\ldots,N_i. \tag{39}$$

Since the integers N_i are very large numbers, the allowed values of **k** are very closely spaced. The volume in **k** space per allowed value of **k** corresponds to the parallelepiped with edges $\mathbf{b}_i/N_i$ $(i=1,2,3)$ defined by Eq. (39) and is given by (Ashcroft and Mermin, 1976)

$$\Delta\mathbf{k}=\frac{\mathbf{b}_1}{N_1}\cdot\left(\frac{\mathbf{b}_2}{N_2}\times\frac{\mathbf{b}_3}{N_3}\right)=\frac{1}{N}\,\mathbf{b}_1\cdot(\mathbf{b}_2\times\mathbf{b}_3)=\frac{\Omega_\mathbf{k}}{N}, \tag{40a}$$

or

$$\Omega_\mathbf{k}=N\Delta\mathbf{k}, \tag{40b}$$

where $\Omega_\mathbf{k}=\mathbf{b}_1\cdot(\mathbf{b}_2\times\mathbf{b}_3)=(2\pi)^3/\Omega_\mathbf{x}$ is the volume of the reciprocal-lattice primitive cell [Eq. (8)] and $N=N_1N_2N_3$. It follows from Eq. (40b) that *the number of allowed wave vectors in the primitive cell of the reciprocal space is equal to the number of lattice sites (or primitive cells) in the crystal.* By combining Eqs. (40a) and (8), the volume per allowed value of **k** can also be written as

$$\Delta\mathbf{k}=\frac{\Omega_\mathbf{k}}{N}=\frac{(2\pi)^3}{N\Omega_\mathbf{x}}=\frac{(2\pi)^3}{V}, \tag{41}$$

where $V=N\Omega_\mathbf{x}$ is the total volume of the crystal and N is the total number of primitive cells in the crystal.

1.5 General Properties of Bloch States and Energy Bands

In this section, we briefly describe the symmetry properties of the crystal Bloch functions $\psi(\mathbf{k},\mathbf{x})$ and of their associated energy eigenvalue spectrum $\epsilon(\mathbf{k})$. We first discuss certain general properties of the Bloch states arising from the form of the crystal Hamiltonian and from Bloch's theorem. We then describe the additional symmetry properties of the crystal Bloch states due to time-reversal symmetry. Most of the discussions which follows can be found in general solid-state physics texts (Kittel, 1963; Ashcroft and Mermin, 1976).

1.5.1 General Properties of Bloch States. We have seen before that the application of Bloch's theorem led to the introduction of a crystal wave vector **k** labeling the Bloch states $\psi(\mathbf{k},\mathbf{x})$, which we write as a product of phase factor $\exp(i\mathbf{k}\cdot\mathbf{x})$ and a cell-periodic function $u(\mathbf{k},\mathbf{x})$,

$$\psi(\mathbf{k},\mathbf{x})=\exp(i\mathbf{k}\cdot\mathbf{x})u(\mathbf{k},\mathbf{x}). \tag{42}$$

The crystal wave vector **k** plays the same role in the description of the motion of an electron in a periodic potential as does the free-electron wave vector $\mathbf{k}_\text{free}$ in describing the motion of a free electron described by a plane wave of the form $\exp(i\mathbf{k}_\text{free}\cdot\mathbf{x})$. In the case of a free electron, the wave vector $\mathbf{k}_\text{free}$ is related to the momentum **p** by $\mathbf{k}_\text{free}=\mathbf{p}/\hbar$. However, for a Bloch state the wave vector **k** is not proportional to the electronic momentum. In fact, it can be directly shown that a Bloch state $\psi(\mathbf{k},\mathbf{x})$ is not an eigenstate of the momentum operator $\mathbf{p}=-i\hbar\nabla$ (Ashcroft and Mermin, 1976),

$$\mathbf{p}\psi(\mathbf{k},\mathbf{x})\equiv\frac{\hbar}{i}\,\nabla[\exp(i\mathbf{k}\cdot\mathbf{x})u(\mathbf{k},\mathbf{x})] \tag{43a}$$

$$=\hbar\mathbf{k}\psi(\mathbf{k},\mathbf{x})+\exp(i\mathbf{k}\cdot\mathbf{x})\frac{\hbar}{i}\,\nabla u(\mathbf{k},\mathbf{x}). \tag{43b}$$

As a natural extension of the free-electron case, however, the quantity $\hbar\mathbf{k}$ is called the *crystal momentum.* The wave vector **k** should be interpreted as a quantum number characterizing the translational symmetry of the crystal potential [or, equivalently, labeling the one-dimensional irreducible representations $\exp(i\mathbf{k}\cdot\mathbf{R}_j)$ of the translation group] just as the momentum **p** is a quantum number characterizing the full translational symmetry of free space (Ashcroft and Mermin, 1976).

Since the crystal wave vector **k** is used as an index (or label) for the Bloch solutions $\psi(\mathbf{k},\mathbf{x})$, it serves as a parameter that enters the crystal Hamiltonian of Eq. (1), i.e., $H\equiv H(\mathbf{k})$. For each value of the parameter **k**, the many possible eigensolutions and eigenenergies of the Schrödinger equation for the crystal are labeled by a *band index n*, and we write

$$\psi(\mathbf{k},\mathbf{x})\rightarrow\psi_n(\mathbf{k},\mathbf{x}), \tag{44a}$$

and

$$\epsilon(\mathbf{k})\rightarrow\epsilon_n(\mathbf{k}). \tag{44b}$$

For a given band index n, the set of energy levels $\epsilon_n(\mathbf{k})$ is called an *energy band.* The *bandwidth* is the energy spread between the minimum and maximum energy in a band n. The energy $\epsilon_n(\mathbf{k})$ is a continuous function of the wave vector, which has the form of Eq.

(39) imposed by the application of cyclic boundary conditions:

$$\mathbf{k}=\frac{m_1}{N_1}\mathbf{b}_1+\frac{m_2}{N_2}\mathbf{b}_2+\frac{m_3}{N_3}\mathbf{b}_3,\quad m_i=0,\ldots,N_i. \tag{45}$$

We now examine the periodic properties of the crystal electronic states and energy levels. For given band n, the energy $\epsilon_n(\mathbf{k})$ associated with a Bloch state $\psi_n(\mathbf{k},\mathbf{x})$ is periodic in reciprocal space, i.e.,

$$\epsilon_n(\mathbf{k}+\mathbf{G})=\epsilon_n(\mathbf{k}), \tag{46}$$

where $\mathbf{G}$ is a reciprocal-lattice vector of the form of Eq. (9b). The periodicity of the function $\epsilon(\mathbf{k})$ can be demonstrated by writing a Bloch state $\psi(\mathbf{k},\mathbf{x})$ in the form (Kittel, 1963)

$$\psi_n(\mathbf{k},\mathbf{x})=\exp(i\mathbf{k}\cdot\mathbf{x})u_n(\mathbf{k},\mathbf{x}) \tag{47a}$$

$$=\exp[i(\mathbf{k}+\mathbf{G})\cdot\mathbf{x}]\times[\exp(-i\mathbf{G}\cdot\mathbf{x})u_n(\mathbf{k},\mathbf{x})] \tag{47b}$$

$$=\exp[i(\mathbf{k}+\mathbf{G})\cdot\mathbf{x}]\times u_n(\mathbf{k}+\mathbf{G},\mathbf{x}) \tag{47c}$$

$$\equiv\psi_n(\mathbf{k}+\mathbf{G},\mathbf{x}) \tag{47d}$$

where the cell-periodic function defined as

$$u_n(\mathbf{k}+\mathbf{G},\mathbf{x})\equiv\exp(-i\mathbf{G}\cdot\mathbf{x})u_n(\mathbf{k},\mathbf{x}) \tag{48}$$

has the periodicity of the direct lattice since

$$\exp(i\mathbf{G}\cdot\mathbf{R})=1, \tag{49}$$

for all reciprocal-lattice vectors $\mathbf{G}$ and lattice-translation vectors $\mathbf{R}$. From the fact that $\psi_n(\mathbf{k}+\mathbf{G},\mathbf{x})$ can be constructed from $\psi_n(\mathbf{k},\mathbf{x})$, one deduces that $\epsilon_n(\mathbf{k}+\mathbf{G})=\epsilon_n(\mathbf{k})$. The periodicity of the energy eigenvalue $\epsilon_n(\mathbf{k})$ implies that the wave vector $\mathbf{k}$ introduced in Bloch's theorem can be chosen to lie in the first Brillouin zone since a wave vector $\mathbf{k}'$ not lying in the first Brillouin zone can be translated back within the first Brillouin zone by a reciprocal-lattice vector $\mathbf{G}$,

$$\mathbf{k}'=\mathbf{k}+\mathbf{G}, \tag{50}$$

where the wave vector $\mathbf{k}$ lies within the first Brillouin zone.

From the above discussion, we see that the *electronic band structure* of a crystalline solid is described in terms of a family of energy band functions $\{\epsilon_n(\mathbf{k})\}$ that are continuous in the wave-vector parameter $\mathbf{k}$ and periodic with the periodicity of the reciprocal space. We state without proof that the mean velocity $\mathbf{v}_n(\mathbf{k})$ of an electron associated with a band n at a wave vector $\mathbf{k}$ is proportional to the derivative of the energy function $\epsilon_n(\mathbf{k})$ with respect to $\mathbf{k}$ (Ashcroft and Mermin, 1976),

$$\mathbf{v}_n(\mathbf{k})=\frac{1}{\hbar}\left(\frac{\partial\epsilon_n(\mathbf{k})}{\partial\mathbf{k}}\right)\equiv\frac{1}{\hbar}\nabla_{\mathbf{k}}\epsilon_n(\mathbf{k}). \tag{51}$$

1.5.2 Energy Bands and Energy-Band Gap. Having described in somewhat general terms the mathematical properties of the crystal Bloch states $\psi_n(\mathbf{k},\mathbf{x})$ and their associated energy bands $\epsilon_n(\mathbf{k})$, we now use a simple physical picture to discuss how these quantities determine the electronic properties of a solid. The discussion which follows is qualitative and can be found, in one form or another, in general solid-state physics texts (Kittel, 1986; Ashcroft and Mermin, 1976).

We have seen that the solutions to the one-electron crystal Hamiltonian, Eq. (1), are the Bloch functions $\psi(\mathbf{k},\mathbf{x})$ of the form given by Eq. (42) and associated with the energy eigenvalue $\epsilon(\mathbf{k})$. Consequently, we can write the crystal Schrödinger equation in the form

$$[-(\hbar^2/2m)\nabla^2+V(\mathbf{x})]\psi_n(\mathbf{k},\mathbf{x})=\epsilon_n(\mathbf{k})\psi_n(\mathbf{k},\mathbf{x}), \tag{52}$$

where, as in Eqs. (44), we have classified the crystal eigenfunctions $\psi_n(\mathbf{k},\mathbf{x})$ and the eigenvalues $\epsilon_n(\mathbf{k})$ according to the band index n for a given value of the crystal wave vector $\mathbf{k}$. The single most important feature of Eq. (52) is that it leads to two classes of solutions depending on whether the Bloch state $\psi_n(\mathbf{k},\mathbf{x})$ has a propagating or evanescent character. For a fixed (real) value of the energy $\epsilon_n(\mathbf{k})$, a propagating Bloch state corresponds to a real value of the crystal wave vector $\mathbf{k}$, whereas an evanescent solution is associated with a complex value of $\mathbf{k}$. As a result, the energy eigenvalue spectrum $\epsilon_n(\mathbf{k})$ consists of sets of energy bands supporting wavelike (real values of $\mathbf{k}$) Bloch states, separated by forbidden energy regions, where the solutions are evanescent (complex values of $\mathbf{k}$) and do not propagate throughout the solid. This feature is the single most important effect arising from the presence of the periodic crystal potential $V(\mathbf{x})$ in Eq. (52). The magnitude of these forbidden energy regions separating the energy bands is of decisive importance in determining whether the solid is a metal, semiconductor, or insulator. This classification is discussed below.

We now illustrate the concept of energy bands and the physical origin of the band gap. We have seen that Bragg reflection is a characteristic feature of wave propagation in crystals. Bragg reflection of electron waves in crystals is the cause of energy gaps since, as we show below, wavelike solutions of the Schrödinger equation do not exist at Bragg reflection. This property can be most directly demonstrated by introducing the *nearly-free-electron model* (Kittel, 1986; Ashcroft and Mermin, 1976), in which we consider the effect of the crystal potential $V(\mathbf{x})$ on the otherwise free-electron solutions. For the free-electron Hamiltonian, we have $V(\mathbf{x}) \equiv 0$, and the solutions are plane waves,

$$\psi(\mathbf{k},\mathbf{x}) \sim \exp(i\mathbf{k}\cdot\mathbf{x}), \tag{53a}$$

corresponding to the free-electron energy,

$$\epsilon(\mathbf{k}) = (\hbar^2/2m)\mathbf{k}^2. \tag{53b}$$

Now consider the effect of a weak periodic potential $V(\mathbf{x})$ on the free-electron solutions. For simplicity we assume a one-dimensional model describing a linear solid of lattice constant a. The first Brillouin zone consists of the region $-\pi/a < k < \pi/a$, and the set of one-dimensional reciprocal-lattice vectors is of the form

$$G = n(2\pi/a), \quad n = \text{integer}. \tag{54}$$

Since the one-dimensional potential is periodic with the periodicity of the lattice,

$$V(x) = V(x+a), \tag{55}$$

a Fourier expansion of $V(x)$ will only contain Fourier components associated with the reciprocal-lattice vectors G,

$$V(x) = \sum_G V(G)\exp(iGx). \tag{56}$$

Consequently, the potential $V(x)$ can only admix Bloch solutions $\psi(k,x)$ whose values of k differ by a multiple of G. In the language of elastic scattering theory in a periodic potential introduced in Sec. 1.3.2, this phenomenon is described by saying that electrons are *Bragg reflected* when their wave vector $\mathbf{k}$ satisfies the condition for constructive interference [Eq. (20b)] (Kittel, 1986),

$$\mathbf{k}\cdot\hat{\mathbf{G}} = \tfrac{1}{2}G. \tag{57}$$

In one dimension, Bragg reflections occur at values of k given by

$$k = \pm\tfrac{1}{2}G = n(\pi/a), \quad n = \text{integer}. \tag{58}$$

The first Bragg reflection occurs at $k = \pm\pi/a$ and arises because the electron reflected from one atom in the linear lattice interferes constructively with a phase difference of 2π with the electron reflected from a nearest-neighbor atom. As a result, the first *energy gap* E_g opens up at $k \pm (\pi/a)$ and is due to the admixture of the free-electron solutions by the Fourier component of the periodic potential $V(\frac{1}{2}G)$ at the Brillouin-zone boundary. The magnitude of the energy gap can be shown (Ashcroft and Mermin, 1976) to be equal to the magnitude of the admixing Fourier component of the potential, $E_g = |V(\frac{1}{2}G)|$. Other energy gaps occur at other values of the integer n in Eq. (58). The opening of a gap in a free-electron spectrum due to a periodic potential is schematically indicated in Fig. 5.

We now discuss the physical origin of the energy gap. At the values $k = \pm\pi/a$, the solutions correspond to equal admixture of waves

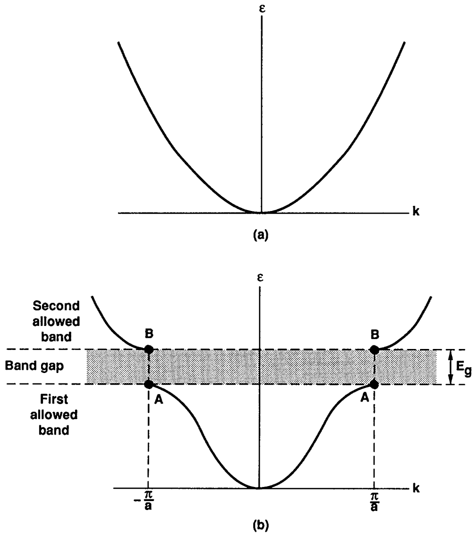

FIG. 5. (a) Parabolic dispersion relation between the energy ϵ and the wave vector k for a free electron, $\epsilon(k) \sim k^2$. (b) Dispersion relation between the energy ϵ and the wave vector k for an electron in a monoatomic linear lattice of lattice constant a. The energy gap E_g separating the first and second allowed energy bands is associated with the first Bragg reflection at $k = \pm\pi/a$. Other gaps are found at higher energies of $k = \pm n\pi/a$, where n is an integer. (Reproduced with permission from Kittel, 1986, p. 161.)

traveling to the right and to the left because the direction of travel is reversed upon each Bragg reflection (Kittel, 1986). We construct symmetric and antisymmetric standing-wave solutions at $k=\pm\pi/a$ from the plane waves $\exp[\pm i(\pi/a)x]$ as follows:

$$\psi^{(+)}(k_0,x)=\exp(ik_0x)+\exp(-ik_0x)$$
$$=2\cos(k_0x), \qquad (59a)$$

$$\psi^{(-)}(k_0,x)=\exp(ik_0x)-\exp(-ik_0x)$$
$$=2i\sin(k_0x), \qquad (59b)$$

where $k_0=\pi/a$. The standing-wave solution $\psi^{(+)}(k_0,x)$ is even under space inversion, whereas the standing-wave solution $\psi^{(-)}(k_0,x)$ is odd under space inversion.

We can now understand the physical origin of the energy gap by considering a simple electrostatic argument based on the electronic charge distribution generated by the symmetric and antisymmetric standing-wave solutions $\psi^{(+)}(k_0,x)$ and $\psi^{(-)}(k_0,x)$, respectively, at the Brillouin-zone boundary compared to the charge density associated with the free-electron solution. The electronic charge density arising from a free-electron solution is simply a constant independent of position,

$$n_0=|\exp(\pm ik_0x)|^2=1. \qquad (60a)$$

However, the symmetric standing-wave solution gives rise to an electronic charge density

$$n^{(+)}(x)=|\psi^{(+)}(k_0,x)|^2\sim\cos^2[(\pi/a)x], \qquad (60b)$$

which concentrates negative charge *on* the lattice sites occupied by the positive ion cores where the potential energy (electron scale) is lowest. The antisymmetric standing-wave solution gives rise to an electronic charge density

$$n^{(-)}(x)=|\psi^{(-)}(k_0,x)|^2\sim\sin^2[(\pi/a)x], \qquad (60c)$$

which concentrates negative charge midway *between* the lattice sites occupied by the positive ion cores. Sometimes the two linear combinations of Eqs. (59) are called s-like ($|\psi^{(+)}|^2\sim\cos^2[(\pi/a)x]$) or p-like ($|\psi^{(-)}|^2\sim\sin^2[(\pi/a)x]$). The s-like combination is maximum at the ion-core site, like an atomic s orbital. On the other hand, the p-like combination vanishes as the square of the distance from the ion site for small distances, like an atomic p orbital. The one-dimensional electron charge densities n_0, $n^{(+)}(x)$, and $n^{(-)}(x)$ are illustrated in Fig. 6 along the linear lattice formed by the ion cores.

Because of the attractive electron–ion interaction, a calculation of the average electrostatic energy indicates that the potential energy associated with the charge distribution $n^{(+)}(x)$ is lower than that associated with n_0, whereas the potential energy associated with the charge distribution $n^{(-)}(x)$ is higher than that associated with n_0. Consequently, $n^{(+)}(x)$ lowers the energy in comparison with the average potential energy "seen" by a free-electron wave, and $n^{(-)}(x)$ raises the energy in comparison with the average potential energy "seen" by a free-electron wave. The energy gap E_g is related to the energy difference between the charge distributions $n^{(-)}(x)$ and $n^{(+)}(x)$. In the case where $V(\frac{1}{2}G)<0$, the crystal wave function just ***below*** the energy gap at points A in Fig. 5(b) is the symmetric standing-wave combination $\psi^{(+)}(k_0,x)$, and the crystal wave function just ***above*** the energy gap at points B in Fig. 5(b) is the antisymmetric standing-wave combination $\psi^{(-)}(k_0,x)$.

1.5.3 Band Occupation, Fermi Surface, and Density of States.

Having schematically indicated the effect of a periodic poten-

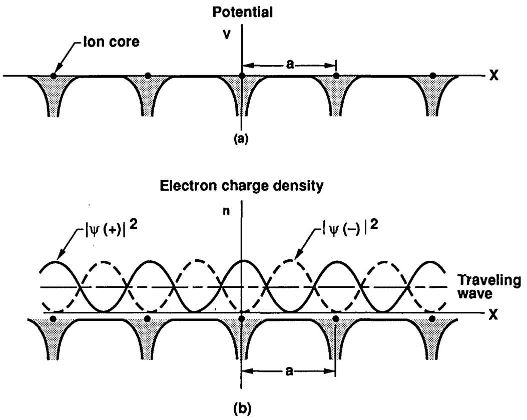

FIG. 6. (a) Variation of the potential "seen" by a conduction electron in the field of the ion cores of a linear lattice of lattice constant a. (b) Electron charge density $n(x)$ in the linear lattice for three cases: $n^{(+)}=|\psi^{(+)}|^2\sim\cos^2[(\pi/a)x]$, $n^{(-)}=|\psi^{(-)}|^2\sim\sin^2[(\pi/a)x]$ and the free-electron case $|\psi^{(0)}|^2=1$. (Reproduced with permission from Kittel, 1986, p. 162.)

tial on the free-electron solutions and energy spectrum and having given a simple physical interpretation of the concepts of energy bands and band gaps, we now turn to the important question of determining the filling of the energy bands by one-electron states. This question is central in deciding whether the solid is a metal or an insulator.

The concept of band occupation leads naturally to a discussion of Fermi level and density of states. Consider the ground state of N Bloch states. Since the energies $\epsilon_n(\mathbf{k})$ are periodic in the reciprocal space, i.e., $\epsilon_n(\mathbf{k} + \mathbf{G}) = \epsilon_n(\mathbf{k})$, we restrict the wave vector $\mathbf{k}$ to lie within the first Brillouin zone to enumerate the energy levels only once. This procedure is completely sufficient to describe the electronic band structure of the crystal.

The filling of the one-electron levels $\epsilon_n(\mathbf{k})$ determines, to a large extent, the general electronic properties of the solid. We have seen above that the number of allowed wave vectors $\mathbf{k}$ in the primitive cell of the reciprocal space is equal to the number of primitive cells in the crystal. The volume per allowed value of $\mathbf{k}$ is given by Eq. (41) as $\Delta\mathbf{k}=(2\pi)^3/V$, where V is the total volume of the crystal. As a result, the number of levels $\epsilon_n(\mathbf{k})$ in a band n is equal to the number of primitive cells N in the crystal. Since each level $\epsilon_n(\mathbf{k})$ can accommodate two electrons (one electron per spin), an energy band contains $2N$ accessible states. An energy band can either be completely or partially filled depending on the number of electrons per primitive cell. We distinguish these two important cases (Ashcroft and Mermin, 1976):

1. In certain cases, some energy bands are completely filled and all the other bands are completely empty [Fig. 7(a)]. Filled bands are sometimes referred to as *valence bands* and empty bands are called *conduction bands*. As illustrated in the previous section, the energy band gap E_g is defined as the energy difference between the lowest empty band and the highest filled band. If the band gap E_g is much larger than k_BT at room temperature ($k_B=1.3807\times10^{-23}$ J K^{-1} is Boltzmann's constant), the solid is called an *insulator*. If the band gap E_g is of the order of k_BT at room temperature, the solid is called a *semiconductor*. Since an energy band can accommodate $2N$ electrons, a band gap can arise only if the number of electrons per primitive cell is even. However, a crystal with an even number of electrons per primitive cell does not guarantee the existence of a band gap since certain energy bands may overlap in energy and, instead of one completely filled band, one has two partially filled bands and the solid is a *semimetal* [Fig. 7(b)]. The band overlap need not occur along the

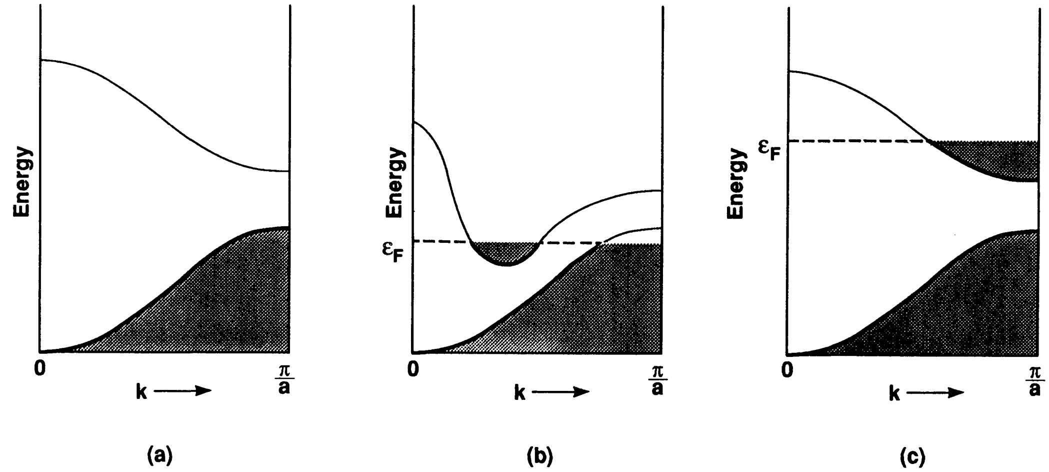

FIG. 7. The occupation of the energy bands of a solid by electrons determines its insulating or metallic behavior. (a) In an *insulator* or *semiconductor*, completely filled bands are separated from completely empty bands by an energy gap E_g. (b) In a *semimetal*, energy bands overlap in energy yielding two partially filled bands. The band overlap need not occur along the same $\mathbf{k}$ direction in the Brillouin zone. (c) In a *metal*, the topmost band is partially filled. The highest occupied state is called the *Fermi level*, ϵ_F, and lies within the energy range of one or more bands. Portions of energy bands which are filled are shaded. (Reproduced with permission from Kittel, 1986, p. 178.)

same **k** direction in the Brillouin zone.

2. In certain cases, some energy bands are partially filled. In this situation, the solid is a *metal* [Fig. 7(c)]. The highest occupied state is called the *Fermi level* ϵ_F and lies within the energy range of one or more bands. The *Fermi surface* is the surface of constant energy ϵ_F in **k** space. At absolute zero temperature, the Fermi surface separates the filled and empty levels. The branch of the Fermi surface in the band n is defined as

$$\epsilon_n(\mathbf{k}) = \epsilon_F. \tag{61}$$

A schematic representation of the above classification based on the filling of the energy levels of a solid is indicated in Fig. 7 where it is shown how the occupation of the energy bands of a solid by electrons determines its insulating, semimetallic, or metallic behavior.

The concept of *density of states* is used to enumerate the number of allowed states in a given energy range. The density of states $g_n(\epsilon)$ associated with the band n is a quantity defined such that the product $g_n(\epsilon)d\epsilon$ is equal to the number of allowed states in the band n in the energy range between ϵ and $\epsilon+d\epsilon$ per unit volume. The number of allowed states associated with the band in the energy range between ϵ and $\epsilon+d\epsilon$ is twice the volume of **k** space with $\epsilon \leqslant \epsilon_n(\mathbf{k}) \leqslant \epsilon+d\epsilon$ divided by the volume per allowed wave vector, $\Delta\mathbf{k} = (2\pi)^3/V$. Consequently, the density of states associated with the band n is (Ashcroft and Mermin, 1976)

$$\begin{aligned} g_n(\epsilon) &= \frac{2}{V}\frac{V}{(2\pi)^3}\int d^3k\, \delta^3(\epsilon-\epsilon_n(\mathbf{k})) \\ &= \frac{1}{4\pi^3}\int d^3k\, \delta^3(\epsilon-\epsilon_n(\mathbf{k})). \end{aligned} \tag{62}$$

The factor 2 arises since there are two accessible states per allowed wave vector **k**.

The integration over the volume in **k** space appearing in Eq. (62) can be transformed using the following property of δ distributions in one dimension (Bassani and Pastori Parravicini, 1975):

$$\int_a^b dx\, g(x)\delta(f(x)) = \sum_{x_0} g(x_0)\left(\left|\frac{df}{dx}\right|_{x_0}\right)^{-1}, \tag{63}$$

where x_0 are the zeroes of the function $f(x)$ on the interval (a,b). Using the property Eq. (63) in the definition Eq. (62), we obtain

$$g_n(\epsilon) = \frac{1}{4\pi^3}\int_{\epsilon=\epsilon_n(\mathbf{k})} dS_n \frac{1}{|\nabla_\mathbf{k}\epsilon_n(\mathbf{k})|}, \tag{64}$$

where dS_n is an element of surface in **k** space on the surface defined by the equation $\epsilon = \epsilon_n(\mathbf{k})$. Equation (64) gives an explicit relation between the energy eigenvalue spectrum $\epsilon_n(\mathbf{k})$ and the density of states $g_n(\epsilon)$. The total density of states is the sum of the contributions from all the bands,

$$g(\epsilon) = \sum_n g_n(\epsilon). \tag{65}$$

We now discuss some features of the density of states $g(\epsilon)$ related to the energy eigenvalue spectrum $\epsilon_n(\mathbf{k})$ (Kittel, 1963). The function $\epsilon_n(\mathbf{k})$ is periodic in reciprocal space [Eq. (46)]. Any function of more than one independent variable that is periodic in all its variables, such as $\epsilon_n(\mathbf{k})$, exhibits saddle points (van Hove, 1953). The number of saddle points depends only on the number of independent variables and is determined by topological considerations. Saddle points in the function $\epsilon_n(\mathbf{k})$ generally lead to singularities in the density of states $g(\epsilon)$. For example, in two dimensions the singularity in $g(\epsilon)$ is logarithmic, whereas in three dimensions the density of states $g(\epsilon)$ is continuous but the energy derivative $dg(\epsilon)/d\epsilon$ has an infinite discontinuity. These singularities are called *van Hove singularities* and they occur at values of ϵ on the constant-energy surface $\epsilon = \epsilon_n(\mathbf{k})$ for which the velocity vanishes, i.e., $\nabla_\mathbf{k}\epsilon_n(\mathbf{k}) = \mathbf{0}$. A characteristic profile of the density of states $g_n(\epsilon)$ associated with a band n is represented in Fig. 8. The density of states shown in Fig. 8 exhibits van Hove singularities where the density of states $g(\epsilon)$ is continuous but the energy derivative $dg(\epsilon)/d\epsilon$ has an infinite discontinuity.

1.5.4 Time-Reversal Symmetry. The Bloch solutions have symmetry properties other than those imposed by the space group of the crystal. These symmetries give rise to degeneracies in addition to those introduced by the space group of the crystal. One such important symmetry is *time-reversal symmetry*. We now briefly describe the consequences

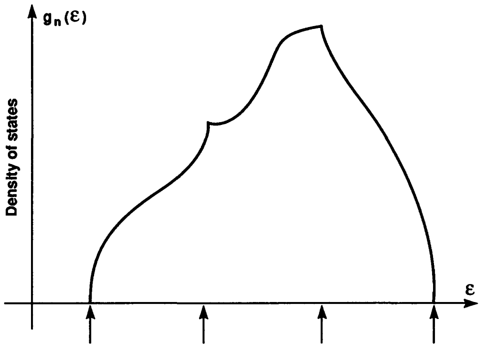

FIG. 8. Characteristic profile of the density of state $g_n(\epsilon)$ associated with the band n. van Hove singularities occur at values of the energy ϵ on the constant- energy surface $\epsilon=\epsilon_n(\mathbf{k})$ for which the velocity vanishes, i.e., $\nabla_{\mathbf{k}}\epsilon_n(\mathbf{k})=\mathbf{0}$. At these singularities, the density of states $g(\epsilon)$ is continuous but the energy derivative $dg(\epsilon)/d\epsilon$ has an infinite discontinuity. (Reproduced with permission from Ashcroft and Mermin, 1976, p. 145.)

of time-reversal symmetry in quantum mechanics (Bassani and Pastori Parravicini, 1975).

In quantum mechanics, the state of a system is specified by a wave function $\psi(\mathbf{x},t)$ whose evolution in time is determined by the time-dependent Schrödinger equation

$$H(\mathbf{x},\mathbf{p})\psi(\mathbf{x},t)=i\hbar\frac{\partial}{\partial t}\psi(\mathbf{x},t), \tag{66}$$

where $\mathbf{p}=-i\hbar\nabla$ is the momentum operator. We now perform the transformation $t\rightarrow -t$ and take the complex conjugate of Eq. (66):

$$H(\mathbf{x},-\mathbf{p})\psi^*(\mathbf{x},-t)=i\hbar\frac{\partial}{\partial t}\psi^*(\mathbf{x},-t). \tag{67}$$

In an isolated system without a magnetic field, we have $H(\mathbf{x},-\mathbf{p})=H(\mathbf{x},\mathbf{p})$, and consequently Eqs. (66) and (67) indicate that if $\psi(\mathbf{x},t)$ describes the evolution of a state, then $\psi^*(\mathbf{x},-t)$ also describes the evolution of a complex-conjugate state in reversed chronological order. If we ignore spin, the state $\psi^*(\mathbf{x})$ is called the *time-reversed conjugate* of $\psi(\mathbf{x})$. Therefore, for a spinless particle, the time-reversal operator K_0 transforms a state function $\psi(\mathbf{x})$ into its complex conjugate $\psi^*(\mathbf{x})$,

$$K_0\psi(\mathbf{x})=\psi^*(\mathbf{x}). \tag{68}$$

When spin is considered, a commonly used form for the time-reversal operator K is

$$K\equiv -i\sigma_2K_0, \tag{69}$$

where σ_2 is one of the Pauli spin operator matrices defined as

$$\sigma=\hat{\mathbf{x}}\sigma_1+\hat{\mathbf{y}}\sigma_2+\hat{\mathbf{z}}\sigma_3, \tag{70a}$$

where

$$\sigma_1=\begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix},\quad \sigma_2=\begin{pmatrix}0 & -i\\ i & 0\end{pmatrix},$$

$$\sigma_3=\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}, \tag{70b}$$

for quantization of the electron spin along the $\hat{\mathbf{z}}$ direction.

The time-reversal operator K obeys the following commutation rules (Kittel, 1963):

$$K\mathbf{x}K^{-1}=\mathbf{x}, \tag{71a}$$

$$K\mathbf{p}K^{-1}=-\mathbf{p}, \tag{71b}$$

$$K\sigma K^{-1}=-\sigma, \tag{71c}$$

and commutes with the Hamiltonian,

$$[K,H]=0. \tag{71d}$$

Kramers's theorem states that, in the absence of an external magnetic field, if ψ is a one-electron eigenstate of H, then $K\psi$ is also an eigenstate of H belonging to the same energy eigenvalue. Moreover, the degenerate eigenstates ψ and $K\psi$ are orthogonal to each other.

The form of K given by Eq. (69), although widely used, is not unique and can be chosen on the basis that it satisfies the commutation rules given by Eqs. (71) and that the application of the time-reversal operator twice to a wave function must produce a state physically indistinguishable from the original state (Callaway, 1974). The latter condition implies that the only permissible effect of the double application of K would be the introduction of a phase factor $\exp(i\theta)$. It can further be shown that this phase factor can only be ± 1 (Wigner, 1959). Thus

$$K^2=\pm I, \tag{72}$$

where I is the identity. The particular form for K given by Eq. (69) yields the $+$ sign in Eq. (72). Other equally valid forms do not include the factor $-i$ appearing in our definition of K (Callaway, 1974).

We now consider the additional degeneracies of the crystal Bloch states introduced by time-reversal symmetry. Consider a Bloch state $\psi(\mathbf{k},\uparrow)$ of the form

$$\psi(\mathbf{k},\uparrow)=\exp(i\mathbf{k}\cdot\mathbf{x})u(\mathbf{k},\mathbf{x};\uparrow), \tag{73}$$

where ↑ indicates the direction of the spin. It can be shown that the action of the time-reversal operator K on $\psi(\mathbf{k},\uparrow)$ is

$$K\psi(\mathbf{k},\uparrow)=\psi(-\mathbf{k},\downarrow), \tag{74}$$

to within a phase factor. Therefore, the states $\psi(\mathbf{k},\uparrow)$ and $\psi(\mathbf{k},\downarrow)$ are associated with the wave vector **k**, and the time-reversed states $K\psi(\mathbf{k},\uparrow)$ and $K\psi(\mathbf{k},\downarrow)$ are associated with the wave vector $-\mathbf{k}$. From Kramers's theorem, it follows that the energies occur twice,

$$\epsilon(\mathbf{k};\uparrow)=\epsilon(-\mathbf{k};\downarrow),\quad \epsilon(\mathbf{k};\downarrow)=\epsilon(-\mathbf{k};\uparrow), \tag{75}$$

which implies that the energy bands are twofold degenerate in the sense that each energy occurs twice but not at the same wave vector **k**. However, if the crystal has inversion symmetry, the energy surface will be doubly degenerate at each **k** point.

The space inversion operator J has the following properties:

$$J\mathbf{x}J^{-1}=-\mathbf{x}, \tag{76a}$$

$$J\mathbf{p}J^{-1}=-\mathbf{p}, \tag{76b}$$

$$J\sigma J^{-1}=\sigma. \tag{76c}$$

The product operation KJ is called the *conjugation operator C* and is defined as

$$C\equiv KJ=-i\sigma_2K_0J=JK. \tag{77}$$

The conjugation operator leads to

$$C\psi(\mathbf{k},\uparrow)=KJ\psi(\mathbf{k},\uparrow)=K\psi(-\mathbf{k},\uparrow)=\psi(\mathbf{k},\downarrow), \tag{78}$$

to within a phase factor, and

$$\epsilon(\mathbf{k};\uparrow)=\epsilon(\mathbf{k};\downarrow). \tag{79}$$

As seen from Eq. (78), the conjugation operator C reverses the spin of a Bloch state, but not its wave vector. As a result, if the crystal exhibits inversion symmetry, the energy eigenvalues are doubly degenerate at each **k** point in the Brillouin zone as indicated by Eq. (79). This property will be illustrated in the next section when we consider the electronic band structure of solids with inversion symmetry.

2. CALCULATIONS OF ELECTRON STATES IN SOLIDS: BAND THEORY

2.1 Introduction: Basic Approximations

In Sec. 1, we showed that symmetry requirements imposed by the translation group required that the electronic solutions in a crystal be of the Bloch form,

$$|\psi(\mathbf{k})\rangle=\exp(i\mathbf{k}\cdot\mathbf{x})u(\mathbf{k},\mathbf{x}), \tag{80}$$

where the cell-periodic function $u(\mathbf{k},\mathbf{x})$ has the periodicity of the lattice,

$$u(\mathbf{k},\mathbf{x}+\mathbf{R}_j)=u(\mathbf{k},\mathbf{x}), \tag{81}$$

and where the wave vector **k** labels the Bloch solutions. In Eq. (80), we have used Dirac's notation, $|\psi(\mathbf{k})\rangle\equiv\psi(\mathbf{k},\mathbf{x})$, to label a Bloch state. In this section, we indicate how to calculate the Bloch function $|\psi(\mathbf{k})\rangle$ in an actual crystal. This field of solid-state physics is generally referred to as *electron band theory.*

Before we embark on a discussion of the various methods used to calculate the Bloch state $|\psi_n(\mathbf{k})\rangle$ and energy bands $\epsilon_n(\mathbf{k})$, we would like to indicate the basic set of approximations embodied within the band theory of solids (Bassani and Pastori Parravicini, 1975).

A solid contains an enormous number (of the order of 10^{23}) of interacting particles, and the theoretical treatment of the wave functions and energy levels of a solid therefore necessitates the use of simplifying approximations. A solid can be described as a collection of mutually interacting electrons and nuclei. The total Hamiltonian of the system is

$$H_t=T_e+T_N+V_{ee}+V_{eN}+V_{NN}, \tag{82}$$

where T_e and T_N represent the kinetic energy of the electrons and nuclei, respectively, and V_{ee}, V_{eN}, and V_{NN} are the electron–electron, electron–nuclei, and nuclei–nuclei interactions, respectively. Since the strongest interactions between the particles are the Coulomb interactions, we use the following expression for H_t:

$$\begin{aligned}H_t=&-\sum_i \frac{\hbar^2}{2m}\nabla_i^2-\sum_I \frac{\hbar^2}{2M_I}\nabla_I^2\\&+e^2\sum_{i<j}\frac{1}{|\mathbf{x}_i-\mathbf{x}_j|}-e^2\sum_{i,I}\frac{Z_I}{|\mathbf{x}_i-\mathbf{R}_I|}\\&+e^2\sum_{I<J}\frac{Z_IZ_J}{|\mathbf{R}_I-\mathbf{R}_J|},\end{aligned} \tag{83}$$

where the indices i, j and I, J refer to the electrons and nuclei, respectively, and Z indicates the nuclear charge. Equation (83) is only an approximation since it does not contain all possible interactions (e.g., spin-spin coupling) and assumes a nonrelativistic expression for the kinetic energy.

Band theory is concerned with the solution of the Schrödinger equation

$$H_t\Psi(\mathbf{R},\mathbf{x})=E\Psi(\mathbf{R},\mathbf{x}), \tag{84}$$

where $\mathbf{R}$ and $\mathbf{x}$ represent the space and spin coordinates of the nuclei and electrons, respectively. A basic approximation used in band theory is the *Born–Oppenheimer approximation* (Born and Oppenheimer, 1927), which consists in splitting the eigenvalue problem Eq. (84) into two separate but interdependent eigenvalue problems for electron and nuclei. This approximation is possible because the nuclei have a much greater mass than the electrons. Let us consider the electron Hamiltonian

$$H_e=T_e+V_{ee}+V_{eN}, \tag{85a}$$

or

$$H_e=-\sum_i \frac{\hbar^2}{2m}\nabla_i^2+e^2\sum_{i<j}\frac{1}{|\mathbf{x}_i-\mathbf{x}_j|} -e^2\sum_{i,I}\frac{Z_I}{|\mathbf{x}_i-\mathbf{R}_I|}. \tag{85b}$$

The Hamiltonian H_e depends parametrically on the nuclei coordinates $\mathbf{R}$. For a *given* nuclear configuration $\mathbf{R}$, we consider the eigenvalue problem

$$(T_e+V_{ee}+V_{eN})\psi_n(\mathbf{R};\mathbf{x})=E_n(\mathbf{R})\psi_n(\mathbf{R};\mathbf{x}), \tag{86}$$

where n indicates the set of quantum numbers for the electronic coordinates $\mathbf{x}$. Since the electronic mass is much smaller than the nuclear masses, we assume that the electrons will adiabatically follow the motion of the nuclei and that the eigenvalues $E_n(\mathbf{R})$ and the eigenfunctions $\psi_n(\mathbf{R};\mathbf{x})$ will be smooth and continuous functions of the nuclear coordinates $\mathbf{R}$.

The eigenfunction of the total Hamiltonian H_t is of the form

$$\Psi_{n,\mu}(\mathbf{R},\mathbf{x})=\chi_{n,\mu}(\mathbf{R})\psi_n(\mathbf{R};\mathbf{x}), \tag{87}$$

where the dependence on the electronic coordinates $\mathbf{x}$ only appears in $\psi_n(\mathbf{R};\mathbf{x})$ and μ labels the quantum numbers for the nuclear coordinates. The total eigenfunction $\Psi_{n,\mu}(\mathbf{R},\mathbf{x})$ is an eigenstate of H_t, and satisfies

$$(T_e+T_N+V_{ee}+V_{eN}+V_{NN})\chi_{n,\mu}(\mathbf{R})\psi_n(\mathbf{R};\mathbf{x}) =E_{n,\mu}\chi_{n,\mu}(\mathbf{R})\psi_n(\mathbf{R};\mathbf{x}). \tag{88}$$

Let us consider the quantity

$$\nabla_{\mathbf{R}}^2[\chi_{n,\mu}(\mathbf{R})\psi_n(\mathbf{R};\mathbf{x})]$$

required for the calculation of T_N. We have

$$\begin{aligned}\nabla_{\mathbf{R}}^2[\chi_{n,\mu}(\mathbf{R})\psi_n(\mathbf{R};\mathbf{x})] &=\psi_n(\mathbf{R};\mathbf{x})\nabla_{\mathbf{R}}^2\chi_{n,\mu}(\mathbf{R})\\ &\quad+2\nabla_{\mathbf{R}}\psi_n(\mathbf{R};\mathbf{x})\cdot\nabla_{\mathbf{R}}\chi_{n,\mu}(\mathbf{R})\\ &\quad+\chi_{n,\mu}(\mathbf{R})\nabla_{\mathbf{R}}^2\psi_n(\mathbf{R};\mathbf{x}).\end{aligned} \tag{89}$$

Because of the smooth parametric dependence of $\psi_n(\mathbf{R};\mathbf{x})$ on $\mathbf{R}$, the term $\psi_n(\mathbf{R};\mathbf{x}) \times\nabla_{\mathbf{R}}^2\chi_{n,\mu}(\mathbf{R})$ in Eq. (89) is the dominant one and we make the basic approximation of retaining only this term. Consequently, the nuclear kinetic operator T_N can be written as

$$T_N[\chi_{n,\mu}(\mathbf{R})\psi_n(\mathbf{R};\mathbf{x})]\approx\psi_n(\mathbf{R};\mathbf{x})T_N\chi_{n,\mu}(\mathbf{R}). \tag{90}$$

Substituting Eqs. (86) and (90) into Eq. (88) and dividing by $\psi_n(\mathbf{R};\mathbf{x})$, we obtain an eigenvalue equation of the nuclear eigenfunctions,

$$[T_N+V_{NN}+E_n(\mathbf{R})]\chi_{n,\mu}(\mathbf{R})=E_{n,\mu}\chi_{n,\mu}(\mathbf{R}). \tag{91}$$

Equations (86) and (91) are the fundamental equations of the Born–Oppenheimer (or adiabatic) approximation. Equation (86) gives the energy levels $E_n(\mathbf{R})$ of the electronic states when the nuclei have the fixed positions $\mathbf{R}$. The electronic energy eigenvalues $E_n(\mathbf{R})$ then appear as a *potential function* in the eigenvalue equation for the nuclear wave function $\chi_{n,\mu}(\mathbf{R})$. Equations (86) and (91) therefore permit a separate, but interdependent, evaluation of the energy eigenvalues $E_n(\mathbf{R})$ associated with the electronic states $\psi_n(\mathbf{R};\mathbf{x})$ as well as a calculation of the lattice vibrational states. Relaxation of the adiabatic approximation requires a consideration of the electron–lattice coupling and the evaluation of the second and third terms in Eq. (89).

To determine the electronic states $\psi_n(\mathbf{R};\mathbf{x})$ of a crystal, we use Eq. (86) with the nuclei at their equilibrium positions, giving rise to a one-electron potential representing the electron–nuclear Coulomb interaction. Equation (86) represents a very complicated many-body problem that cannot be exactly solved. To simplify its solution, one relies on the *one-electron band approximation.*

The central approximation of band theory is that the exact many-body problem of solving the Schrödinger equation can be meaningfully mapped into a one-electron problem for a single electron moving in an effective potential. The corresponding one-electron Schrödinger equation reduces to

$$\left(\frac{-\hbar^2}{2m}\nabla^2+V(\mathbf{x})\right)|\psi_n(\mathbf{k})\rangle=\epsilon_n(\mathbf{k})|\psi_n(\mathbf{k})\rangle, \tag{92}$$

where the crystal potential $V(\mathbf{x})$ is invariant under all the symmetry operations of the space group. We assume that the crystal potential $V(\mathbf{x})$ can be written as a linear superposition of atomic potentials $v_\mu(\mathbf{x})$ corresponding to an atomic species μ,

$$V(\mathbf{x})=\sum_{\mathbf{R}_j}\sum_{\mathbf{d}_\mu} v_\mu(\mathbf{x}-\mathbf{R}_j-\mathbf{d}_\mu), \tag{93}$$

where the vectors $\mathbf{R}_j$ label the primitive cells of the crystal and the vectors $\mathbf{d}_\mu$ indicate the positions of the atoms of type μ within a unit cell. A typical electron wave function in a crystal (Ziman, 1984) is shown in Fig. 9: Outside the ion-core region (i.e., the region near the atomic nucleus), the wave function looks very much like a plane wave, whereas it looks like an atomic orbital within the core region. Near the nucleus, the ionic potential is very attractive and the electron has a high kinetic energy (short-wavelength oscillations). The purpose of this section is to describe some of the modern theoretical schemes used to calculate the crystal Bloch states and their associated energy eigenvalue spectrum.

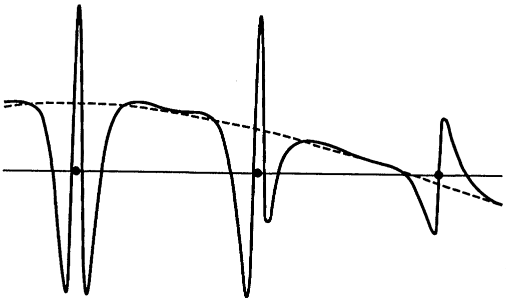

FIG. 9. Typical electron wave function in a solid. Outside the ion core region (i.e., the region near the atomic nucleus), the wave function looks very much like a plane wave, whereas it looks like an atomic orbital within the core region. Near the nucleus, the ionic potential is very attractive and the electron has a high kinetic energy (short-wavelength oscillations). The solid circles indicate the positions of the ions in the crystal and the dashed line represents a plane wave. (Reproduced with permission from Ziman, 1984, p. 92.)

The underlying idea behind the success of the band approximation is that the eigenvalues for the electronic states depend to a large extent on the symmetry properties of the lattice and are not very sensitive to small changes in the form of the crystal potential $V(\mathbf{x})$. There exist two general classes of methods for solving Eq. (92) for the energy eigenvalues $\epsilon_n(\mathbf{k})$ and wave functions $|\psi_n(\mathbf{k})\rangle$ within the band approximation. One class of methods is based on an expansion of the wave functions $|\psi_n(\mathbf{k})\rangle$ in a complete set of Bloch-type basis functions. The expansion coefficients are determined by solving the appropriate Schrödinger equation. We refer to these methods as *fixed-basis-set methods*. The other class of methods is based on an expansion of the wave functions $|\psi_n(\mathbf{k})\rangle$ in a complete set of functions, which are solutions to Schrödinger's equation within a unit cell. The resulting expansion coefficients are determined by imposing appropriate boundary conditions at the unit cell boundaries. We refer to methods based on such a construction as *scattering methods*. Band-structure calculation schemes based on fixed-basis-set methods include local-orbital methods, orthogonalized-plane-wave methods, and pseudopotential formalisms. Band-structure techniques based on scattering methods include the cellular method, the muffin-tin and augmented-plane-wave methods, and the Green's-function method. We discuss, in turn, fixed-basis-set and scattering methods. We emphasize again that the above classification is adopted for presentation purposes only and that each of the electronic band-structure techniques presented below has been highly developed over the years and constitutes a self-contained method in its own right.

The formalisms described within this section can be implemented using two different approaches that differ as to whether the solutions of Schrödinger's equation, Eq. (92), are obtained self-consistently or not. In calculations where the band equation, Eq. (92), is solved self-consistently, the crystal potential $V(\mathbf{x})$ is iteratively recomputed from the electron charge density constructed from the eigenfunctions $|\psi_n(\mathbf{k})\rangle$. This self-consistent procedure requires a simultaneous solution of Poisson's equation (relating the electrostatic potential to the charge density) and Schrödinger's equation. On the other hand, solutions that are not self-consistent do not involve a recalculation of the crystal potential.

2.2 Fixed-Basis-Set Methods

In electron-structure calculation schemes based on fixed-basis-set methods, the crystal electronic eigenfunctions $|\psi_n(\mathbf{k})\rangle$ are expanded in a complete set of fixed basis functions. The basis functions themselves are constructed to satisfy Bloch's theorem. The expansion coefficients are then determined by solving the resulting Schrödinger equation in the appropriate representation. We consider below two classes of fixed-basis-set methods depending on whether the basis functions used for the expansion of $|\psi_n(\mathbf{k})\rangle$ represent primarily *localized* or *itinerant* electrons.

2.2.1 Local-Orbital Methods. The local-orbital, or tight-binding, method was originally suggested by Bloch (1928) and uses the atomic orbitals of the atoms within a unit cell as the basis set on which the electron wave functions $|\psi_n(\mathbf{k})\rangle$ are expanded. Atomic orbitals, each centered on a particular atom, are combined to describe a Bloch state delocalized throughout the whole crystal. Let $\varphi_\mu^\alpha(\mathbf{x})$ denote the atomic orbital corresponding to the atom of type μ and characterized by the atomic quantum number α $(\alpha=n,l,m)$. These local atomic orbitals are combined into a *Bloch sum*, corresponding to the wave vector $\mathbf{k}$ and satisfying Bloch's theorem. Such a linear combination is given by

$$|\Phi_\mu^\alpha(\mathbf{k})\rangle=\frac{1}{\sqrt{N}}\sum_{\mathbf{R}_j}\exp(i\mathbf{k}\cdot\mathbf{R}_j)\varphi_\mu^\alpha(\mathbf{x}-\mathbf{R}_j-\mathbf{d}_\mu), \tag{94}$$

where N indicates the number of primitive cells in the crystal and $\varphi_\mu^\alpha(\mathbf{x}-\mathbf{R}_j-\mathbf{d}_\mu)$ is an atomic orbital centered at the site $\mathbf{R}_j+\mathbf{d}_\mu$. The electron Bloch function is then expanded as a linear combination of the Bloch sums $|\Phi_\mu^\alpha(\mathbf{k})\rangle$ as

$$|\psi_n(\mathbf{k})\rangle=\sum_{\mu,\alpha}|\Phi_\mu^\alpha(\mathbf{k})\rangle C_\mu^\alpha(n,\mathbf{k}), \tag{95}$$

where the expansion coefficients $C_\mu^\alpha(n,\mathbf{k})$ are to be determined by solving the eigensystem resulting from the substitution of Eq. (95) into Schrödinger's equation. The tight-binding expansion of the Bloch state $|\psi_n(\mathbf{k})\rangle$ in terms of the Bloch sums $|\Phi_\mu^\alpha(\mathbf{k})\rangle$ is a useful procedure in cases where a small number of basis functions $|\Phi_\mu^\alpha(\mathbf{k})\rangle$ are important in the expansion of $|\psi_n(\mathbf{k})\rangle$. This applies to low-energy atomic orbitals that are strongly localized around the nucleus and are little modified when the atoms are brought together to form the crystal (Bassani and Pastori Parravicini, 1975).

The evaluation of the expansion coefficients $C_\mu^\alpha(n,\mathbf{k})$ requires a knowledge of the Hamiltonian matrix elements between two Bloch sums,

$$H_{\mu,\mu'}^{\alpha,\alpha'}(\mathbf{k})\equiv\langle\Phi_\mu^\alpha(\mathbf{k})|H|\Phi_{\mu'}^{\alpha'}(\mathbf{k})\rangle. \tag{96}$$

The matrix elements $H_{\mu,\mu'}^{\alpha,\alpha'}(\mathbf{k})$ are of the form

$$H_{\mu,\mu'}^{\alpha,\alpha'}(\mathbf{k})=\sum_{\mathbf{R}_j}\exp(i\mathbf{k}\cdot\mathbf{R}_j)\int d^3x\,\varphi_\mu^{\alpha*}(\mathbf{x}-\mathbf{d}_\mu)$$
$$\times H\varphi_{\mu'}^{\alpha'}(\mathbf{x}-\mathbf{R}_j-\mathbf{d}_{\mu'}) \tag{97a}$$
$$\equiv\sum_{\mathbf{R}_j}\exp(i\mathbf{k}\cdot\mathbf{R}_j)H_{\mu,\mu'}^{\alpha,\alpha'}(\mathbf{R}_j). \tag{97b}$$

In practice, two approaches are followed for the evaluation of the matrix elements $H_{\mu,\mu'}^{\alpha,\alpha'}(\mathbf{R}_j)$. In one approach, one assumes an analytic form for the localized atomic orbitals $\varphi_\mu^\alpha(\mathbf{x})$ (Gaussian orbitals, Slater orbitals, etc.), and then explicitly evaluates the matrix elements $H_{\mu,\mu'}^{\alpha,\alpha'}(\mathbf{R}_j)$. This approach also requires the evaluation of the overlap matrix elements between atomic orbitals centered at different sites. This approach is sometimes referred to as the *linear combination of atomic orbitals (LCAO) method.* In another approach, the matrix elements $H_{\mu,\mu'}^{\alpha,\alpha'}(\mathbf{R}_j)$ are considered as empirical parameters to be fitted in such a way as to recover the "correct" (i.e., as extracted from experiments or calculated from first-principles methods) energy eigenvalue spectrum $\epsilon_n(\mathbf{k})$ at high-symmetry $\mathbf{k}$ points within the Brillouin zone. In this method, known as the *empirical tight-binding method,* the matrix elements $H^{\alpha,\alpha'}_{\mu,\mu'}(\mathbf{R}_j)$ are not explicitly calculated.

We now consider an example to illustrate the features of the LCAO and tight-binding methods. Consider a simple-cubic Bravais lattice of lattice constant a. Application of the LCAO method to an s band derived from a single atomic orbital of $\alpha = s$ $(l=0)$ symmetry yields an energy band of the form (Ziman, 1984)

$$\epsilon(\mathbf{k}) \approx \epsilon^s_a + 2\epsilon_{100}[\cos(k_x\, a) + \cos(k_y\, a) + \cos(k_z\, a)], \qquad (98)$$

where ϵ^s_a is the atomic energy of an s state in the isolated atom. In the dispersion relation $\epsilon(\mathbf{k})$ given by Eq. (98), the energy ϵ_{100} is a matrix element of the form $H^{\alpha,\alpha'}_{\mu,\mu'}(\mathbf{R}_j)$ (with $\mathbf{R}_j = \pm a\hat{\mathbf{x}}, \pm a\hat{\mathbf{y}}, \pm a\hat{\mathbf{z}}$), which is negative and which determines the bandwidth. The Brillouin zone is a cube and the energy surfaces within the zone are shown in Fig. 10(a) (Ziman, 1984). The corresponding energy dispersion $\epsilon(\mathbf{k})$ along a cube axis is indicated in Fig. 10(b) (Ziman, 1984) for $-\pi/a < k_x < \pi/a$, $k_y = k_z = 0$. From the tight-binding dispersion of Eq. (98), one deduces that the bandwidth is $12|\epsilon_{100}|$ and that the bottom of the band (lowest energy) is at $\epsilon^s_a + 6\epsilon_{100}$.

The band structure depends on the tight-binding integrals $H^{\alpha,\alpha'}_{\mu,\mu'}(\mathbf{R}_j)$ of the form shown in Eqs. (97): They are functions of the orbitals $\varphi^{\alpha}_{\mu}(\mathbf{x} - \mathbf{R}_j - \mathbf{d}_\mu)$ and of the crystal structure $\mathbf{R}_j$. The energy bands tend to become narrow if the atomic orbitals are strongly localized or if the lattice spacing is increased. In the limit where the atoms are infinitely far apart, the energy bands reduce to an N-fold-degenerate atomic level of the atoms brought together to form the crystal.

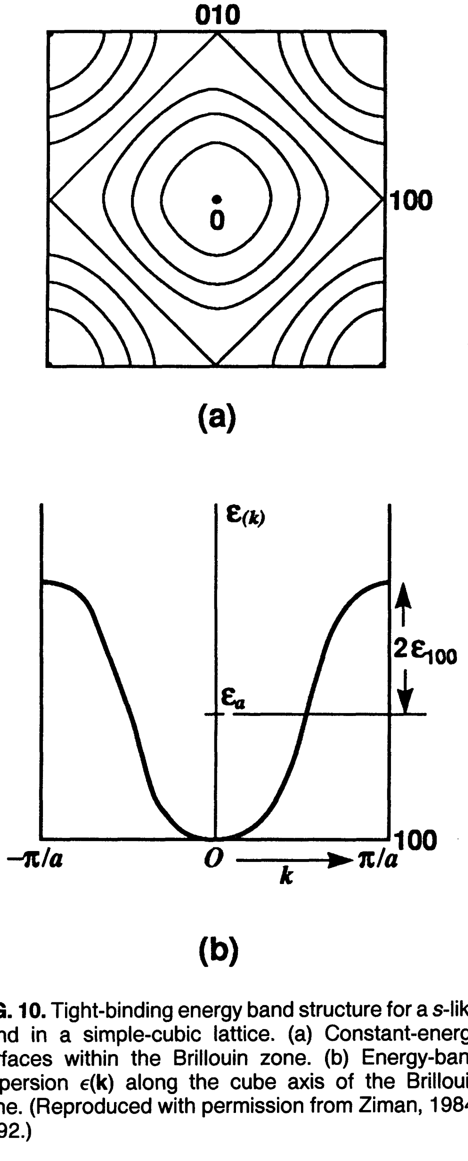

FIG. 10. Tight-binding energy band structure for a s-like band in a simple-cubic lattice. (a) Constant-energy surfaces within the Brillouin zone. (b) Energy-band dispersion $\epsilon(\mathbf{k})$ along the cube axis of the Brillouin zone. (Reproduced with permission from Ziman, 1984, p. 92.)

2.2.2 Orthogonalized-Plane-Wave Method.

We now discuss the orthogonalized-plane-wave method which, while not widely used nowadays, has enjoyed many early successes and serves as the basis to develop the very useful concept of pseudopotential. The orthogonalized-plane-wave method is based on a description of the crystal Bloch states $|\psi_n(\mathbf{k})\rangle$ in terms of plane waves that form a simple and convenient basis set. The idea of expanding the crystal electronic states in terms of plane waves was first proposed by Sommerfeld and Bethe (1933). The Bloch state is a product of a phase times a cell-periodic function,

$$|\psi_n(\mathbf{k})\rangle = \exp(i\mathbf{k}\cdot\mathbf{x})\, u_n(\mathbf{k},\mathbf{x}), \qquad (99)$$

and since the function $u_n(\mathbf{k},\mathbf{x})$ is periodic in the lattice translation vector,

$$u_n(\mathbf{k},\mathbf{x}+\mathbf{R}_j) = u_n(\mathbf{k},\mathbf{x}), \qquad (100)$$

a plane-wave expansion will only contain Fourier components associated with a reciprocal-lattice vector $\mathbf{G}$ of the form given by Eq. (9b). Therefore, the plane-wave expansion of the Bloch function $|\psi_n(\mathbf{k})\rangle$ is written as

$$
\begin{aligned}
|\psi_n(\mathbf{k})\rangle &= \exp(i\mathbf{k}\cdot\mathbf{x})u_n(\mathbf{k},\mathbf{x}) \\
&= \exp(i\mathbf{k}\cdot\mathbf{x})\left(\frac{1}{\sqrt{N\Omega_{\mathbf{x}}}}\right. \\
&\quad \times \left.\sum_{\mathbf{G}} \exp(i\mathbf{G}\cdot\mathbf{x})C_n(\mathbf{k}+\mathbf{G})\right) \\
&= \frac{1}{\sqrt{N\Omega_{\mathbf{x}}}} \sum_{\mathbf{G}} \exp[i(\mathbf{k}+\mathbf{G})\cdot\mathbf{x}] \\
&\quad \times C_n(\mathbf{k}+\mathbf{G}) \\
&\equiv \sum_{\mathbf{G}} |\mathbf{k}+\mathbf{G}\rangle C_n(\mathbf{k}+\mathbf{G}), \qquad (101)
\end{aligned}
$$

where we have defined the plane wave with momentum $\mathbf{k}+\mathbf{G}$ as

$$
|\mathbf{k}+\mathbf{G}\rangle \equiv \frac{1}{\sqrt{N\Omega_{\mathbf{x}}}} \exp[i(\mathbf{k}+\mathbf{G})\cdot\mathbf{x}], \qquad (102)
$$

and where $\Omega_{\mathbf{x}}$ is the volume of a lattice primitive cell and N is the total number of primitive cells in the crystal.

As is the case in every fixed-basis-set method, the expansion coefficients $C_n(\mathbf{k}+\mathbf{G})$ of the plane-wave expansion Eq. (101) are determined by solving the eigensystem resulting from the substitution of Eq. (101) in Schrödinger's equation. This eigensystem involves the calculation of Hamiltonian matrix elements between two plane waves,

$$
H(\mathbf{k}+\mathbf{G},\mathbf{k}+\mathbf{G}') = \langle \mathbf{k}+\mathbf{G}|H|\mathbf{k}+\mathbf{G}'\rangle. \qquad (103)
$$

It is apparent that the plane-wave expansion of Eq. (101) suffers from one important difficulty: the expansion is very slowly convergent (i.e., a very large number of plane waves is needed) for the low-energy, strongly localized core states of the crystal. These states are very well described by atomic orbitals. In order to overcome this problem, a conceptual advance was made by Herring (1940). He realized that the crystal states lying at higher energy (valence- and conduction-band states) must be orthogonal to the crystal core states since they are eigenfunctions of the same crystal Hamiltonian but have different energies. Consequently, Herring suggested using, as the basis set, *plane waves that have been orthogonalized (by construction) to the core states*. An expansion in terms of these *orthogonalized plane waves* (OPW) does indeed exhibit vastly improved convergence properties over simple plane waves.

A plane wave can be made orthogonal to a core state $|\varphi_c\rangle$ by a Gram–Schmidt procedure (Arfken, 1985). We construct an OPW associated with a momentum $\mathbf{k}+\mathbf{G}$ by projecting out the core states $|\varphi_c\rangle$ from a plane wave $|\mathbf{k}+\mathbf{G}\rangle$:

$$
|\text{OPW: } \mathbf{k}+\mathbf{G}\rangle = \left(1-\sum_c |\varphi_c\rangle\langle\varphi_c|\right)|\mathbf{k}+\mathbf{G}\rangle, \qquad (104)
$$

where $|\mathbf{k}+\mathbf{G}\rangle$ is the plane wave defined in Eq. (102) and $|\varphi_c\rangle \equiv |\varphi_c(\mathbf{k})\rangle$ represents a Bloch sum of core states of the form given in Eq. (94). The construction of an OPW is schematically indicated in Fig. 11. A valence- or conduction-band state $|\psi_v(\mathbf{k})\rangle$ (from now on, we will refer to the term valence states to designate noncore valence and conduction states and use the index v to label a valence- or conduction-band state) can be expanded in terms of OPWs in the following manner:

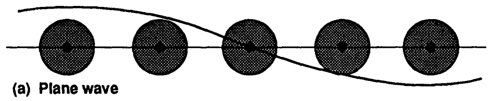
$$
\begin{aligned}
&|\psi_v(\mathbf{k})\rangle \\
&\quad = \sum_{\mathbf{G}} |\text{OPW:}\mathbf{k}+\mathbf{G}\rangle C_v(\mathbf{k}+\mathbf{G}) \\
&\quad = \sum_{\mathbf{G}} \left(1-\sum_c |\varphi_c\rangle\langle\varphi_c|\right)|\mathbf{k}+\mathbf{G}\rangle \\
&\quad\quad \times C_v(\mathbf{k}+\mathbf{G}). \qquad (105)
\end{aligned}
$$

The expansion coefficients $C_v(\mathbf{k}+\mathbf{G})$ are determined by solving the eigensystem in the OPW basis. This eigenvalue problem involves Hamiltonian matrix elements between two OPWs,

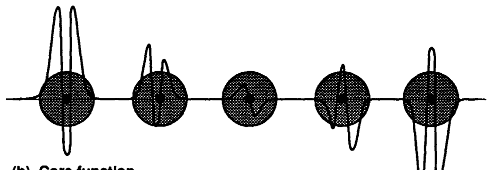
$$
\begin{aligned}
&H^{\text{OPW}}(\mathbf{k}+\mathbf{G},\mathbf{k}+\mathbf{G}') \\
&\quad = \langle \text{OPW: } \mathbf{k}+\mathbf{G}|H|\text{OPW: } \mathbf{k}+\mathbf{G}'\rangle. \qquad (106)
\end{aligned}
$$

The important point to appreciate is that the convergence is much better for the eigenvalue problem expressed in terms of the OPW basis $|\text{OPW: } \mathbf{k}+\mathbf{G}\rangle$ than it is in terms of the simple plane waves $|\mathbf{k}+\mathbf{G}\rangle$.

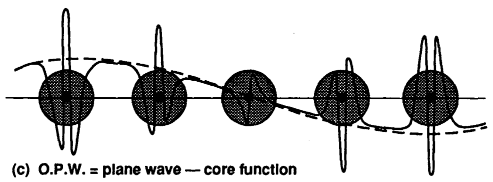
The OPW method is very advantageous and practical since the level of convergence of a particular calculation can be systematically tested by increasing the number of OPW basis functions in the expansion of $|\psi_v(\mathbf{k})\rangle$. The method is well suited to study the valence- and conduction-band structure of a large number of solids in which the core states do not



(a) Plane wave



(b) Core function



(c) O.P.W. = plane wave — core function

FIG. 11. Schematic construction of an orthogonalized plane wave (c) in which a plane wave (a) is orthogonalized to a core state (b) by construction. (Reproduced with permission from Ziman, 1984, p. 100.)

participate in the bonding and are well separated in energy from the valence states. Examples of such systems include group-IV semiconductors, III-V compound semiconductors, alkali halides, rare-gas solids, etc. One drawback of the OPW method is the assumption that the core states $|\varphi_c\rangle$ in the crystal are identical to the corresponding core states in the isolated atom. In the case in which this assumption is not realized, one must self-consistently recalculate the core states in the crystal. Moreover, the OPW method assumes a separation of the crystal eigenstates in terms of core states $|\varphi_c\rangle$ and valence states $|\psi_v(\mathbf{k})\rangle$. In some instances, such a separation is difficult to achieve in practice, as is the case for crystals containing incomplete *d* shells (Bassani and Pastori Parravicini, 1975).

We close this section by noting that, while the OPW method is not widely used nowadays, its application has been highly successful in the early development of electron band theory. In particular, pioneering utilizations of the OPW method by Herman have served as the basis for accurate band calculations of Si and Ge (Herman, 1954). Our main purpose in presenting the OPW method is its direct connection with the pseudopotential formalism.

2.2.3 Pseudopotential Theory. We now indicate how the OPW construction naturally leads to the pseudopotential concept (Heine, 1970; Harrison, 1980). It is based on the same concept that the crystal valence states $|\psi_v(\mathbf{k})\rangle$ must be orthogonal to the crystal core states $|\varphi_c\rangle$. It is possible to incorporate this idea into a form that is suitable for useful approximations.

A crystal valence state $|\psi_v(\mathbf{k})\rangle$ satisfies Schrödinger's equation

$$\left(\frac{-\hbar^2}{2m}\nabla^2+V(\mathbf{x})\right)|\psi_v(\mathbf{k})\rangle=\epsilon_v(\mathbf{k})\,|\psi_v(\mathbf{k})\rangle, \tag{107}$$

and must be orthogonal to the core states,

$$\langle\varphi_c|\psi_v(\mathbf{k})\rangle=0. \tag{108}$$

It is possible to write the valence state $|\psi_v(\mathbf{k})\rangle$ in the OPW form

$$|\psi_v(\mathbf{k})\rangle=\left(1-\sum_c|\varphi_c\rangle\langle\varphi_c|\right)|\varphi_v(\mathbf{k})\rangle, \tag{109a}$$

or, equivalently,

$$|\varphi_v(\mathbf{k})\rangle=|\psi_v(\mathbf{k})\rangle+\sum_c|\varphi_c\rangle\langle\varphi_c|\varphi_v(\mathbf{k})\rangle, \tag{109b}$$

which clearly indicates that the *pseudofunction* $|\varphi_v(\mathbf{k})\rangle$ is constructed from the valence state $|\psi_v(\mathbf{k})\rangle$, which has been smoothed in the core region by subtracting out the core orthogonality wiggles. The Schrödinger equation satisfied by the pseudofunction $|\varphi_v(\mathbf{k})\rangle$ is obtained simply by substituting Eq. (109b) in Eq. (107) and noting that the core state $|\varphi_c\rangle$ is an eigenstate of the crystal Hamiltonian with energy ϵ_c,

$$\left(\frac{-\hbar^2}{2m}\nabla^2+V(\mathbf{x})\right)|\varphi_v(\mathbf{k})\rangle+\sum_c[\epsilon_v(\mathbf{k})-\epsilon_c]\times|\varphi_c\rangle\langle\varphi_c|\varphi_v(\mathbf{k})\rangle=\epsilon_v(\mathbf{k})\,|\varphi_v(\mathbf{k})\rangle. \tag{110}$$

By comparing the OPW expansion Eq. (105) with the form of Eq. (109), we can identify the pseudofunction $|\varphi_v(\mathbf{k})\rangle$ with the plane-wave expansion (Heine, 1970)

$$|\varphi_v(\mathbf{k})\rangle = \sum_{\mathbf{G}} |\mathbf{k}+\mathbf{G}\rangle C_v(\mathbf{k}+\mathbf{G}). \tag{111}$$

Since the OPW determinant equation converges rapidly, the coefficients $C_v(\mathbf{k}+\mathbf{G})$ rapidly go to zero for large $\mathbf{k}+\mathbf{G}$, and *the pseudofunction is the smooth part of the all-electron wave function that remains after the oscillations in the core region* ($r < r_c$) *have been removed.* Consequently, the pseudofunction $|\varphi_v(\mathbf{k})\rangle$ is identically equal to the all-electron wave function $|\psi_v(\mathbf{k})\rangle$ outside the atomic core radius r_c and extends smoothly inside the core without the oscillations that $|\psi_v(\mathbf{k})\rangle$ exhibits in the core region,

$$|\varphi_v(\mathbf{k})\rangle \equiv \begin{cases} |\psi(\mathbf{k})\rangle & \text{for } r > r_c \\ \text{smooth nodeless function} & \\ \quad \text{for } r < r_c\,. & \end{cases} \tag{112}$$

Operationally, a pseudopotential can be defined as an effective potential that generates a pseudofunction $|\varphi_v(\mathbf{k})\rangle$ which is *smooth and nodeless throughout space* and whose energy eigenvalue spectrum $\epsilon_v(\mathbf{k})$ is identical to that of the corresponding all-electron wave function $|\psi_v(\mathbf{k})\rangle$. A comparison between a pseudofunction and an all-electron wave function for silicon is indicated in Fig. 12 (Yin and Cohen, 1982).

The pseudofunction $|\varphi_v(\mathbf{k})\rangle$ is a solution of the Schrödinger equation Eq. (110) associated with an effective energy-dependent *pseudopotential*

$$\begin{aligned} \hat{V}^{\text{ps}} &= V(\mathbf{x}) + \sum_c [\epsilon_v(\mathbf{k}) - \epsilon_c]\,|\varphi_c\rangle\langle\varphi_c| \\ &\equiv V(\mathbf{x}) + \hat{V}_R, \end{aligned} \tag{113}$$

where $V(\mathbf{x})$ is the crystal potential and $\hat{V}_R = \Sigma_c[\epsilon_v(\mathbf{k}) - \epsilon_c]\,|\varphi_c\rangle\langle\varphi_c|$ is a nonlocal potential operator that arises from the imposition of the orthogonalization condition, Eq. (108). The form of $\hat{V}^{\text{ps}}$ given by Eq. (113) is referred to as the Phillips–Kleinman (Phillips and Kleinman, 1959) pseudopotential.

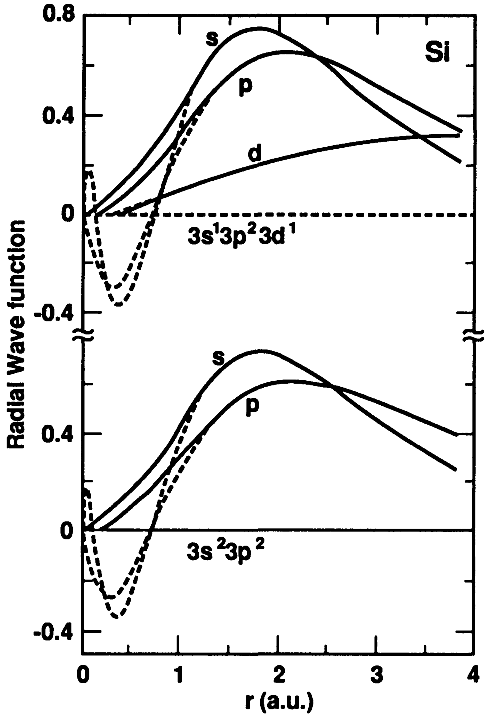


FIG. 12. Comparison between the nodeless pseudofunction (solid lines) and corresponding all-electron (dashed lines) radial wave functions of silicon for the atomic configurations $3s^1 3p^2 3d^1$ and $3s^2 3p^2$ (atomic units: 1 a.u. = 0.529 Å). (Reproduced with permission from Yin and Cohen, 1982b, p. 5671.)

Any amount of core states can be added to the pseudofunction $|\varphi_v(\mathbf{k})\rangle$ since these core states are automatically projected out by the construction in Eq. (109). This arbitrariness in the construction of the pseudofunction can be transferred to the pseudopotential itself. Consequently, there is a high degree of arbitrariness in the construction of the pseudopotential. For example, a general nonlocal pseudopotential can be defined by adding an arbitrary operator $\hat{A}$,

$$\hat{V}^{\text{ps}} = V(\mathbf{x}) + \sum_c \hat{A}\,|\varphi_c\rangle\langle\varphi_c|. \tag{114}$$

The operator $\hat{A}$ can be chosen such as to simplify the calculation of the matrix elements. The pseudopotential $\hat{V}^{\text{ps}}$ of Eq. (113) defines a pseudopotential Hamiltonian

$$\hat{H}^{\text{ps}} = \frac{-\hbar^2}{2m}\nabla^2 + \hat{V}^{\text{ps}}. \tag{115}$$

The pseudopotential concept can be formulated in the following manner: The pseudofunction equation, Eq. (110), is a transformation of the Schrödinger equation that retains the same energy eigenvalue $\epsilon_v(\mathbf{k})$ but transforms the wave function from $|\psi_v(\mathbf{k})\rangle$ to

$|\varphi_v(\mathbf{k})\rangle$. Since the core states lie at lower energy than the valence states, $\epsilon_c < \epsilon_v(\mathbf{k})$, the potential operator $\hat{V}_R$ is *repulsive* and leads to a nodeless pseudofunction $|\varphi_v(\mathbf{k})\rangle$. The popularity and usefulness of the pseudopotential concept emerge from the fact that because $\hat{V}^{\mathrm{ps}}$ is much weaker than the full potential, it leads to good convergence properties at the cost of introducing the additional complexity indicated by the form Eq. (113). Figure 13 indicates a typical pseudopotential for silicon as currently used in modern first-principles pseudopotential calculations (Yin and Cohen, 1982).

The central idea of the pseudopotential concept is the separation of the crystal eigenfunctions into core states and valence states and the solution of the resulting Hamiltonian for the energies and wave functions within the valence subspace. The resulting orthogonalization of the valence states from the core states leads to a weak pseudopotential that produces a smooth, nodeless pseudofunction $|\varphi_v(\mathbf{k})\rangle$ for which a fixed-basis-set expansion will converge rapidly. In actual calculations, the pseudofunction $|\varphi_v(\mathbf{k})\rangle$ is expanded in a convenient basis set. An extremely popular expansion set is provided by plane waves,

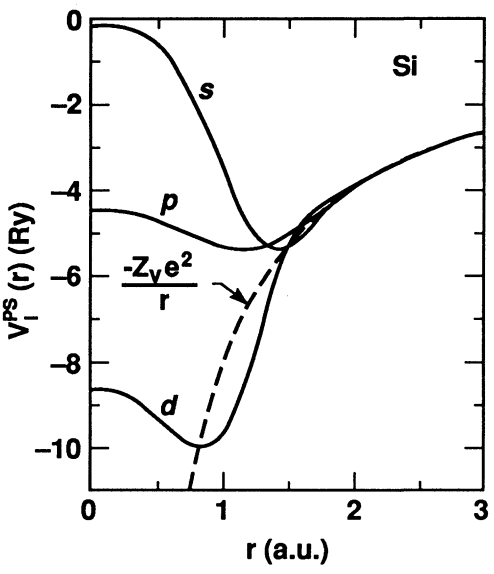

FIG. 13. *Ab initio* ionic pseudopotential of silicon. The letters *s*, *p*, and *d* denote the (nonlocal) pseudopotential for angular momenta $l=0$, 1, and 2, respectively. The dashed line indicates the bare Coulomb potential of a pointlike atomic core (atomic units: 1 Ry=13.603 eV, 1 a.u.=0.529 Å). (Reproduced with permission from Yin and Cohen, 1982b, p. 5670.)

$$|\varphi_v(\mathbf{k})\rangle = \sum_{\mathbf{G}} |\mathbf{k}+\mathbf{G}\rangle C_v(\mathbf{k}+\mathbf{G}), \tag{116}$$

where the expansion coefficients $C_v(\mathbf{k}+\mathbf{G})$ are determined by solving the resulting eigenvalue problem involving the pseudopotential Hamiltonian between two plane-wave states,

$$H^{\mathrm{ps}}(\mathbf{k}+\mathbf{G},\mathbf{k}+\mathbf{G}') = \langle \mathbf{k}+\mathbf{G}|\hat{H}^{\mathrm{ps}}|\mathbf{k}+\mathbf{G}'\rangle. \tag{117}$$

The pseudopotential method is best applicable in systems where the core states do not appreciably overlap with the valence states and are well separated in energy. Its usefulness lies in the fact that a plane-wave expansion leads to a rapid convergence. The calculation of the pseudopotential matrix elements is particularly simple in a plane-wave basis, even in the case where nonlocal pseudopotentials are used. Moreover, the solution of Poisson's equation is trivial when a plane-wave basis is used. Consequently, plane-wave basis functions are well suited for self-consistent electronic-structure calculations where Poisson's equation and Schrödinger's equation must be solved simultaneously. The pseudopotential method does not rely on any assumptions regarding the shape of the potential and affords a treatment of low-symmetry and open-structure systems. Let us mention also that the pseudopotential scheme has also been successfully implemented within a local-orbital scheme (Chelikowsky and Louie, 1984). Moreover, generalized pseudopotential schemes have been developed and applied to the treatment of solids with incomplete *d* shells (Harrison, 1969).

The pseudopotential method has been implemented within both empirical and first-principles contexts. Within the empirical pseudopotential method, the matrix elements $H^{\mathrm{ps}}(\mathbf{k}+\mathbf{G},\mathbf{k}+\mathbf{G}')$ are used as empirical parameters determined by fitting the calculated band structure $\epsilon_n(\mathbf{k})$ to experimental spectroscopic data. Within the first-principles pseudopotential method, a (generally nonlocal) pseudopotential is constructed from the all-electron potential in such a way as to reproduce the all-electron energy eigenvalue spectrum and to generate a nodeless pseudofunction that is identically equal to the all-electron wave function for $r > r_c$. We close this section by suggesting that the interested reader consult a recent comprehensive review of the utilization of pseudopotential methods in modern electronic-structure calculations (Pickett, 1989).

2.3 Scattering Methods

In electron-structure calculation schemes based on scattering methods, the crystal Bloch states $|\psi_n(\mathbf{k})\rangle$ are obtained by solving the Schrödinger equation within a Wigner–Seitz primitive cell. The solution for the entire crystal is then obtained by imposing appropriate boundary conditions at the cell boundaries. We refer to these methods as scattering methods since they often rely on basic results derived from scattering theory in the application of the boundary conditions. Scattering methods usually treat both the valence and core states and are therefore all-electron methods. The method was originally proposed by Wigner and Seitz (1933,1934) to study the cohesive energy of sodium. We indicate below extensions and refinements of this method (Bassani and Pastori Parravicini, 1975).

2.3.1 Cellular Method. Most scattering methods are based, in essence or at least in spirit, on the *cellular method.* We first present the original derivation of the cellular method and indicate modern refinements later. The fundamental principle underlying the cellular method is the expansion of the Bloch state $\psi(\mathbf{k},\mathbf{x})$ in terms of the solution of Schrödinger's equation for the atoms within one Wigner–Seitz primitive cell,

$$\psi(\mathbf{k},\mathbf{x}) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} C_{lm}(\mathbf{k}) Y_l^m(\hat{\mathbf{x}}) R_l(E;r), \tag{118}$$

where $Y_l^m(\hat{\mathbf{x}})$ are spherical harmonics and the functions $R_l(E;r)$ are solutions of the atomic radial Schrödinger equation

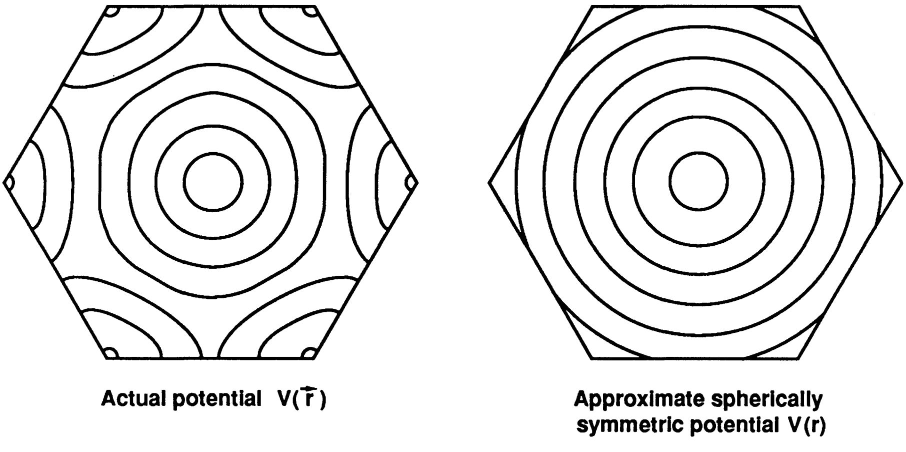
$$\frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{dR_l(E;r)}{dr}\right) + \left(\frac{2m}{\hbar^2}[E-V(r)] - \frac{l(l+1)}{r^2}\right)R_l(E;r) = 0, \tag{119}$$

in which $V(r)$ is the spherically symmetric cellular potential. The true crystal potential $V(\mathbf{x})$ is not spherically symmetric and the utilization of an atomic spherical potential $V(r)$ to generate the basis functions $Y_l^m(\hat{\mathbf{x}})R_l(E;r)$ is an approximation. A comparison between the actual crystal potential $V(\mathbf{x})$ and the spherically symmetric potential $V(r)$ within a primitive cell is indicated in Fig. 14 (Ashcroft and Mermin, 1976).

The coefficients $C_{lm}(\mathbf{k})$ appearing in the expansion Eq. (118) are determined by suitable boundary conditions imposed at the boundaries between primitive cells. For every pair of points $\mathbf{R}_j$ and $\mathbf{R}_i$ on opposite faces of the Wigner–Seitz primitive cell, the eigenfunction $\psi(\mathbf{k},\mathbf{x})$ must satisfy the boundary conditions required by Bloch's theorem,

$$\psi(\mathbf{k},\mathbf{R}_i) = \exp(i\mathbf{k}\cdot\mathbf{R})\psi(\mathbf{k},\mathbf{R}_j), \tag{120a}$$

$$\hat{\mathbf{n}}\cdot\nabla\psi(\mathbf{k},\mathbf{R}_i) = \exp(i\mathbf{k}\cdot\mathbf{R})\hat{\mathbf{n}}\cdot\nabla\psi(\mathbf{k},\mathbf{R}_j), \tag{120b}$$



Actual potential V($\vec{r}$)
Approximate spherically symmetric potential V(r)

FIG. 14. Equipotential contours showing the true crystal potential $V(\mathbf{x})$ and the spherically symmetric potential $V(r)$ within a primitive cell. (Reproduced with permission from Ashcroft and Mermin, 1976, p. 196.)

where $\mathbf{R}=\mathbf{R}_j-\mathbf{R}_i$ is a lattice-translation vector and $\hat{\mathbf{n}}$ is a unit vector normal to the pair of surfaces to which $\mathbf{R}_i$ and $\mathbf{R}_j$ belong. The boundary conditions Eqs. (120) relate the value of $\psi(\mathbf{k},\mathbf{x})$ and of its normal derivative on opposite faces of the Wigner–Seitz primitive cell.

The prescription for calculating the crystal energy levels $\epsilon(\mathbf{k})$ and eigenfunctions $\psi(\mathbf{k},\mathbf{x})$ in the cellular method is the following: One solves the radial Schrödinger equation Eq. (119) to obtain the radial solutions $R_l(E;r)$ within the Wigner–Seitz cell. The expansion of the crystal eigenfunction $\psi(\mathbf{k},\mathbf{x})$ for a given $\mathbf{k}$ is then performed in terms of the solutions $Y_l^m(\hat{\mathbf{x}})R_l(E;r)$ as indicated by Eq. (118). The boundary conditions Eqs. (120) are then imposed for every pair of points $\mathbf{R}_i$ and $\mathbf{R}_j$ on the cell boundary. In practical implementations, however, the matching is done only at a finite number of points on the Wigner–Seitz cell. The matching points are chosen on the basis of some method. During this process, the energy E is considered as a parameter. For a given wave vector $\mathbf{k}$, the expansion Eq. (118) will satisfy the boundary conditions Eqs. (120) for every pair of points on opposite faces of the Wigner–Seitz cell only for certain values of E and $C_{lm}(\mathbf{k})$. These allowed values of E and $C_{lm}(\mathbf{k})$ for which the boundary conditions are satisfied determine the energy eigenvalue spectrum $\epsilon(\mathbf{k})=E$ and eigenfunctions $\psi(\mathbf{k},\mathbf{x})$ of the crystal (Bassani and Pastori Parravicini, 1975).

The application of the cellular method was originally performed with a spherically symmetric potential which is equal to the atomic potential $V_{\text{atom}}(r)$ inside a sphere of radius r_s, and a constant V_0 outside this sphere. Typically, the radius r_s is of the order of half the first-nearest-neighbor distance. Such a potential is said to be of the *muffin-tin* form and is written as

$$V_{\text{MT}}(r)\equiv\begin{cases}V_{\text{atom}}(r) & \text{for } r<r_s\\ V_0 & \text{for } r>r_s\,.\end{cases} \tag{121}$$

The form of the muffin-tin potential $V_{\text{MT}}(r)$ is shown in Fig. 15 (Ashcroft and Mermin, 1976).

The cellular method is an all-electron method, in contrast to the pseudopotential method in which only the valence states are calculated, and the core states are frozen at their atomic values. There are two major difficulties associated with the cellular method as originally implemented. One unsatisfactory feature concerns the application of the boundary conditions and is related to the arbitrariness in choosing the finite set of matching points on the surface of the Wigner–Seitz cell. Another difficulty concerns the *shape approximation* arising when a spherically symmetric potential is used inside the Wigner–Seitz primitive cell. In certain types of materials, such as alkali metals, the crystal potential is indeed nearly spherically symmetric and the utilization of a muffin-tin potential $V_{\text{MT}}(r)$ of the form of Eq. (121) constitutes a good approximation. In other materials, such as covalently bonded open structures, the crystal potential is poorly approximated by the spherical form of $V_{\text{MT}}(r)$. Recall that the LCAO and pseudopotential methods do not rely on any shape approximation and are more suited to treat the electronic structure of low-symmetry open structures than the cellular method is.

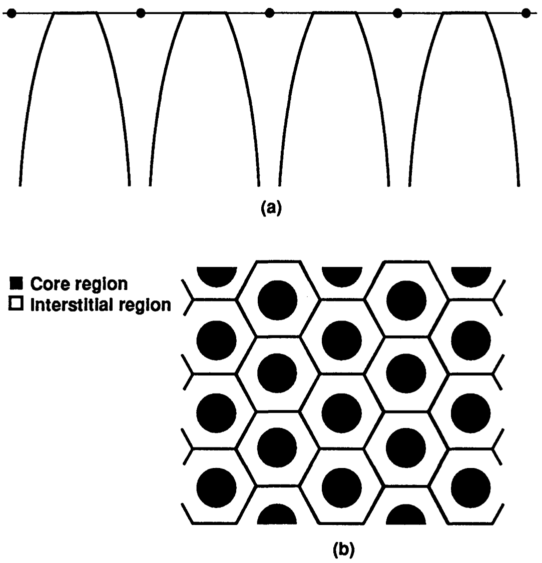


FIG. 15. Muffin-tin potential $V_{\text{MT}}(r)$. (a) Muffin-tin potential plotted along a line of ions. (b) The muffin-tin potential is constant in the interstitial regions and describes an isolated ion in the core regions. (Reproduced with permission from Ashcroft and Mermin, 1976, p. 200.)

We close this section by indicating that modern refinements of the cellular method that do not require the utilization of a muffin-tin potential $V_{\text{MT}}(r)$ have been developed (Nesbet, 1984, 1986). In these modern formulations of the cellular method, the solutions are matched over the entire surface of the Wigner–Seitz cell and can accommodate general shape-corrected as well as spherical cellular potentials.

2.3.2 Augmented Plane-Wave and Linear Muffin-Tin Methods. A solution to overcome the boundary condition problem inherent to the cellular method was originally proposed by Slater (1937). The basic principle is to augment the basis set on which $\psi(\mathbf{k},\mathbf{x})$ is expanded to include

1. the radial solutions $R_l(E;r)$ as in Eq. (118) and
2. plane waves in the interstitial regions where the potential is slowly varying.

This new basis function is called an *augmented plane wave* (APW) and is defined as

$$|\mathrm{APW}{:}\ \mathbf{k}\rangle \equiv \begin{cases} \displaystyle\sum_{l=0}^{\infty}\sum_{m=-1}^{l} a_{lm}(\mathbf{k})Y_l^m(\hat{\mathbf{x}})\ R_l(E;r) & \text{if } r<r_s \\ \exp(i\mathbf{k}\cdot\mathbf{x}) & \text{if } r>r_s\,. \end{cases} \tag{122}$$

The APW basis function $|\mathrm{APW}{:}\mathbf{k}\rangle$ contains two pieces:

1. an expansion in terms of the spherical-wave basis functions $Y_l^m(\hat{\mathbf{x}})R_l(E;r)$ within the muffin-tin sphere $r<r_s$ where the potential is atomiclike, and
2. a plane wave for $r>r_s$ where the potential is slowly varying.

The plane wave is joined to the spherical waves on a sphere whose radius r_s is usually determined by requiring that it be the largest sphere which can be inscribed within the Wigner–Seitz cell. They key point in the APW method is that the boundary conditions Eqs. (120) are already satisfied by the APW basis function $|\mathrm{APW}{:}\mathbf{k}\rangle$ at the surface of the Wigner–Seitz cell, and a much easier matching problem at the sphere surface (i.e., at $r=r_s$) provides the eigenvalues more efficiently than in the cellular method. This matching at the sphere boundary can be done by adjusting the expansion coefficients $a_{lm}(\mathbf{k})$ to assure the continuity of $|\mathrm{APW}{:}\mathbf{k}\rangle$ at $r=r_s$. By expanding the plane wave $\exp(i\mathbf{k}\cdot\mathbf{x})$ in spherical harmonics, it follows that the continuity of the function $|\mathrm{APW}{:}\mathbf{k}\rangle$ at $r=r_s$ is assured if we choose

$$a_{lm}(\mathbf{k})=4\pi Y_l^{m*}(\hat{\mathbf{k}})j_l(kr_s)\ /R_l(E;r_s)\ , \tag{123}$$

where $j_l(kr_s)$ is a spherical Bessel function (Bassani and Pastori Parravicini, 1975). In general, the slope of $|\mathrm{APW}{:}\mathbf{k}\rangle$ will be discontinuous at $r=r_s$.

The APW scheme is based on the expansion of the Bloch state $|\psi_n(\mathbf{k})\rangle$ in terms of the APW basis functions,

$$|\psi_n(\mathbf{k})\rangle=\sum_{\mathbf{G}}\ |\mathrm{APW}{:}\mathbf{k}+\mathbf{G}\rangle C_n(\mathbf{k}+\mathbf{G}), \tag{124}$$

where the expansion coefficients $C_n(\mathbf{k}+\mathbf{G})$ are obtained by solving the eigenvalue system resulting from substituting the APW expansion Eq. (122) in Schrödinger's equation. Hamiltonian matrix elements between two APWs must be computed,

$$H^{\mathrm{APW}}(\mathbf{k}+\mathbf{G},\mathbf{k}+\mathbf{G}';E) =\langle \mathrm{APW}{:}\mathbf{k}+\mathbf{G}|H|\mathrm{APW}{:}\ \mathbf{k}+\mathbf{G}'\rangle. \tag{125}$$

The evaluation of the APW matrix elements $H^{\mathrm{APW}}(\mathbf{k}+\mathbf{G},\mathbf{k}+\mathbf{G}';E)$ requires some care because of the discontinuity of slope at $r=r_s$ exhibited by the basis functions $|\mathrm{APW}{:}\mathbf{k}+\mathbf{G}\rangle$ (Bassani and Pastori Parravicini, 1975).

Contrary to the OPW method, the APW Hamiltonian matrix elements

$$H^{\mathrm{APW}}(\mathbf{k}+\mathbf{G},\mathbf{k}+\mathbf{G}';E)$$

depend on the energy and it is more efficient to perform a *linearization* about a fixed energy to cast the problem in an eigensystem form (Andersen, 1975). The resulting method, called the *linearized augmented-plane-wave (LAPW) method,* is extremely efficient and has allowed faster APW calculations by a factor of approximately 100 (Andersen *et al.*, 1987).

In the above discussion of the APW method, we have implicitly assumed that the potential was of the muffin-tin spherical form given by $V_{\mathrm{MT}}(r)$. However, it is possible to formulate the APW method without making any spherical shape approximation for the crystal potential. In this formulation, the matching sphere is immaterial and is used only in the definition of the APW basis functions $|\mathrm{APW}{:}\mathbf{k}+\mathbf{G}\rangle$. This shape-corrected formulation is known as the *full-potential linearized augmented-plane-wave (FLAPW) method.* Consequently, the FLAPW method should be regarded as being a fully shape-corrected method just as are the LCAO, OPW, and pseudopotential methods discussed above.

Another attractive feature of the APW method is that no assumptions are made about the core states and all the states (core and valence) can be treated on an equal footing. This is in contrast to the OPW and pseudopotential methods, which project out the core states from the all-electron wave function. A *panel method* is often used within the APW method to treat semicore states that are close in energy to the valence states (Skriver, 1984) and participate in the bonding in the solid. In this method, core and valence states are described by linearizing about two different energies: one near the middle of the valence band for the valence states and another one in the energy region of the core states. Consequently, the APW method can successfully be applied to the study of transition-metal elements where the pseudopotential prescription based on the separation between the core and valence states is questionable.

The form of the function in Eq. (122) can be made more general depending on the form of the function outside the sphere, $r > r_s$: If the function outside the sphere defined by the radius r_s is a plane wave, as in Eq. (122), the function is an augmented plane wave (APW); if the function outside the sphere is a Hankel function of zero kinetic energy, the function is a muffin-tin orbital (MTO); and if the function outside the sphere is a Slater orbital, the function is called a Slater-type orbital (STO) (Andersen *et al.*, 1987).

Given the importance of the MTO method in band theory and because of the impact it has had in the field of electronic structure calculations of transitions metals, we briefly discuss its major aspects. Just as in the cellular and APW methods, the crystal is divided into muffin-tin spheres of radius r_s where the atomic potential is taken to be spherically symmetric, separated by interstitial regions of constant potential [cf. the definition of $V_{\mathrm{MT}}(r)$ in Eq. (121)]. In the *atomic-sphere approximation (ASA)*, the piece of the MTO extending in the interstitial region is taken to have zero kinetic energy.

A MTO is an energy-dependent orbital constructed by a procedure similar to the APW of Eq. (122) (Skriver, 1984),

$$\chi_{lm}(E,\mathbf{x}) \equiv i^l Y_l^m(\hat{\mathbf{x}}) \times \begin{cases} R_l(E;r)+p_l(E)(r/r_s)^l & \text{if } r<r_s \\ (r_s/r)^{l+1} & \text{if } r>r_s\,. \end{cases} \tag{126}$$

The MTO defined by Eq. (126) is regular, continuous, and differentiable in all space. The *potential function* $p_l(E)$ appearing in the definition of $\chi_{lm}(E,\mathbf{x})$ is determined by the requirement of continuity and differentiability at the sphere radius r_s (Skriver, 1984),

$$p_l(E)=\frac{D_l(E)+l+1}{D_l(E)-l}, \tag{127}$$

where

$$D_l(E)\equiv\frac{r_s}{R_l(E;r_s)}\left(\frac{\partial R_l(E;r)}{\partial r}\right)_{r=r_s}. \tag{128}$$

The tail of the MTO $\chi_{lm}(E,\mathbf{x})$ is taken to be of the form $(r_s/r)^{l+1}$ and has zero kinetic energy, i.e., it is a solution of Laplace's equation, $\nabla^2\chi_{lm}(E,\mathbf{x})=0$.

The MTOs defined by Eq. (126) are combined into Bloch sums,

$$|\chi_{lm}(E,\mathbf{k})\rangle=\sum_{\mathbf{R}_j}\exp(i\mathbf{k}\cdot\mathbf{R}_j)\chi_{lm}(E,\mathbf{x}-\mathbf{R}_j). \tag{129}$$

The MTO band structure scheme involves the expansion of the Bloch state $|\psi_n(\mathbf{k})\rangle$ in terms of the MTO Bloch sums,

$$|\psi_n(\mathbf{k})\rangle=\sum_{l,m}|\chi_{lm}(E,\mathbf{k})\rangle C_{lm}(n,\mathbf{k}). \tag{130}$$

The Bloch function $|\psi_n(\mathbf{k})\rangle$ expressed by Eq. (130) will be an eigenfunction of the crystal Hamiltonian provided that the tails $(r_s/|\mathbf{x}-\mathbf{R}_j|)^{l+1}$ for all $\mathbf{R}_j\neq\mathbf{0}$ cancel the term $p_l(E)(r/r_s)^l$ appearing in the definition of $\chi_{lm}(E,\,\mathbf{x})$ inside the sphere $r<r_s$ centered at $\mathbf{R}=\mathbf{0}$. This principle of *tail cancellation* can be expressed mathematically by requiring that

$$0=\sum_{l,m}C_{lm}(n,\mathbf{k})\left[i^lY_l^m(\hat{\mathbf{x}})\frac{p_l(E)}{2(2l+1)}\left(\frac{r}{r_s}\right)^l + \sum_{\mathbf{R}_j\neq\mathbf{0}}\exp(i\mathbf{k}\cdot\mathbf{R}_j)i^lY_l^m(\hat{\mathbf{u}}_j) \times\left(\frac{r_s}{|\mathbf{x}-\mathbf{R}_j|}\right)^{l+1}\right], \tag{131}$$

where $\mathbf{u}_j=(\mathbf{x}-\mathbf{R}_j)$. A closed form for this condition can be obtained by expanding the tail centered at $\mathbf{R}_j$ in terms of the functions $i^l Y_l^m(\hat{\mathbf{x}})(r/r_s)^l$ centered at $\mathbf{R}=\mathbf{0}$:

$$\sum_{\mathbf{R}_j\neq\mathbf{0}} \exp(i\mathbf{k}\cdot\mathbf{R}_j)\, i^l Y_l^m(\hat{\mathbf{u}}_j)\left(\frac{r_s}{|\mathbf{x}-\mathbf{R}_j|}\right)^{l+1} = \sum_{l',m'} -\frac{1}{2(2l'+1)}\, S_{l'm'}^{lm}(\mathbf{k})\, i^{l'} Y_{l'}^{m'}(\hat{\mathbf{x}})\left(\frac{r}{r_s}\right)^{l'}, \tag{132}$$

where the expansion coefficients $S_{l'm'}^{lm}(\mathbf{k})$ are called *structure constants.* The tail cancellation condition, Eq. (132), can be expressed as a secular equation by collecting the coefficients of $Y_l^m(\hat{\mathbf{x}})$ $(r/r_s)^l$,

$$\sum_{l,m} [p_l(E)\delta_{l,l'}\delta_{m,m'} - S_{l'm'}^{lm}(\mathbf{k})]\, C_{lm}(n,\mathbf{k}) = 0. \tag{133}$$

Solution of Eq. (133) completely specifies the Bloch state by simultaneously satisfying the boundary conditions and Bloch's theorem.

The muffin-tin orbital method can also be linearized and, in this form, is called the linear muffin-tin orbital method (LMTO). As in the case of the APW method, the utilization of a spherically symmetric potential is not necessary within the LMTO method. The implementation of the LMTO method with a spherically symmetric potential is called the LMTO–atomic-sphere approximation (LMTO-ASA), whereas it is called the full-potential LMTO when the spherical shape approximation is relaxed (Methfessel *et al.*, 1989).

2.3.3 Green's-Function Method. Other methods based on scattering techniques have been proposed and are currently used in electron band-structure calculations. One such method is the *Green's-function* or *KKR method,* originally proposed by Korringa (1947) and Kohn and Rostoker (1954). This method uses standard Green's-function techniques to transform Schrödinger's equation into an equivalent integral equation. This method avoids the problems associated with the boundary conditions inherent to the cellular method. However, the Green's-function method usually requires the utilization of a spherical muffin-tin potential $V_{\mathrm{MT}}(r)$ as given by Eq. (121).

In the Green's-function method, the calculation of the crystal Bloch states $\psi(\mathbf{k},\mathbf{x})$ requires a knowledge of the Green's function $G(\mathbf{k},\mathbf{x}-\mathbf{x}';E)$ satisfying the free-particle Schrödinger equation

$$[(\hbar^2/2m)\nabla^2 + E]\, G(\mathbf{k},\mathbf{x}-\mathbf{x}';E) = \delta^3(\mathbf{x}-\mathbf{x}'), \tag{134}$$

describing the response to a delta-function excitation $\delta^3(\mathbf{x}-\mathbf{x}')$. The Green's function must satisfy the boundary condition

$$G(\mathbf{k},\mathbf{x}+\mathbf{R}_j;E) = \exp(i\mathbf{k}\cdot\mathbf{R}_j)\, G(\mathbf{k},\mathbf{x};E), \tag{135}$$

imposed by Bloch's theorem. The Green's function is expanded in terms of plane-wave eigenfunctions of the free-particle operator,

$$H_0 = (\hbar^2/2m)\nabla^2 + E. \tag{136}$$

Using such a plane-wave expansion, we find by direct substitution in Eq. (134)

$$G(\mathbf{k},\mathbf{x}-\mathbf{x}';E) = -\frac{1}{\Omega_{\mathbf{x}}} \sum_{\mathbf{G}} \frac{\exp[i(\mathbf{k}+\mathbf{G})\cdot(\mathbf{x}-\mathbf{x}')]}{(-\hbar^2/2m)(\mathbf{k}+\mathbf{G})^2 - E}, \tag{137}$$

where $\Omega_{\mathbf{x}}$ is the volume of the primitive cell.

The Schrödinger equation associated with a scattering potential $V(\mathbf{x})$ for a Bloch state in a crystal,

$$[-(\hbar^2/2m)\nabla^2 + V(\mathbf{x})]\,\psi(\mathbf{k},\mathbf{x}) = \epsilon(\mathbf{k})\,\psi(\mathbf{k},\mathbf{x}), \tag{138}$$

is then transformed, using standard results of scattering theory, into an integral equation

$$\psi(\mathbf{k},\mathbf{x}) = \int d^3\mathbf{x}'\, G(\mathbf{k},\mathbf{x}-\mathbf{x}';E)\, V(\mathbf{x}')\,\psi(\mathbf{k},\mathbf{x}'), \tag{139}$$

Within the muffin-tin approximation, the true crystal potential $V(\mathbf{x})$ appearing in the integral equation Eq. (139) is replaced by its spherically symmetric muffin-tin form, $V_{\mathrm{MT}}(r)$, and we obtain

$$\psi(\mathbf{k},\mathbf{x}) = \int d^3\mathbf{x}'\, G(\mathbf{k},\mathbf{x}-\mathbf{x}';E)\, V_{\mathrm{MT}}(r')\,\psi(\mathbf{k},\mathbf{x}'). \tag{140}$$

In practical implementations of the Green's-function method, the Bloch state $\psi(\mathbf{k},\mathbf{x})$ is expanded within the muffin-tin sphere as

$$\psi(\mathbf{k},\mathbf{x}) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} C_{lm}(\mathbf{k})\, Y_l^m(\hat{\mathbf{x}})\, R_l(E;r). \tag{141}$$

When the expansion Eq. (141) is substituted into the integral equation, a determinant compatibility relation is obtained, and its solution allows a determination of the energy eigenvalues E and the expansion coefficients, $C_{lm}(\mathbf{k})$. Explicit expression for the Green's-function matrix elements can be found in the literature (Bassani and Pastori Parravicini, 1975).

Application of the boundary conditions and Bloch's theorem lead to a secular equation similar to that encountered in the discussion of the LMTO method [Eq. (132)]. However, in the KKR–Green's-function method, energy-dependent tail functions of the form of spherical Bessel and Neumann functions $[j_l(\kappa r)$ and $n_l(\kappa r)$ where $\kappa \sim \sqrt{E}]$ are used instead of the functions $(r/r_s)^l$ and $(rs/r)l+1$ appearing in the definition of $\chi_{lm}(E,\mathbf{x})$ [Eq. (126)]. Consequently, in the KKR–Green's-function method the structure constants $S^{lm}_{l'm'}(\mathbf{k},E)$ are energy-dependent. The resulting secular equations are known as the *KKR equations*.

As in the case of the linearized APW (LAPW) and MTO (LMTO) method, the Green's function can be made more efficient and cast in an eigensystem form by performing a linearization of the Green's-function matrix elements. The basic principles of the Green's-function method are very similar to those of the APW method, and both methods lead to the same results when the same muffin-tin potential is used.

2.4 Applications of Band Theory

The problem of calculating the electronic band structure of materials has interested a very large number of workers in the field of solid-state physics. It is clearly impossible even to summarize the outstanding achievements that have been accomplished in this field. While the quantitative features of the band structure depend on the details of the crystal potential, it is useful to emphasize general features. The purpose of this section is merely to put the somewhat abstract concepts introduced above and in the preceding section in a more practical context where the reader can appreciate the high degree of agreement between calculated band structures and experimental measurements. Moreover, we would like to give the reader a sense of the order of magnitude of important quantities: energy-band gap, bandwidth, etc.

2.4.1 Pseudopotential Band Structure of Silicon. We now present results of pseudopotential calculations of the band structure, density of states, and valence charge density for silicon (Cohen and Chelikowsky, 1982). Silicon crystallizes in the cubic diamond structure. This structure is based on a face-centered-cubic Bravais lattice (see Fig. 2) with a basis of two atoms: one at $\mathbf{d}_1=\mathbf{0}$ and one at $\mathbf{d}_2=(a/4)(\hat{\mathbf{x}}+\hat{\mathbf{y}}+\hat{\mathbf{z}})$, where a is the length of the cube side. The atoms exhibit perfect tetrahedral coordination with bond angles $\theta=\arccos\left(-\frac{1}{3}\right)=109.47°$. The cubic diamond structure is indicated in Fig. 16 (Kittel, 1957). It possesses inversion symmetry with respect to the point $(a/8)(\hat{\mathbf{x}}+\hat{\mathbf{y}}+\hat{\mathbf{z}})$ at the center of the bond joining the two basis atoms in the primitive cell.

The energy-band structure of silicon is shown in Fig. 17(a) where the energy bands $\epsilon_n(\mathbf{k})$ are plotted along high-symmetry $\mathbf{k}$ directions within the Brillouin zone (Cohen and Chelikowsky, 1982). These calculations were performed with the empirical pseudopotential method. The method is not self-consistent because the crystal potential is not recalculated due to the screening by the valence electrons, and is called empirical because the local and nonlocal pseudopotential matrix elements of Eq. (117) are fitted to reflectivity and photoemission measurements. The symbols Γ_j, X_j, and L_j label the irreducible representations of the point group at high-symmetry $\mathbf{k}$ points within the Brillouin zone (Bouckaert *et al.*, 1936). Spin-orbit interac-

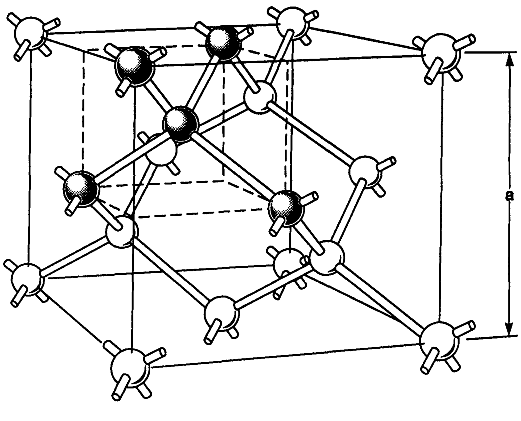

FIG. 16. Cubic diamond structure. The cubic diamond structure is based on a face-centered-cubic Bravais lattice (see Fig. 2) with a two-atom basis. (Reproduced with permission from Kittel, 1957, p. 37.)

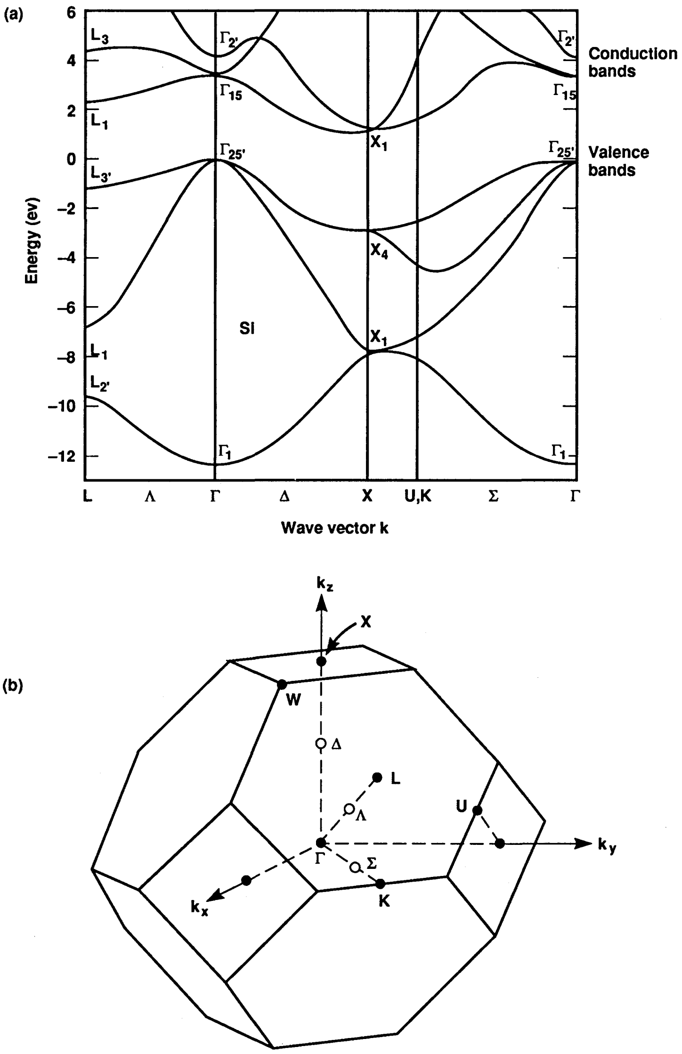

FIG. 17. (a) Energy-band structure of silicon as calculated by the empirical pseudopotential method. The calculations were performed using empirical nonlocal pseudopotentials. Spin-orbit effects are neglected. The valence-band maximum is taken as the zero of energy. The filled valence bands span the energy region $\epsilon < 0$ and the empty conduction bands span the energy region $\epsilon > 0$ as indicated. The symbols Γ_j, X_j, and L_j label the irreducible representations of the point group at high-symmetry **k** points within the Brillouin zone. Standard notation (Bouckaert *et al.*, 1936) is used to indicate the symmetry points and lines within the Brillouin zone (also shown in Fig. 2) shown in (b). (Reproduced with permission from Cohen and Chelikowsky, 1982, p. 230.) (b) Brillouin zone for the face-centered-cubic lattice. (Reproduced with permission from Kittel, 1963, p. 213.)

tions were not considered in these calculations. The Brillouin zone is shown in Fig. 17(b) with the appropriate symmetry labels [see also Fig. 2(b)].

Inspection of Fig. 17(a) reveals the existence of an *energy-band gap* separating the filled valence bands and the empty conduction bands, and, consequently, silicon is a semiconductor [see Fig. 7(a)]. Silicon exhibits an indirect band gap since the valence-band maximum and the conduction-band minimum do not occur at the same point in the Brillouin zone (**k** space): The valence-band maximum occurs at the Γ point ($\mathbf{k}=\mathbf{0}$) whereas the conduction-band minimum occurs near the X point [$\mathbf{k}=(2\pi/a)(1,0,0)$].

We now discuss the symmetry features of the energy band at the center ($\mathbf{k}=\mathbf{0}$) of the Brillouin zone. The valence-band maximum is at $\mathbf{k}=\mathbf{0}$. It is threefold degenerate (neglecting spin) and belongs to the irreducible representation $\Gamma_{25'}^{v}$, whose basis functions transform like xy,yz,zx about the center of the line joining the two basis atoms in the primitive cell. The threefold-degenerate irreducible representation $\Gamma_{25'}^{v}$ of the valence-band maximum may be formed from the ***bonding*** linear combination of p orbitals on the two silicon atoms. Similarly, the threefold-degenerate irreducible representation Γ_{15}^{c} of the conduction band may be formed from the ***antibonding*** linear combination of the p orbitals on the two silicon atoms. The ***bonding*** linear combination of the s orbitals on the silicon atoms forms the one-dimensional Γ_1^{v} irreducible rep-

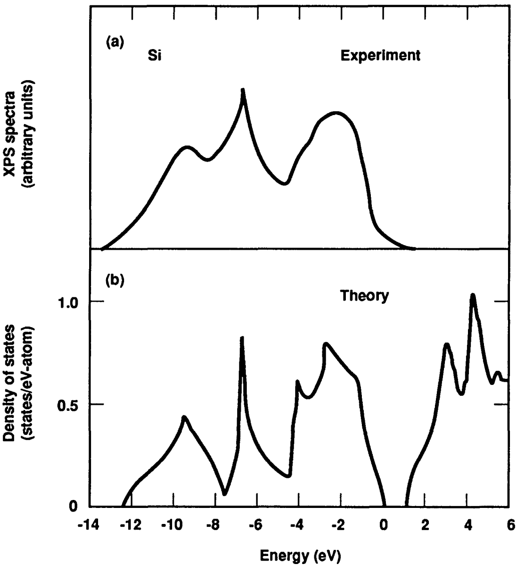

FIG. 18. Calculated electron density of states for silicon (Cohen and Chelikowsky, 1982) compared with x-ray photoemission spectroscopy measurements (Ley *et al.*, 1974). The calculations were performed using empirical nonlocal pseudopotentials. Spin-orbit effects are neglected. The van Hove singularities discussed in Sec. 1.5.3 and shown in Fig. 8 are clearly apparent in the profile of the silicon density of states. (Reproduced with permission from Cohen and Chelikowsky, 1982, p. 231.)

resentation at the bottom of the valence band, whereas the *antibonding* linear combination of the *s* orbitals on the silicon atoms forms the one-dimensional $\Gamma_{2'}^{c}$ irreducible representation of the conduction band. The inclusion of spin-orbit interactions introduces additional energy-band splittings and degeneracies due to time-reversal symmetry. The ordering and degeneracy of the bands at various points of the Brillouin zone depend sensitively on the details of the crystal potential and on the symmetry of the lattice. If spin-orbit interactions were included in the calculation, the energy bands would be doubly degenerate at each **k** point within the Brillouin zone by a combination of time-reversal and inversion symmetries [see Eq. (79)].

Figure 18 shows the calculated electron density of states for silicon (Cohen and Chelikowsky, 1982) along with x-ray photoemission spectroscopy measurements (Ley *et al.*, 1974). The general features of the density of states observed experimentally are well reproduced by the pseudopotential calculations. The van Hove singularities discussed in Sec. 1.5.3 and shown in Fig. 8 are clearly apparent in the profile of the silicon density of states. In Fig. 19, we indicate the calculated valence pseudocharge density for silicon obtained by summing the individual energy-band contributions over the occupied bands (Cohen and Chelikowsky, 1982). X-ray measurements of the charge density of silicon are also shown in Fig. 19. The agreement between the calculated and measured charge density is excellent. The pseudopotential calculation reproduces very well the essential feature of the silicon covalent bond, i.e., the accumulation of electronic charge in the bond region between nearest-neighbor silicon atoms.

2.4.2 Electron-Structure Trends among the Elements. An important goal of electron-structure theory is to establish trends and relationships between calculated energy bands and the chemical composition and crystal structure of solids. Much effort has been

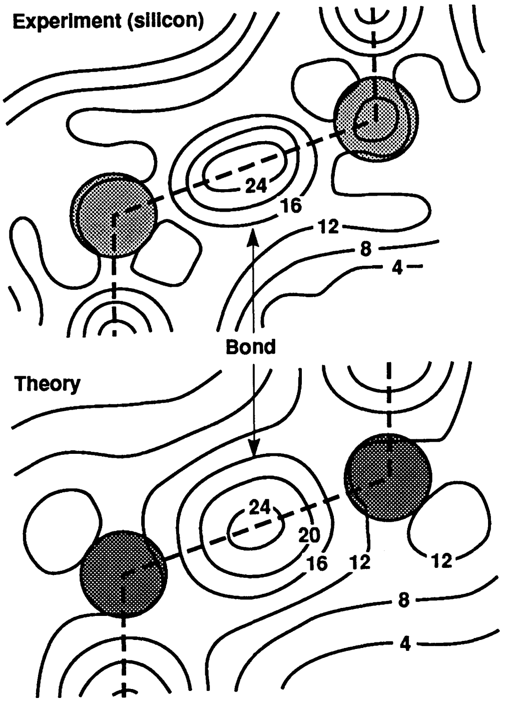

FIG. 19. Valence charge density for silicon as determined from x-ray measurements (Yang and Coppens, 1974) and as calculated using a nonlocal pseudopotential. The atomic cores are represented by the shaded regions where the pseudopotential results are not expected to be accurate. The charge contours are measured in units of e/Ω_x, where Ω_x is the volume of the unit cell. (Reproduced with permission from Cohen and Chelikowsky, 1982, p. 235.)

expended at refining the quantitative aspects of these relationships. Space limitation does not permit us to present trends of calculated quantities (energy-band gaps, bandwidths, etc.) among the various elements. Excellent contributions have appeared in the literature (Moruzzi *et al.*, 1978; Papaconstantopoulos, 1986) with the purpose of collecting calculated energy-band structures and ground-state properties of many elements. The reader interested in getting a sense of general band-structure trends among the elements is urged to consult these references.

3. FIRST-PRINCIPLES TOTAL-ENERGY METHODS

In the preceding section, our discussion has been restricted to the electron band-structure problem, i.e., the calculation of the crystal energy bands $\epsilon_n(\mathbf{k})$ and corresponding Bloch states $|\psi_n(\mathbf{k})\rangle$. We now turn to the calculation of the *total energy* of a solid. The calculation of the total energy involves the evaluation of the electronic charge density $n(\mathbf{x})$ from a knowledge of the crystal Bloch solutions $|\psi_n(\mathbf{k})\rangle$.

A tremendous conceptual advance was realized in the mid-1960s by Hohenberg, Kohn, and Sham (Hohenberg and Kohn, 1964; Kohn and Sham, 1965), who formulated the *density-functional theory.* This framework provides an extremely powerful technique for electronic-structure and total-energy calculations in solids, atoms, and molecules. In fact, it is the single most widely used formalism in first-principles electronic-structure calculations within a band-theoretical framework.

3.1 Density-Functional Theory

The basic postulate of the density-functional theory is that the ground-state energy E_N of a system of N electrons moving in a given external potential $v(\mathbf{x})$ can be obtained from a knowledge of the self-consistent charge density $n(\mathbf{x})$. This concept offers tremendous computational advantages since the electron density $n(\mathbf{x})$ is considered the basic variable rather than the complex many-electron wave function.

We now indicate the basic postulates of the density functional theory (Lang, 1973). Consider a many-electron system in its (nondegenerate) ground state and moving in a static external potential $v(\mathbf{x})$. We denote the many-electron ground state by $|\Psi\rangle$. The Hamiltonian operator of the system is

$$H=T+V+U, \tag{142a}$$

where

$$T=\frac{\hbar^2}{2m}\int d^3x \nabla\psi^\dagger(\mathbf{x})\nabla\psi(\mathbf{x}) \tag{142b}$$

is the kinetic energy,

$$V=\int d^3x\, v(\mathbf{x})\psi^\dagger(\mathbf{x})\psi(\mathbf{x}) \tag{142c}$$

is the interaction described by the external potential $v(\mathbf{x})$, and

$$U=\frac{e^2}{2}\int d^3x\, d^3y \frac{1}{|\mathbf{x}-\mathbf{y}|} \times\psi^\dagger(\mathbf{x})\psi^\dagger(\mathbf{y})\psi(\mathbf{y})\psi(\mathbf{x}) \tag{142d}$$

is the Coulomb electron–electron interaction. [In Eqs. (142), $\psi(\mathbf{x})$ refers to a fermion field operator and not to a wave function.] The equilibrium electron density $n(\mathbf{x})$ corresponding to the ground state $|\Psi\rangle$ is the expectation value

$$n(\mathbf{x})\equiv\langle\Psi|\psi^\dagger(\mathbf{x})\psi(\mathbf{x})|\Psi\rangle, \tag{143}$$

and is clearly a functional of the external potential $v(\mathbf{x})$. However, it can also be shown that $v(\mathbf{x})$ is *uniquely* determined by $n(\mathbf{x})$. Hohenberg and Kohn demonstrated that the external potential $v(\mathbf{x})$ of a nondegenerate ground state is (apart from an additive constant) a *unique functional of the ground-state electronic charge density* $n(\mathbf{x})$: Only one $v(\mathbf{x})$ can result in a given $n(\mathbf{x})$. In other words, the density distribution $n(\mathbf{x})$ associated with a ground state $|\Psi\rangle$ corresponding to an external potential $v(\mathbf{x})$ cannot be reproduced by the ground state $|\Psi'\rangle$ corresponding to another potential $v'(\mathbf{x})\neq v(\mathbf{x})$, apart from an additive constant. As a result, the many-electron ground state $|\Psi\rangle$ is also a unique functional of $n(\mathbf{x})$, since the potential $v(\mathbf{x})$ fixes the Hamiltonian H that determines $|\Psi\rangle$.

Let us define an *electron energy functional,*

$$E_v[n(\mathbf{x})]=\int d^3x\, v(\mathbf{x})n(\mathbf{x})+F[n(\mathbf{x})], \tag{144a}$$

where the quantity $F[n(\mathbf{x})]$ is a universal [i.e., it does not explicitly depend on $v(\mathbf{x})$] functional of $n(\mathbf{x})$ defined as

$$F[n(\mathbf{x})] \equiv \langle \Psi | T+U | \Psi \rangle. \qquad (144b)$$

An important theorem of the density-functional theory is that the energy functional $E_v[n(\mathbf{x})]$ obeys a variational principle in the charge density $n(\mathbf{x})$: For the correct ground-state density $n(\mathbf{x}) = \hat{n}(\mathbf{x})$ associated with the external potential $v(\mathbf{x})$ and integrating to the total number N of electrons in the system,

$$\int d^3x\, \hat{n}(\mathbf{x}) = N, \qquad (145)$$

the functional $E_v[\hat{n}(\mathbf{x})]$ evaluated at the density $n(\mathbf{x}) = \hat{n}(\mathbf{x})$ is minimum and equal to the ground-state energy E_N. Therefore, E_N is the minimum value of $E_v[n(\mathbf{x})]$ with respect to variations in densities $n(\mathbf{x})$, i.e.,

$$E_N = \min_{n(\mathbf{x})} E_v[n(\mathbf{x})], \qquad (146)$$

for densities $n(\mathbf{x})$ satisfying

$$\int d^3x\, n(\mathbf{x}) = N. \qquad (147)$$

The density $\hat{n}(\mathbf{x})$ that minimizes the energy functional $E_v[n(\mathbf{x})]$ is the correct ground-state density. The power of the Hohenberg–Kohn theorem is that useful approximations can be made, even through the exact form of the functional is not known.

It is convenient to separate the electron-electron Coulomb term from the functional $F[n(\mathbf{x})]$ and write

$$F[n(\mathbf{x})] = \frac{e^2}{2} \int d^3x\, d^3y \frac{n(\mathbf{x})n(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|} + T_s[n(\mathbf{x})] + E_{\text{xc}}[n(\mathbf{x})], \qquad (148)$$

where $T_s[n(\mathbf{x})]$ is a kinetic energy functional for a noninteracting system of electrons of density $n(\mathbf{x})$ and $E_{\text{xc}}[n(\mathbf{x})]$ is a functional which contains all the many-body effects of exchange and correlation. The electron energy functional can therefore be written as

$$E_v[n(\mathbf{x})] = \int d^3x\, v(\mathbf{x})n(\mathbf{x}) + \frac{e^2}{2} \int d^3x\, d^3y \frac{n(\mathbf{x})n(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|} + T_s[n(\mathbf{x})] + E_{\text{xc}}[n(\mathbf{x})]. \qquad (149)$$

The functional $E_v[n(\mathbf{x})]$ given in Eq. (149), when evaluated at the correct ground-state density $n(\mathbf{x}) = \hat{n}(\mathbf{x})$, is the expression for the ground-state energy of a many-electron system in a fixed external potential $v(\mathbf{x})$.

The exact form of $E_v[n(\mathbf{x})]$ is, of course, unknown. There are essentially three difficulties in evaluating the functional $E_v[n(\mathbf{x})]$ in actual calculations:

1. one needs to calculate the self-consistent $n(\mathbf{x})$ that minimizes $E_v[n(\mathbf{x})]$ and yields E_N;
2. the evaluation of the kinetic energy $T_s[n(\mathbf{x})]$ from the density $n(\mathbf{x})$ is not trivial since no information on the wave function is available; and
3. the exact form of the exchange- correlation functional $E_{\text{xc}}[n(\mathbf{x})]$ is unknown, except for a few simple systems, and approximations have to be made.

The first two difficulties can be overcome by a variational principle: Kohn and Sham (1965) used the variational principle for the minimization of $E_v[n(\mathbf{x})]$ to derive a set of one-electron equations,

$$\{ -(\hbar^2/2m)\nabla^2 + v_{\text{eff}}[n(\mathbf{x})] \} \psi_i(\mathbf{x}) = \epsilon_i \psi_i(\mathbf{x}), \qquad (150)$$

where $\psi_i(\mathbf{x})$ are the one-electron wave functions, ϵ_i are the one-electron energy eigenvalues, and $v_{\text{eff}}[n(\mathbf{x})]$ is an integro-differential potential operator defined as

$$v_{\text{eff}}[n(\mathbf{x})] = v(\mathbf{x}) + e^2 \int d^3y \frac{n(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|} + \frac{\delta E_{\text{xc}}[n(\mathbf{x})]}{\delta n(\mathbf{x})} \equiv \varphi(\mathbf{x}) + \mu_{\text{xc}}[n(\mathbf{x})], \qquad (151)$$

where we have defined the *electrostatic potential*

$$\varphi(\mathbf{x}) \equiv v(\mathbf{x}) + e^2 \int d^3y \frac{n(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|}, \qquad (152a)$$

and the *exchange-correlation potential*

$$\mu_{\text{xc}}[n(\mathbf{x})] \equiv \frac{\delta E_{\text{xc}}[n(\mathbf{x})]}{\delta n(\mathbf{x})}. \qquad (152b)$$

The self-consistent solution of the *single-particle Kohn–Sham equations* Eq. (150) forms the basis of the most self-consistent electron structure calculations performed in electron band theory.

The charge density $n(\mathbf{x})$ is calculated from a knowledge of the single-particle wave functions $\psi_i(\mathbf{x})$,

$$n(\mathbf{x}) = \sum_{i(\text{occ.})} |\psi_i(\mathbf{x})|^2, \tag{153}$$

where the summation runs over occupied states. The kinetic energy functional can be evaluated from a knowledge of the energy eigenvalues ϵ_i (Lang, 1973),

$$T_s[n(\mathbf{x})] = \sum_{i(\text{occ.})} \epsilon_i - \int d^3x v_{\text{eff}}[n(\mathbf{x})]n(\mathbf{x}). \tag{154}$$

The solution of the one-electron Kohn-Sham equations requires a knowledge of the exchange-correlation potential $\mu_{\text{xc}}[n(\mathbf{x})]$. Since the exact form of $E_{\text{xc}}[n(\mathbf{x})]$ is not known, the *local-density approximation (LDA)* is almost universally made in actual calculations. In the LDA, the exchange-correlation functional $E_{\text{xc}}[n(\mathbf{x})]$ is approximated by

$$\begin{aligned} E_{\text{xc}}[n(\mathbf{x})] &\approx E_{\text{xc}}^{\text{LDA}}[n(\mathbf{x})] \\ &= \int d^3x\, n(\mathbf{x})\epsilon_{\text{xc}}[n(\mathbf{x})], \end{aligned} \tag{155}$$

where $\epsilon_{\text{xc}}[n(\mathbf{x})]$ is the exchange-correlation energy per electron of a *uniform electron gas* of density n evaluated at the *local density* $n(\mathbf{x})$. The exchange-correlation potential in the LDA becomes

$$\begin{aligned} \mu_{\text{xc}}^{\text{LDA}}[n(\mathbf{x})] &= \frac{\delta E_{\text{xc}}^{\text{LDA}}[n(\mathbf{x})]}{\delta n(\mathbf{x})} \\ &= \frac{d}{dn(\mathbf{x})}\{n(\mathbf{x})\epsilon_{\text{xc}}[n(\mathbf{x})]\}. \end{aligned} \tag{156}$$

There exist a number of expressions for $\epsilon_{\text{xc}}[n(\mathbf{x})]$ in the literature (Lang, 1973).

The Kohn–Sham equations must be solved self-consistently: for a given atomic structure, one starts with an assumed density $n(\mathbf{x})$ and constructs the potential $v_{\text{eff}}[n(\mathbf{x})]$ from which a new density $n(\mathbf{x})$ is obtained. The procedure is repeated until self-consistency is achieved and the density $n(\mathbf{x})$ and potential $v_{\text{eff}}[n(\mathbf{x})]$ no longer change. A schematic flow diagram of the self-consistent procedure is indicated in Fig. 20 (Cohen and Chelikowsky, 1982). The solution of the one-electron Kohn-Sham equations can be obtained with the band-structure techniques discussed in Sec. 2. When the evaluation of the Hamiltonian matrix elements does not require the use of empirical parameters, the methods described in this section are commonly referred to as *first-principles* (or *ab initio*) *self-consistent electron-structure calculations*.

3.2 Total Energy

The self-consistent solution of the Kohn–Sham equations allows a calculation of the ground-state energy of the system by minimization of the energy functional

$$\begin{aligned} E_v[n(\mathbf{x})] &= \int d^3x\, v(\mathbf{x})n(\mathbf{x}) \\ &+ \frac{e^2}{2}\int d^3\mathbf{x}\, d^3\mathbf{y} \frac{n(\mathbf{x})n(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|} \\ &+ T_s[n(\mathbf{x})] + E_{\text{xc}}[n(\mathbf{x})], \end{aligned} \tag{157}$$

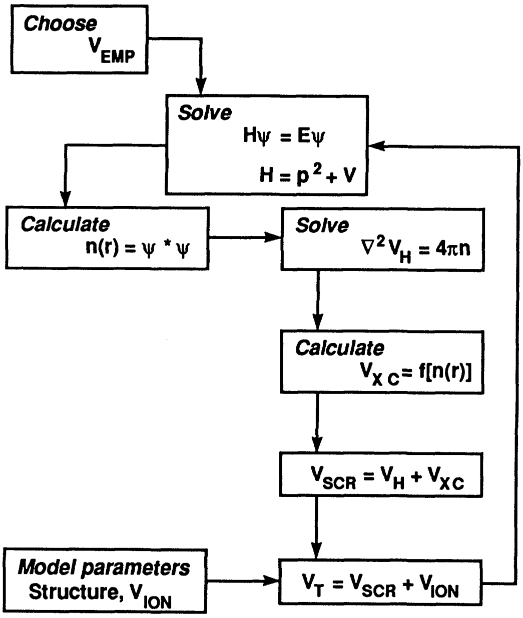

FIG. 20. Flow diagram of the self-consistent solution of Kohn–Sham one-electron equations. (Reproduced with permission from Cohen and Chelikowsky, 1982, p. 226.)

which can be written in a somewhat more useful form in terms of the energy eigenvalues ϵ_i,

$$\begin{aligned} E_v[n(\mathbf{x})] = {} & \sum_{i(\text{occ.})} \epsilon_i - \frac{e^2}{2} \int d^3x\, d^3y \\ & \times \frac{n(\mathbf{x})n(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|} + E_{\text{xc}}[n(\mathbf{x})] \\ & - \int d^3x\, \mu_{\text{xc}}[n(\mathbf{x})]n(\mathbf{x}), \qquad (158) \end{aligned}$$

where we have used the expression for $T_s[n(\mathbf{x})]$ given by Eq. (154). In order to evaluate the total energy of the solid, one must add the ion-ion Coulomb interaction to the electron functional $E_v[n(\mathbf{x})]$ given by Eqs. (157) and (158):

$$\begin{aligned} E_{\text{total}} & = E_{\text{ion-ion}} + E_v[n(\mathbf{x})] \\ & = e^2 \sum_{I<J} \frac{Z_I Z_J}{|\mathbf{R}_I - \mathbf{R}_J|} + \int d^3x\, v(\mathbf{x})n(\mathbf{x}) \\ & \quad + \frac{e^2}{2} \int d^3x\, d^3y\, \frac{n(\mathbf{x})n(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|} \\ & \quad + T_s[n(\mathbf{x})] + E_{\text{xc}}[n(\mathbf{x})] \\ & \equiv E_{\text{ion-ion}} + E_{\text{hartree}} + E_{\text{kinetic}} + E_{\text{xc}}, \qquad (159) \end{aligned}$$

where $\mathbf{R}_I$ ($\mathbf{R}_J$) are the positions of the ions of ionic charge Z_I (Z_J). In actual calculations, the functional $E_v[n(\mathbf{x})]$ to be minimized is evaluated by Eq. (158) using the energy eigenvalues ϵ_i of the Kohn–Sham equations. The resulting expression,

$$\begin{aligned} & E_{\text{total}}[\{\psi_i(\mathbf{x})\},\{\mathbf{R}_I\}] \\ & \quad = e^2 \sum_{I<J} \frac{Z_I Z_J}{|\mathbf{R}_I - \mathbf{R}_J|} + \sum_{i(\text{occ.})} \epsilon_i \\ & \quad - \frac{e^2}{2} \int d^3x\, d^3y \frac{n(\mathbf{x})n(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|} + E_{\text{xc}}[n(\mathbf{x})] \\ & \quad - \int d^3x\, \mu_{\text{xc}}[n(\mathbf{x})]n(\mathbf{x}), \qquad (160) \end{aligned}$$

gives the total energy of the system as a function of the electronic variables $\{\psi_i(\mathbf{x})\}$ and ionic variables $\{\mathbf{R}_I\}$.

3.3 Recent Developments in Density-Functional Theory: Harris Functional

An efficient strategy to perform total-energy LDA calculations using a non-self-consistent, yet accurate, technique has recently been proposed (Harris, 1985). The starting point of this approach is to construct an initial charge density by summing the individual overlapping contributions of atomiclike densities,

$$n_f(\mathbf{x}) = \sum_k n_k(\mathbf{x}) \qquad (161)$$

where the isolated atomiclike charge densities $n_k(\mathbf{x})$ need not be the true atomic densities and the density $n_f(\mathbf{x})$ is the sum of these individual contributions or fragments. A one-electron potential $\hat{v}_{\text{eff}}[n_f(\mathbf{x})])$ is then constructed from the overlapping fragment densities $n_f(\mathbf{x})$,

$$\hat{v}_{\text{eff}}[n_f(\mathbf{x})] = \varphi_f(\mathbf{x}) + \mu_{\text{xc}}[n_f(\mathbf{x})], \qquad (162)$$

where the potential $\varphi_f(\mathbf{x})$ is given by Eq. (152a) and evaluated for the density $n_f(\mathbf{x})$,

$$\varphi_f(\mathbf{x}) \equiv v(\mathbf{x}) + e^2 \int d^3y\, \frac{n_f(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|}. \qquad (163)$$

Similarly, the exchange-correlation potential $\mu_{\text{xc}}[n_f(\mathbf{x})]$ is given by Eq. (152b) and evaluated for the density $n_f(\mathbf{x})$. The energy eigenvalues $\hat{\epsilon}_i$ corresponding to the potential $\hat{v}_{\text{eff}}[n_f(\mathbf{x})]$ are determined by the solution of Eq. (150).

The difference between the true self-consistent charge density $n(\mathbf{x})$ and $n_f(\mathbf{x})$ is

$$\Delta n(\mathbf{x}) \equiv n(\mathbf{x}) - n_f(\mathbf{x}). \qquad (164)$$

Similarly, the difference between the true self-consistent potential $v_{\text{eff}}[n(\mathbf{x})]$ and the potential $\hat{v}_{\text{eff}}[n_f(\mathbf{x})]$ is

$$\begin{aligned} \Delta v_{\text{eff}}(\mathbf{x}) & \equiv v_{\text{eff}}[n(\mathbf{x})] - \hat{v}_{\text{eff}}[n_f(\mathbf{x})] \\ & = [\varphi(\mathbf{x}) - \varphi_f(\mathbf{x})] + \{\mu_{\text{xc}}[n(\mathbf{x})] \\ & \quad - \mu_{\text{xc}}[n_f(\mathbf{x})]\}, \qquad (165) \end{aligned}$$

which is assumed to be small.

It can be shown (Harris, 1985) that the use of the $n_f(\mathbf{x})$ in the total-energy functional, Eq. (160), introduces corrections which are of order $[\Delta n(\mathbf{x})]^2$ and $[\Delta v_{\text{eff}}(\mathbf{x})]^2$. The total energy can be expressed entirely in terms of the overlapping fragment density $n_f(\mathbf{x})$ and the energy eigenvalues $\hat{\epsilon}_i$,

$$\begin{aligned}E_{\text{total}} \approx e^2 \sum_{I<J} \frac{Z_I Z_J}{|\mathbf{R}_I - \mathbf{R}_J|} + \sum_{i(\text{occ.})} \hat{\epsilon}_i \\ - \frac{e^2}{2} \int d^3x\, d^3y\, \frac{n_f(\mathbf{x}) n_f(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|} \\ + E_{\text{xc}}[n_f(\mathbf{x})] \\ - \int d^3x\, \mu_{\text{xc}}[n_f(\mathbf{x})] n_f(\mathbf{x}), \qquad (166)\end{aligned}$$

to within the corrections indicated above. The importance of the method derives from the fact that an accurate evaluation of the total energy E_{total} is possible through the use of Eq. (166) without the need to perform a self-consistent calculation on the charge density and the potential. Successful applications of the Harris functional have been performed on numerous solid-state systems and molecules and will be discussed in the next section.

3.4 Applications of Total-Energy Methods

Self-consistent first-principles total-energy methods have been applied to a wide variety of problems: determination of structural properties of bulk materials and solid surfaces, prediction of phase transformation between solid phases, electron structure of alloys, calculation of phonon dispersion relations in bulk and at surfaces, etc. These methods have reached a high level of sophistication and maturity. The interested reader is advised to consult the numerous recent reviews which have appeared in the field (DeVreese and Van Camp, 1985; Srivastava and Weaire, 1987; Jones and Gunnarson, 1989).

The examples given in this section will give the reader a sense of the level of accuracy and the predictive power of modern first-principles total-energy methods. As an illustration, we focus on the effect of hydrostatic pressure on the atomic and electron structure of the elements. First-principles total-energy calculations have had a tremendous impact on this area of condensed-matter physics and form the basis of our understanding of pressure-induced structural transformations among the elements (McMahan, 1986). First we examine the ability of first-principles pseudopotential methods to predict the ground-state properties and pressure-induced phase transformations of various tetrahedrally bonded materials exhibiting covalent bonding at atmospheric pressure. We then indicate similar predictions for alkali and alkaline-earth metals as afforded by the LMTO method. The first-principles pseudopotential method has had an enormous impact on our understanding of the electronic structure of simple metals and covalent materials, whereas all-electron methods such as the LMTO and the APW have had the same level of impact for transition metals. We then compare the predictions obtained by different electron-structure methods for a single material. Finally, we present recent applications of the Harris functional to a wide range of materials and compare its predictions with those afforded by self-consistent LDA calculations and with available experiments.

3.4.1 First-Principles Pseudopotentials: Covalent Materials. As a first illustration of the power of modern total-energy methods, we will examine the determination of the crystal stability and pressure-induced phase transformations in covalently bonded elemental and compound semiconductors. There is ample experimental and theoretical evidence that the application of pressure is inimical to the covalent bond. In a general argument, localization of charge in the covalent bond minimizes the potential energy at the expense of the kinetic energy. Given the respective $V^{-1/3}$ and $V^{-2/3}$ scaling of the potential and kinetic energy contributions with volume V, the latter must eventually dominate as V decreases, favoring more uniform electron density and more close-packed structures. An important aspect of pressure-induced phase transformations in materials is the general tendency for heavier members of a given group to represent high-pressure forms of lighter members (McMahan, 1986). This behavior follows from an increase in the size of the ion core radius relative to the atomic or Wigner–Seitz radius as one moves to heavier group members, thus effectively compressing the valence electrons between the two radii. The examples indicated below refine this perspective.

The first calculation which established that the determination of the static structural properties, the crystal stability, and the pressure-induced phase transformations could be achieved by first-principles total-energy methods (within the LDA) is due to Yin and Cohen (1982b). Their calculations are based on the first-principles pseudopotential method, and the input information consists only of the atomic number of the elements and the crystal structure. Numerous subsequent applications of first-principles pseudopotential total-energy methods have established that the calculated values agree with observed quantities generally to within 1% for lattice constants, 6% for bulk moduli, and 5% for cohesive energies. A summary of calculated bulk properties using first-principles total-energy methods is indicated in Table 2, where calculated values are compared with available experimental measurements for elemental and compound tetrahedrally coordinated semiconductors and insulators. Inspection of Table 2 reveals the tremendous predictive power of modern total-energy methods formulated within the LDA.

Table 2. Calculated bulk ground-state properties of elemental and compound tetrahedrally coordinated semiconductors and insulators using first-principles pseudopotential total-energy methods within the local-density approximation. The quantities shown are the equilibrium lattice constant a_0, the bulk modulus B_0, the cohesive energy E_{coh}, and the transition pressure p_{trans}. For each material, the first line gives the calculated value and the second line (in parentheses) gives the experimental result.

Material	a_0 (Å)	B_0 (GPa)	E_{coh} (eV)	p_{trans} (GPa)

[a] Cohen (1986).
[b] Zhang and Cohen (1987).

We now examine the equation of state and pressure-induced phase transformations in the group-IV elements C, Si, and Ge. Although these elements all have the same number of valence electrons participating in the bonding, an essential difference between C and Si or Ge is the absence of *p* states in the core of C. For Si and Ge, the *p* core states push the *p* valence electrons into the bond region between the atoms to form a single peak in the electron charge density. For C, there are no *p* core states or repulsive *p* pseudopotential and the electron charge density exhibits two peaks along the C—C bond. This difference in core structure is at the origin of many differences in the bonding properties and equations of state between C and Si or Ge.

Results of first-principles pseudopotential total-energy calculations are shown in Fig. 21 for carbon (C: Fahy and Louie, 1984), silicon (Si: Yin and Cohen, 1982b) and germanium (Ge: Yin and Cohen, 1982b) where the calculated total (pseudo)energy is calculated as a function of atomic volume. For Si and Ge, the cubic diamond structure is calculated to be the lowest-energy (i.e., most stable) phase at zero pressure and temperature. For C, the total energy of the hexagonal graphite phase [not shown in Fig. 21(a)] is experimentally known to be lower than that of cubic diamond by approximately 27 meV/atom. This result has also been theoretically confirmed (Yin and Cohen, 1984) and demonstrates that very small differences in structural energies can be accurately extracted from first-principles total energy calculations.

The external pressure that must be applied to induce a phase transformation (the transition pressure) can be extracted by a calculation of the enthalpy or graphically by drawing a common tangent joining two total-energy curves. The slope of that common tangent is the negative of the transition pressure between the two phases through the relation $p = -dE/dV$. Inspection of Fig. 21 reveals that first-principles pseudopotential calculations correctly predict that Si and Ge will transform from a cubic diamond to a β-Sn structure under the application of pressure. The pressure-induced cubic diamond $\rightarrow \beta$-Sn structural trans-

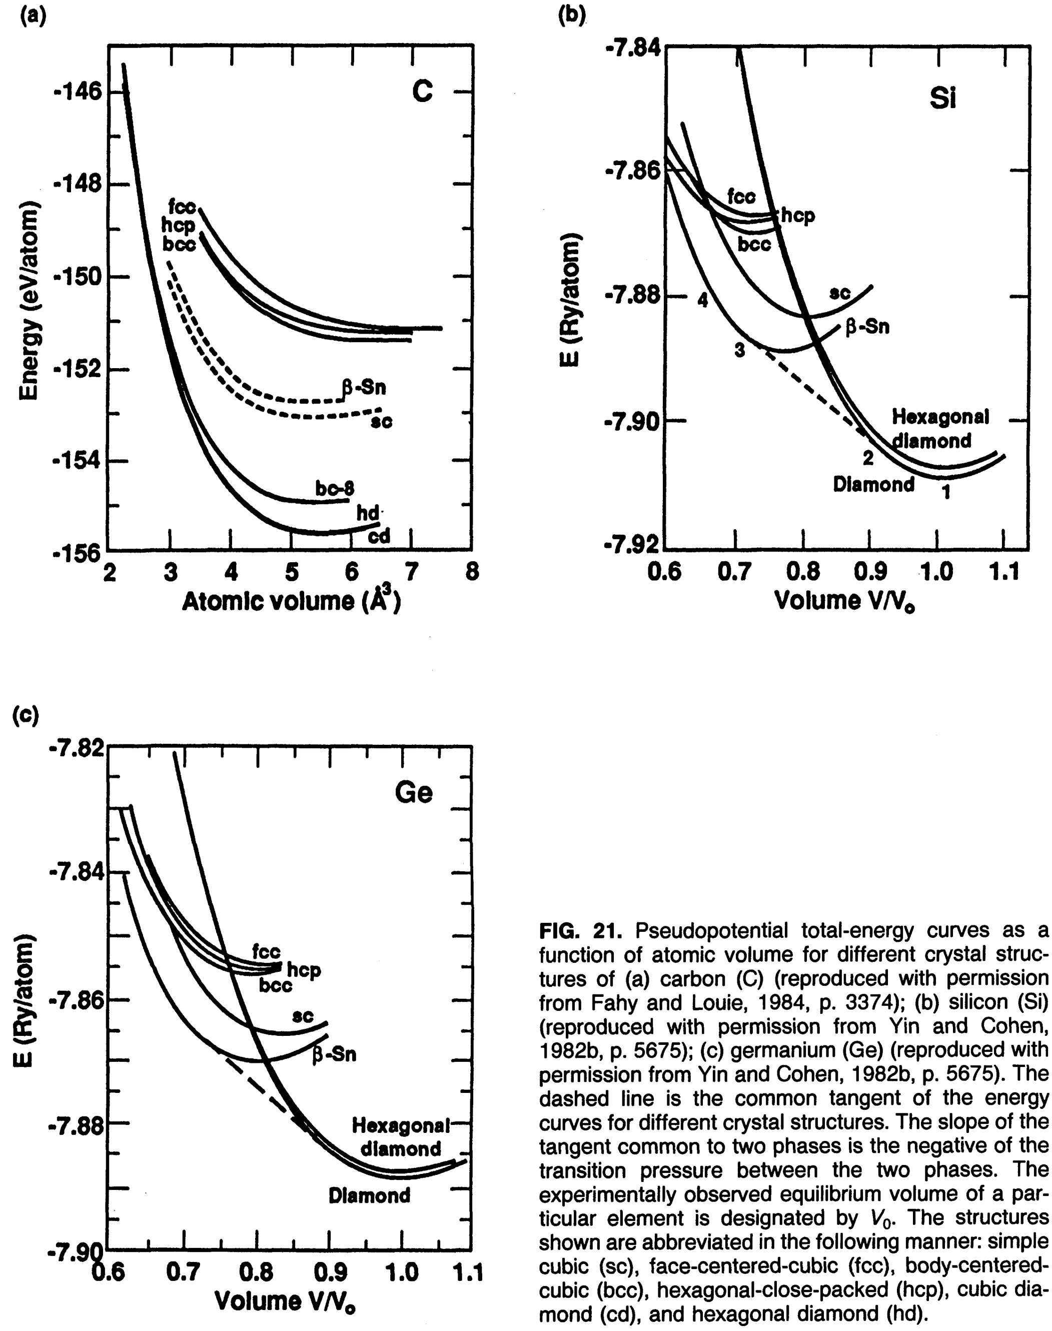

FIG. 21. Pseudopotential total-energy curves as a function of atomic volume for different crystal structures of (a) carbon (C) (reproduced with permission from Fahy and Louie, 1984, p. 3374); (b) silicon (Si) (reproduced with permission from Yin and Cohen, 1982b, p. 5675); (c) germanium (Ge) (reproduced with permission from Yin and Cohen, 1982b, p. 5675). The dashed line is the common tangent of the energy curves for different crystal structures. The slope of the tangent common to two phases is the negative of the transition pressure between the two phases. The experimentally observed equilibrium volume of a particular element is designated by V_0. The structures shown are abbreviated in the following manner: simple cubic (sc), face-centered-cubic (fcc), body-centered-cubic (bcc), hexagonal-close-packed (hcp), cubic diamond (cd), and hexagonal diamond (hd).

formation in Si and Ge does confirm the general tendency, mentioned above, for heavier members of a given group to represent high-pressure forms of lighter members. The complete structural sequence for Si is predicted to be cubic diamond→β-Sn→simple hexagonal →phase VI→hexagonal close-packed→face-centered cubic (Cohen, 1986). The cubic diamond→β-Sn transition pressure is calculated to be 9.9 GPa (12.5 GPa experimentally) for Si and 9.6 GPa (10.0 GPa experimentally) for Ge. On the other hand, no pressure-induced transformation from cubic diamond to a simple phase is predicted for C as is seen in Fig. 21. However, theoretical investigations of more complex phases (Biswas *et al.*, 1984) indicate that C would transform from the cubic diamond structure to the fourfold-coordinated bc-8 (body-centered-cubic Bravais lattice with an eight-atom basis per body-centered-cubic primitive cell) phase under the application of a pressure of approximately 1.2 TPa. It has been shown (Mailhiot and McMahan, 1991) that the phases of carbon characterized by a coordination number (number of first nearest neighbors) higher than four, such as simple-cubic, β-Sn, body-centered-cubic, hexagonal-close-packed, and face-centered-cubic, are mechanically unstable against a spontaneous transformation into the cubic diamond phase. On the basis of these results, one might speculate that all high-coordination phases of carbon would exhibit mechanical instabilities at atmospheric pressure. They also suggest the unlikely occurrence of stable or metastable local structure with coordination number higher than four in liquid and amorphous carbon as well as in carbon clusters, unlike the situation for Si. *Ab initio* molecular dynamics simulations of liquid and amorphous carbon have recently confirmed these expectations (Galli *et al.*, 1989).

3.4.2 All-Electron LMTO Method: Metals. All-electron methods have had a tremendous impact on our understanding of the electron structure of transition metals. Traditionally, the nontransition metals, e.g., alkali and alkali-earth metals, have been treated by means of pseudopotential theory, and the crystal structures predicted by this method are generally in good agreement with experiments (Heine and Weaire, 1970). It has, however, not been entirely straightforward to generalize the pseudopotential method to treat narrow *d*-band materials. All-electron methods such as the LMTO, APW, and KKR, on the other hand, afford accurate descriptions of these materials with great efficiency when implemented in linearized form. An important result emerging from first-principles all-electron calculations is that the crystal structures of elemental metals tend to occur in certain sequences when viewed as functions of atomic number or hydrostatic pressure. For example, the most striking example of this phenomenon occurs for the *d* transition metals where all the three transition series exhibit the same hexagonal-close-packed → body-centered-cubic → hexagonal-close-packed → face-centered-cubic sequence as the *d* bands become progressively filled (Skriver, 1985).

As a second illustration of the predictive power of *ab initio* total-energy methods, we consider the pressure-induced phase transformations occurring in the alkali and alkaline-earth metals. The structural transformation trend mentioned above, although adequate for the *d* transition metals, will fail in cases where states of non-*d* character are equally or more important. Examples of such materials include the alkali, the alkaline-earth, and light actinide metals. We present below results of LMTO calculations that aim at establishing correct structural trends among the alkali and alkaline-earth elements (Skriver, 1985).

According to LMTO calculations, all the alkali metals should exhibit the same crystal structure transformation, body-centered-cubic → hexagonal-close-packed → face-centered-cubic, as the atomic volume is reduced. The predicted structural energy differences for the five alkali metals as a function of the relative volume V/V_0 and LMTO pressure p are shown in Fig. 22(a). These structural transitions are driven by the pressure-induced lowering of the initially unoccupied *d* states through the Fermi level, thereby gradually transferring electrons from the *s* into the *d* band (Skriver, 1985; McMahan, 1986). The particular details of these transitions for each element depend on the relative position of the Fermi level within the density of states. Crystal structures calculated as a function of *d* occupation number indicate that this mechanism is at work only in the heavy alkali metals (K, Rb, and Cs), while the transitions in Li and Na have a different origin, at least below 35 GPa. Experimental measurements partially confirm this conclusion, but suggest that the intermediate hexagonal-close-packed structure is suppressed at room temperature (Skriver, 1985).

Calculated structural energy differences for the alkaline-earth and the two divalent rare-earth metals as a function of the relative volume V/V_0 and LMTO pressure p are indicated in Fig. 22(b). In the case of the alkaline-earth elements, there is a strong correlation between the calculated *d* occupation number and the calculated crystal structure according to which the heavy alkaline-earth metals should

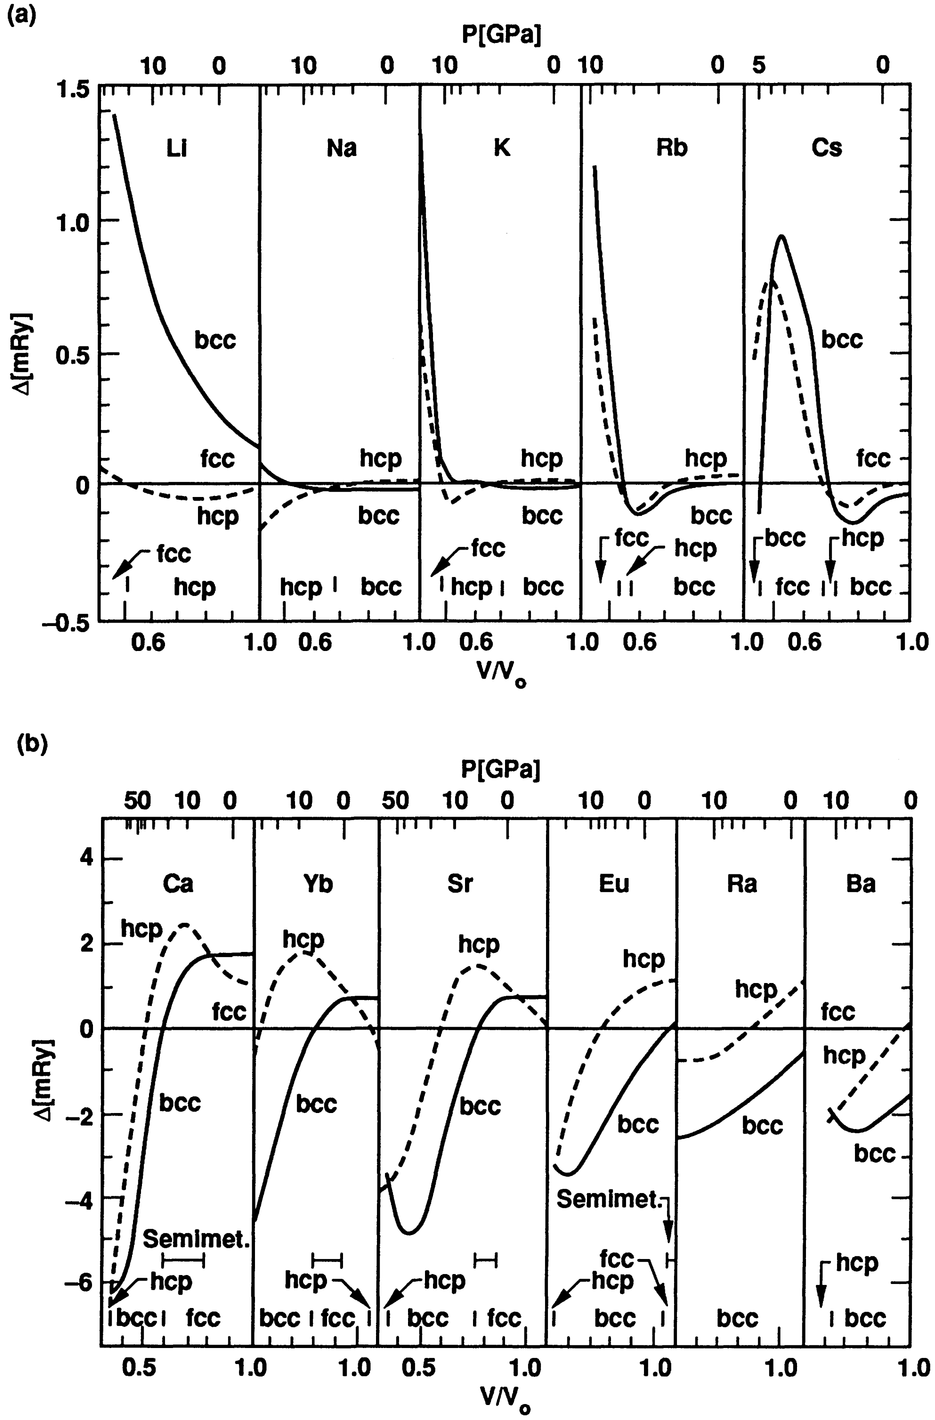

FIG. 22. (a) Structural energy differences (with respect to face-centered cubic) for the five alkali metals as a function of the relative volume V/V_0 and LMTO pressure p. (b) Structural energy differences (with respect to face-centered cubic) for the alkaline earth and the two divalent rare-earth metals as a function of the relative volume V/V_0 and LMTO pressure p. The structures shown are abbreviated in the following manner: face-centered-cubic (fcc), body-centered-cubic (bcc), and hexagonal-close-packed (hcp). (Reproduced with permission from Skriver, 1985.)

be part of the same hexagonal-close-packed→face-centered-cubic→body-centered-cubic→hexagonal-close-packed structural transformation sequence. At zero pressure, each individual metal may be characterized as being at different stages on the continuous *s*-to-*d* transition as determined by their *d* occupation number. The structural phase transitions are then driven by the pressure-induced lowering of the *d* band relative to the *s* band. The correlation is, however, not perfect and the calculated crystal structures transformations occur over a narrow range of *d* occupation numbers. Moreover, band-structure calculations indicate that Ca, Sr, and Yb in the face-centered-cubic phase should undergo a metal-semimetal-metal transition under hydrostatic pressure. The face-centered-cubic→body-centered-cubic part of the above structural sequence has been observed experimentally at room temperature, but the body-centered-cubic→hexagonal-close-packed transition is found in Ba. The experimentally determined transition pressures are also in good correspondence with the predicted values (Skriver, 1985).

3.4.3 Comparison between Different First-Principles Methods. We now compare the predictions obtained by different first-principles total-energy methods regarding the ground-state properties of a single material. The simple metals are the solids for which the most direct comparisons can be made between the different methods of calculations. The calculation of the electron structure of simple metals presents a severe test: the energy differences between various structures are small and, because the density of states is finite at the Fermi level, the calculation of the total energy requires integrals over the Brillouin zone, which necessitates the utilization of very accurate sampling techniques.

A comparison of the results obtained by different first-principles total-energy methods is illustrated in Table 3 (Martin, 1985) for aluminum. The results shown in Table 3 were obtained from various theoretical techniques: the plane-wave pseudopotential method, the Korringa–Kohn–Rostoker method, the augmented-spherical-wave method, the augmented-plane-wave method, and the linear combination of Gaussian-type orbitals method. Inspection of Table 3 clearly indicates that the results obtained by different electronic structure methods are in very good agreement between themselves. Consequently, one can conclude that careful calculations by any first-principles total-energy methods yield essentially the same results.

3.4.4 Applications of the Harris Functional. We now indicate recent applications of the Harris functional to the calculation of the ground-state properties of materials. Recall that the basis of the Harris functional (Sec. 3.3) is the construction of a charge density, $n_f(\mathbf{x})$, from the individual overlapping contributions of the fragments forming the solid or molecule, $\Sigma_k n_k(\mathbf{x})$. The total energy is then evaluated, using Eq. (166), without requiring convergence of the potential

Table 3. Calculated bulk ground-state properties of aluminum using different first-principles total-energy methods. The quantities shown are the equilibrium lattice constant a_0 (in atomic units: 1 a.u.=0.529 18 Å), the bulk modulus B_0, and the cohesive energy E_{coh}. The experimental value is also given. The theoretical techniques are the plane-wave pseudopotential, Korringa-Kohn-Rostoker (KKR), augmented-spherical-wave (ASW), augmented-plane-wave (APW), and the linear combination of Gaussian-type orbitals (LCGTO).

Calculation	a_0 (a.u.)	B_0 (GPa)	E_{coh} (Ry/atom)
Lam and Cohen (1981) pseudopotentials	7.59	71.5	−0.268
Liberman (1970,1971) KKR	7.65	78.0	−0.245
Janak (1974) KKR	7.59	80.1	−0.285
Williams *et al.* (1979) ASW	7.60	87.0	−0.298
Ross and Johnson (1970) APW	7.79	94.0	−0.300
Boettger and Trickey (1984) LCGTO	7.65	96.8	−0.235
Experiment	7.60	79.4	−0.248

and charge density to self-consistency. Figure 23 indicates results obtained for the equilibrium volume, cohesive energy, bulk modulus, and shear modulus for many materials using the Harris functional (van Schilfgaarde, 1991). The calculations were performed using the all-electron full-potential LMTO method (van Schilfgaarde, 1991). Comparisons with self-consistent total-energy LDA calculations and with experiments are also indicated. These comparisons reveal a remarkable agreement between the two methods and available exper-

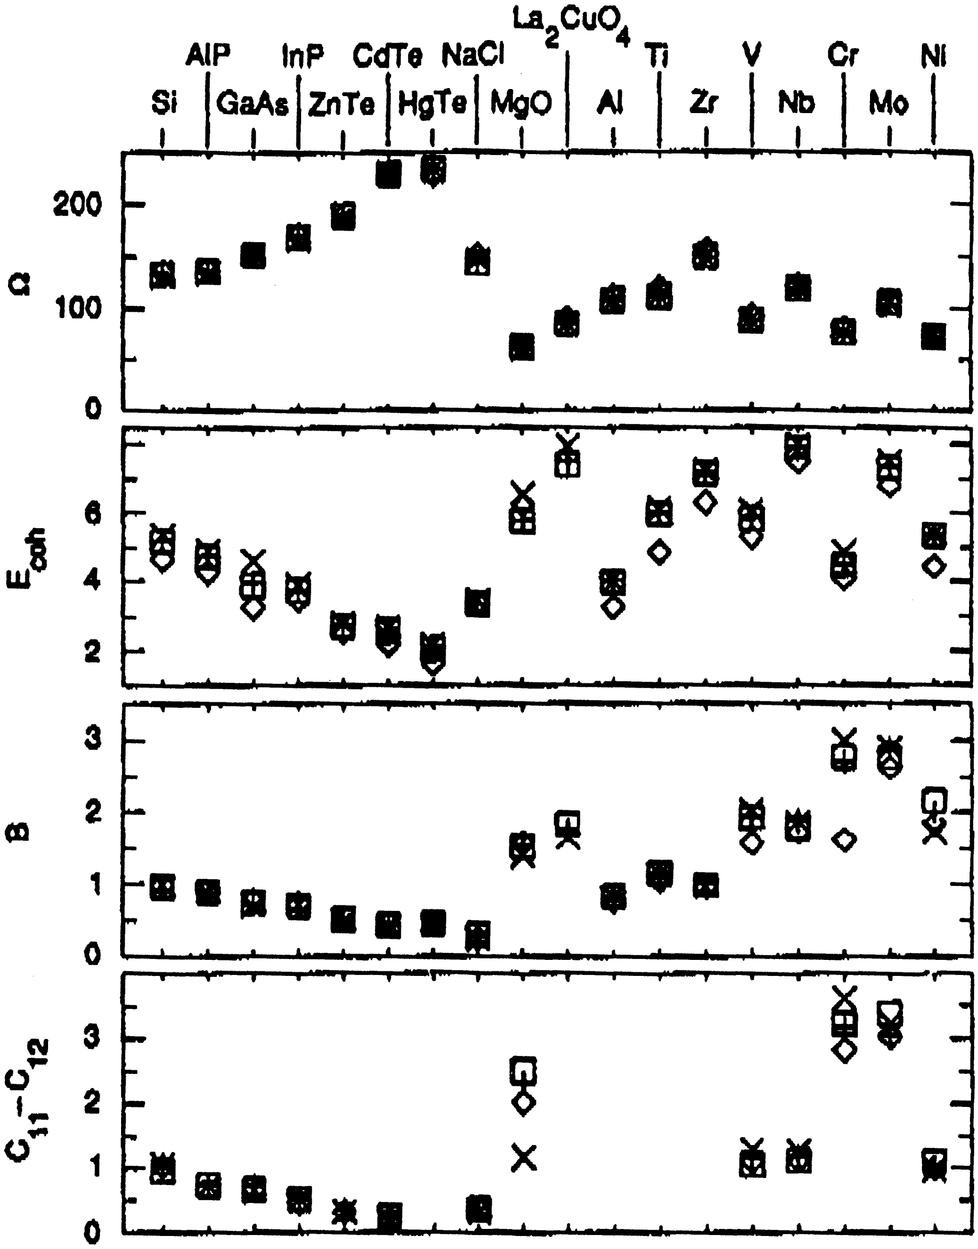

FIG. 23. Atomic volume (a.u.^{3}), cohesive energy (eV), bulk modulus (10^{11} erg cm^{-3}) and shear modulus $c_{11}-c_{12}$ (10^{11} erg cm^{-3}) for selected materials. Experiments (◇) are compared with self-consistent results (□) and with results obtained with the Harris functional using two different forms for the input densities [superposition of free-atomic densities (×) and renormalized densities (+)]. The theoretical results are obtained using the all-electron full-potential LMTO method. (Reproduced with permission from van Schilfgaarde, 1991.)

iments and suggest the substantial predictive power of the method. Also remarkable is the success of the Harris functional in describing the ground-state properties for a wide variety of materials exhibiting very different chemical bonding: covalent materials, ionic solids, oxides, simple and transition metals, etc. Since the utilization of the Harris functional consists of a *single* evaluation of the total energy without the need to perform the calculation self-consistently, the numerical work involved is substantially reduced, and, consequently, the method readily allows the treatment of large-scale materials systems. This spectacular success suggests that the utilization of non-self-consistent total-energy functionals, such as the one proposed by Harris, will have a large impact on electronic-structure calculations of complex materials.

4. *AB INITIO* MOLECULAR DYNAMICS

4.1 Introduction

In the previous sections, we have been concerned with electron-structure calculations of a *static* arrangement of atoms in a solid. In traditional total-energy minimization methods, two sets of iterations must be sequentially performed:

1. for a given set of ionic coordinates, the electronic charge density $n(\mathbf{x})$ must be iteratively recalculated until self-consistency is achieved, and
2. subsequently this procedure must be repeated by varying the ionic positions until the total energy $E_{\text{total}}[\{\psi_i(\mathbf{x})\},\{\mathbf{R}_I\}]$ given by Eq. (160) is minimized.

The present section describes recent theoretical developments aiming at simultaneously performing these two tasks within an *ab initio* framework. We now briefly indicate the essential features of static *ab initio* descriptions and empirical molecular-dynamics simulations.

Ab initio self-consistent total-energy methods involve the minimization of a total-energy functional $E_{\text{total}}[\{\psi_i(\mathbf{x})\},\{\mathbf{R}_I\}]$ with respect to electronic $\{\psi_i(\mathbf{x})\}$ and ionic $\{\mathbf{R}_I\}$ degrees of freedom. This is achieved by obtaining self-consistent solutions for the electron wave functions for a given set of ionic coordinates. The process is repeated for various ionic configurations until the total-energy functional is minimized and a minimum-energy solution has been found. For each set of ionic configurations $\{\mathbf{R}_I\}$, the electronic states of a system are obtained by solving a set of self-consistent field equations (Kohn–Sham equations) repeatedly until convergence is reached. Since perfect electronic self-consistency is achieved for each set of ionic configurations, the system follows exactly the Born–Oppenheimer surface for the ions, Φ, defined as

$$\Phi[\{\mathbf{R}_I\}] \equiv \min_{\{\psi_i(\mathbf{x})\}} E_{\text{total}}[\{\psi_i(\mathbf{x})\},\{\mathbf{R}_I\}]. \qquad (167)$$

The variations of the ionic coordinates $\{\mathbf{R}_I\}$ define the Born–Oppenheimer surface $\Phi[\{\mathbf{R}_I\}]$.

Though impressive advances in materials modeling have been achieved over the last 15 years with electron-structure methods, their application to interesting and technologically important systems that exhibit either very complex structures or large atomic motions remains limited. Moreover, it is not possible to apply these methods to finite-temperature systems where the electronic properties must be averaged over many possible configurations of the constituent ions in the system.

Molecular-dynamics (MD) simulations, on the other hand, are based on the numerical calculation of the trajectories of the atomic motion and are a very powerful tool for the study of complex condensed-matter systems. Molecular-dynamics simulations are usually based on empirical potentials that are chosen to mimic the interatomic potentials in a real material. The simplicity that follows from the use of parametrized potentials is then exploited to treat large numbers of atoms (exceeding one million) which can be in disordered, complex configurations. By varying the temperature (i.e., the mean velocity at which the constituent atoms move) during the MD simulation, technologically interesting processes can be studied: melting, crystal growth and epitaxy, ion implantation, laser annealing, defect motion, mechanical materials processing, etc. Disordered systems can be studied via time averages taken over one or many simulations starting from (usually random) initial conditions.

4.2 Lagrangian Formulation

A useful formulation for combining these two approaches into a single "*ab initio* molecular-dynamics" method has been proposed by Car and Parrinello (Car and Parrinello, 1985). Consider the problem of minimizing an energy functional $E_{\text{total}}[\{\psi_i(\mathbf{x})\},\{\mathbf{R}_I\},\{\alpha_\nu\}]$, such as Eq. (160), where $\{\psi_i(\mathbf{x})\}$ represent the electronic degrees of freedom, $\{\mathbf{R}_I\}$ represent the ionic coordinates, and $\{\alpha_\nu\}$ represent all the possible constraints imposed on the system (volume, strain, etc.). Car and Parrinello realized that the minimization of the energy functional $E_{\text{total}}[\{\psi_i(\mathbf{x})\},\{\mathbf{R}_I\},\{\alpha_\nu\}]$ can be performed using simulated annealing techniques if the concept of force is used to evolve not only the ionic degrees of freedom $\{\mathbf{R}_I\}$, as is traditionally done in MD, but also the electronic degrees of freedom $\{\psi_i(\mathbf{x})\}$ and the external constraints $\{\alpha_\nu\}$. These forces are derived from a Lagrangian for the coupled electron-ion system (Car and Parrinello, 1985, 1988a),

$$L\equiv \sum_{i(\text{occ.})} \mu_i \int d^3x \dot{\psi}_i^*(\mathbf{x},t)\dot{\psi}_i(\mathbf{x},t)+\sum_I \frac{1}{2} M_I\dot{\mathbf{R}}_I^2+\sum_\nu \frac{1}{2}\mu_\nu\dot{\alpha}_\nu^2$$
$$-E_{\text{total}}[\{\psi_i(\mathbf{x})\},\{\mathbf{R}_I\},\{\alpha_\nu\}]+\sum_{ij}\Lambda_{ij}\left(\int d^3x\ \psi_i^*(\mathbf{x},t)\psi_j(\mathbf{x},t)-\delta_{ij}\right), \tag{168}$$

where the wave functions $\psi_i(\mathbf{x})$ are subject to the holonomic constraints of orthogonality,

$$\int d^3x\ \psi_i^*(\mathbf{x},t)\psi_j(\mathbf{x},t)=\delta_{ij}. \tag{169}$$

The coefficients Λ_{ij} are the Lagrange multipliers for the orthogonality constraints and their exact form depends on the particular scheme used to orthogonalize the electronic wave functions.

The Lagrangian of Eq. (168) contains the total energy functional $E_{\text{total}}[\{\psi_i(\mathbf{x})\},\{\mathbf{R}_I\},\{\alpha_\nu\}]$ representing the potential energy, the ionic kinetic energy term, and a fictitious electronic kinetic energy term that generates a dynamics for the expansion coefficients of the electron wave functions $\{\psi_i(\mathbf{x})\}$. Similarly, a fictitious kinetic energy term is added to generate a dynamics for the constraints $\{\alpha_\nu\}$.

Application of the Euler conditions to the Lagrangian of Eq. (168) generates the equations of motion (dynamics) for the different degrees of freedom,

$$\mu_i\ddot{\psi}_i(\mathbf{x},t)=\frac{-\delta E_{\text{total}}}{\delta\psi_i^*(\mathbf{x},t)}+\sum_j\Lambda_{ij}\psi_j(\mathbf{x},t)$$
$$=-H\psi_i(\mathbf{x},t)+\sum_j\Lambda_{ij}\psi_j(\mathbf{x},t), \tag{170}$$

$$M_I\ddot{\mathbf{R}}_I=-\nabla_{\mathbf{R}_I}E_{\text{total}}, \tag{171}$$

$$\mu_\nu\ddot{\alpha}_\nu=\frac{-\partial E_{\text{total}}}{\partial\alpha_\nu}. \tag{172}$$

Equation (171) represents a physical ion dynamics for the ion trajectories. However, Eq. (170) describes a fictitious electron dynamics because the time t is not the real time but rather a construct to parametrize movement through the hyperspace defined by the electronic degrees of freedom [or volume, strain, etc. in the case of Eq. (172)]. The "equation of motion" governing the evolution of the electronic degree of freedom, Eq. (170), must therefore be interpreted in a broader sense than that governing the physical ions' dynamics, Eq. (171). For example the fictitious "mass" μ_i appearing in Eq. (170) is often used as an adjustable parameter determining the size of the time step used in the numerical integration of the equation of motion for the electronic degrees of freedom. The fictitious inertia μ_i has no real meaning, but controls the speed and character of the motion through the hyperspace defined by the electronic (or volume, strain, etc.) degrees of freedom (Remler and Madden, 1990).

The Car–Parrinello approach allows a reformulation of the electron-structure problem in which MD algorithms are used to evolve through time a coupled system of ions and electrons. We refer to this formulation as *ab initio* molecular dynamics since the forces acting on the ions are derived from an *ab* *initio* quantum-mechanical energy functional within the local-density approximation. The system is initially given a finite temperature (by assigning random velocities to the ions) and the temperature is slowly lowered and, as $T \rightarrow 0$, an equilibrium state is reached and $E_{\text{total}}[\{\psi_i(\mathbf{x})\},\{\mathbf{R}_I\},\{\alpha_\nu\}]$ is a minimum. At equilibrium, $\ddot{\psi}_i(\mathbf{x},t)=0$, and Eq. (170) becomes identical, to within a unitary transformation, to the one-electron Kohn–Sham equations [Eq. (150)] and the eigenvalues of the matrix Λ coincide with the occupied Kohn–Sham energy eigenvalues.

4.3 Nonlinear Local Optimization

The Car–Parrinello procedure described above adapts simulated annealing ideas to derive *ab initio* a dynamical model in which the electronic contributions to the atomic forces are calculated within the framework of local-density theory. Practically, the Car–Parrinello method is implemented by integrating the equations of motion Eqs. (170)–(172) and by periodically quenching the fictitious kinetic energy of the electronic system by bringing the electronic system into its ground state for a fixed configuration of the ion cores. This quenching is necessary since, because of the electron–ion interactions, thermal equilibration between the classical degrees of freedom $\{\mathbf{R}_I\}$ and the electronic wave functions $\{\psi_i(\mathbf{x})\}$ will be achieved after some time by equipartition. As a result, the electronic system heats up and moves away from the Born–Oppenheimer surface. It has been recognized that a more direct form of fictitious dynamics could be proposed that eliminates the need to quench the electronic system periodically. Such an algorithm essentially performs a local optimization of the electronic degrees of freedom (Williams and Soler, 1987) using the following "time" evolution (setting $\hbar=\mu=1$):

$$\dot{\psi}_i(\mathbf{x},t)=\frac{-\delta E_{\text{total}}}{\delta\psi_i^*(\mathbf{x},t)}+\sum_j \Lambda_{ij}\psi_j(\mathbf{x},t)$$

$$=-H\psi_i(\mathbf{x},t)+\sum_j \Lambda_{ij}\psi_j(\mathbf{x},t), \qquad (173)$$

$$M_I\ddot{\mathbf{R}}_I=-\nabla_{\mathbf{R}_I}E_{\text{total}}. \qquad (174)$$

Equation (173) can be derived from a steepest-descent condition and is the imaginary-time Schrödinger equation in which excited-state solutions decay exponentially (Woodward *et al.*, 1989). To verify that the solution of Eq. (173) monotonically approaches an energy minimum, we rewrite Eq. (173) using the orthonormality constraint $\Lambda_{ij}=H_{ji}$,

$$\dot{\psi}_i(\mathbf{x},t)=-(1-\hat{P}_N)H\psi_i(\mathbf{x},t), \qquad (175)$$

where the projection operator $\hat{P}_N$ projects on the subspace of the N occupied states $\psi_i(\mathbf{x},t)$,

$$\hat{P}_N\equiv\sum_{i=1}^{N}|\psi_i(\mathbf{x},t)\rangle\langle\psi_i(\mathbf{x},t)|. \qquad (176)$$

The time derivative of the energy eigenvalue ϵ_i associated with the state $\psi_i(\mathbf{x},t)$ is given by

$$\frac{d\epsilon_i}{dt}=-2\langle\psi_i|H(1-\hat{P}_N)H|\psi_i\rangle. \qquad (177)$$

Since $1-\hat{P}_N\geqslant 0$, it follows that $d\epsilon_i/dt\leqslant 0$ and the energy eigenvalues monotonically decrease until a minimum is attained.

The dynamical minimization method just described allows a simultaneous relaxation of the electronic and ionic degrees of freedom. At each set of fixed ionic positions, the electronic degrees of freedom $\{\psi_i(\mathbf{x})\}$ are varied according to the time evolution of Eq. (173) until a minimum on the energy surface is reached. Unlike the Car–Parrinello approach, the steepest-descent method described here ensures that perfect electronic self-consistency is achieved for each set of nuclear configurations. Consequently, the ionic trajectories follow exactly the Born–Oppenheimer surface for the ions, $\Phi[\{\mathbf{R}_I\}]$, defined by Eq. (167). However, the steepest-descent method is a *local* optimization method whereas the Car–Parrinello method is a *global* optimization method. Since the potential energy surface $\Phi[\{\mathbf{R}_I\}]$ exhibits numerous minima, a local optimization method is quite impractical, and simulated annealing techniques such as the Car–Parrinello method described above are more appropriate to identify a global energy minimum. On the other hand, local optimization methods are sufficient in many problems involving the local optimization of complex atomic structures.

Let us close this section by simply mentioning that efforts have been made to incorporate molecular-dynamics ideas within the frameworks of empirical non-self-consistent electron-structure calculation schemes. This approach, while not *ab initio* in nature, nevertheless embodies a quantum-mechanical description of the electron-ion interactions and goes beyond traditional empirical molecular-dynamics simulations using analytic two- and three-body model potentials. An example of this approach is the utilization of empirical tight-binding Hamiltonians to derive a dynamics for the electronic and ionic degrees of freedom (Broughton and Khan, 1989).

4.4 Applications

In this section, we indicate recent applications of the *ab initio* molecular-dynamics method to the study of the atomic and electronic structure of complex systems. A comprehensive description of the applications of molecular-dynamics simulations will be presented in another article and our objective here is only to demonstrate the great impact that the new approaches described above have already had on the field of electron-structure theory. These theoretical methods are in early stages of development and the applications continue to grow at an accelerated rate. Nevertheless, the results obtained so far with the method clearly indicate their predictive power and provide a sense of their usefulness.

Ab initio molecular-dynamics methods have now been applied to several systems in the amorphous or liquid state. In these calculations, the interatomic potential is constructed directly from the electronic ground state, which is treated accurately within the framework of density-functional techniques. The dynamical trajectories obtained from the equations of motion Eqs. (170)–(172) are used to generate a liquid state or an amorphous network resulting from the quenching of a liquid phase. The electron structure is simultaneously generated from the solution of the equations of motion for the electronic degrees of freedom. Examples of such applications include the study of the atomic geometry and electron structure of amorphous (Galli *et al.*, 1989a) and liquid carbon (Galli *et al.*, 1989b; Galli *et al.*, 1990), amorphous (Car and Parrinello, 1988b) and liquid silicon (Štich *et al.*, 1989), liquid sodium (Qian *et al.*, 1990), liquid arsenic (Li *et al.*, 1990), liquid GaAs (Zhang *et al.*, 1990), etc. Moreover, *ab initio* molecular-dynamics and local nonlinear optimization techniques have recently been utilized to determine minimum-energy atomic structures of complex condensed-matter systems such as semiconductor surfaces (Ancilotto *et al.*, 1990; Ihara *et al.*, 1990), clusters (Hohl *et al.*, 1990), vacancies in metals (Gillan, 1989), SiO_2 (Allan and Teter, 1987), etc. We emphasize that these calculations are the first to be performed on low-symmetry complex systems with a level of accuracy such as that afforded by density-functional methods. Previous model-potential-based molecular-dynamics studies of these systems relied on empirically derived force laws and did not offer a quantum-mechanical treatment.

5. SUMMARY

We have presented an overview of modern theoretical methods used for the calculation of the electron structure of condensed-matter systems. We have somewhat arbitrarily classified these electron-structure methods into two categories depending on how the electron states are expanded. One class of method is based on an expansion of the wave functions on a complete set of Bloch-type basis functions. The expansion coefficients are determined by solving the appropriate Schrödinger equation. We refer to these methods as *fixed-basis-set methods*. The other class of methods is based on an expansion of the wave functions on a complete set of functions that are solutions to the Schrödinger equation within a unit cell. The resulting expansion coefficients are determined by imposing appropriate boundary conditions at the unit-cell boundaries or some other more convenient surfaces. Methods based on this construction are referred to as *scattering methods*. Both classes of methods allow the calculation of the wave functions and energy eigenvalue spectrum of electron states in solids. The total energy of the system can be calculated from a knowledge of these electron wave functions and energy eigenvalues by combining the interaction energies between the ions, between the electrons, and between the electrons and the ions. We have given an overview of these total-energy methods based on local-density-functional theory and have indicated recent developments based on the utilization of non-self-consistent total-energy functionals. Examples of the predictive power of modern total-energy methods were given for a wide variety of materials including metals, semiconductors and insulators. A comparison between different implementations of local-density-functional theory was presented. We also discussed recent theoretical developments that combine first-principles electron-structure formalisms with concepts used in model-potential-based molecular-dynamics simulations. In these techniques the forces acting on the (classical) ions are calculated from first principles with an accuracy comparable to that of static calculations. These *ab initio* developments afford first-principles statistical treatments (within the confines of the local-density-functional formalism) of disordered materials (amorphous phases, liquids) at finite temperature. In this sense, they provide a natural intellectual link between *ab initio* electron-structure calculations and materials science.

GLOSSARY

Augmented Plane Wave: Piecewise-defined function consisting of the solution to Schrödinger's equation for an isolated atom within a sphere of given radius r_s and a plane wave outside this region.

Bandwidth: Energy spread between the minimum and maximum energy in a band.

Band Structure: Set of energy eigenvalue functions $\{\epsilon_n(\mathbf{k})\}$ that are continuous in the wave-vector parameter **k** and periodic with the periodicity of the reciprocal space. The band index n labels the energy eigenvalues $\epsilon_n(\mathbf{k})$ within the first Brillouin zone in reciprocal space.

Bloch Function: Eigenfunction of an electron in a crystal. A Bloch function $\psi(\mathbf{k},\mathbf{x})$ can be written as a product of a phase factor $\exp(i\mathbf{k}\cdot\mathbf{x})$ and a cell-periodic function $u(\mathbf{k},\mathbf{x}+\mathbf{R}_j)=u(\mathbf{k},\mathbf{x})$ as $\psi(\mathbf{k},\mathbf{x})=\exp(i\mathbf{k}\cdot\mathbf{x})u(\mathbf{k},\mathbf{x})$.

Bravais Lattice: Three-dimensional infinite array of discrete points with position vectors of the form $\mathbf{R}_j=n_1\mathbf{a}_1+n_2\mathbf{a}_2+n_3\mathbf{a}_3$, where the numbers n_i are integers and the vectors $\mathbf{a}_i$ are any three vectors not all in the same plane. The vectors $\mathbf{a}_i$ are called *primitive lattice vectors*.

Density-Functional Theory: Theory formulated from the realization that the total ground-state energy of a system of interacting electrons moving in an external potential is a unique functional of the electron density.

Density of States: Number of allowed electron states in a given energy range per unit volume.

Energy Band: Set of energy levels $\epsilon_n(\mathbf{k})$ describing the energy eigenvalue spectrum of a Bloch function for a given band index n.

First Brillouin Zone: Wigner–Seitz primitive cell of the reciprocal lattice.

Molecular Dynamics: Numerical simulations consisting of the calculation of dynamical trajectories describing atomic motion.

Muffin-Tin Orbital: Piecewise-defined function consisting of the solution to Schrödinger's equation for an isolated atom within a sphere of given radius r_s and a zero-kinetic-energy tail function outside this region.

Muffin-Tin Potential: Potential that represents an isolated ion within a sphere of given radius r_s about each lattice point and constant elsewhere.

Orthogonalized Plane Wave: Plane-wave function made orthogonal to the atomic core functions.

Primitive Cells: Set of nonoverlapping space-filling (when translated through all the translation vectors of a Bravais lattice) cells each containing exactly a single lattice point.

Pseudopotential: Effective potential that produces a nodeless pseudofunction without binding a core state.

Reciprocal Lattice: The reciprocal lattice of a Bravais lattice is the set of all wave vectors $\mathbf{G}_i$ satisfying the relation $\exp(i\mathbf{G}_i\cdot\mathbf{R}_j)=1$, where $\mathbf{R}_j$ defines the Bravais lattice, and generating plane waves with the periodicity of the Bravais lattice.

Space Group: Set of operations (translations, rotations, and reflections) that take a Bravais lattice into itself.

Tight-Binding Method: Electronic-structure method in which crystal Bloch functions are expanded in a set of atomic orbitals of the atoms within the primitive cell.

van Hove Singularities: Singularities present in the density of states profile of a crystalline solid which occur for energies ϵ on the constant-energy surface $\epsilon=\epsilon_n(\mathbf{k})$ for which the velocity vanishes, i.e., $\nabla_{\mathbf{k}}\epsilon_n(\mathbf{k})=\mathbf{0}$. At these singularities, the density of states $g(\epsilon)$ is continuous but the energy derivative $dg(\epsilon)/d\epsilon$ has an infinite discontinuity.

Wigner–Seitz Primitive Cell: Primitive cell with the full symmetry of the Bravais lattice.

INTRODUCTION

Electronic circuits are electrical circuits containing one or more electronic devices in which the motion of charged particles is used and controlled in order to achieve desired effects. Amplification, switching, and control are but three of these effects. A special type of control is called filtering, which is the process of separating electrical signals on the basis of one or more important characteristics, such as frequency.

The first electronic device was the vacuum diode, but the device that started what is often called the "electronic revolution" was the vacuum triode, invented in 1906. The point-

digital Encyclopedia of Applied Physics

contact transistor was invented in 1947, and the bipolar junction transistor was invented in 1948. In 1959, the integrated circuit was invented.

Classification of electronic circuits is complex because of the wide variety of applications. One scheme is by function, including switching, analog or quasilinear circuits, and power-control circuits. Another is by operating frequency, whether audio frequency, radio frequency, microwave frequency, or optical frequency.

Electronic circuits require power supplies, nearly always in the form of a direct (dc) voltage and current. Power may come from an alternating (ac) source or from a battery. If from an ac source, rectifier circuits are required, and for good performance in most applications, filters and regulators are needed.

Most electronic circuits today are assembled on printed circuit boards, with attention paid to mounting, wires, cables, insulation, connectors, and mechanical properties. The entire process is often called packaging. Wire tables give properties of the many wires available.

The vacuum tube is still important in electronic circuits, though most of its functions are now performed by solid-state devices. Vacuum-tube instrumentation is still in use. Vacuum tubes are required in some high-power applications. There are special applications, such as a class of high-fidelity audio equipment. Analysis of circuits with one or more vacuum tubes requires the use of basic principles of circuit analysis along with the graphical "characteristic curves" that describe the tube. It is necessary to perform both operating-point and small-signal analyses.

Active filters are an important application of electronic devices. The filter design process requires a statement of specifications, development of a suitable approximation, and realization of networks that meet the requirements. Important approximations include the Butterworth, Legendre, Chebyshev, Bessel, and elliptic-function approximations. The functions that result from these approximations can be realized in a variety of active networks. The multiple-feedback, infinite-gain (MFB) filter is described in detail, and others are mentioned, with references.

1. BASIC CONCEPTS

We define an electronic circuit as an electrical circuit or system that depends for its operation on one or more electronic devices. In turn, an electronic device is one in which the motion of charged, subatomic particles (such as electrons) in a vacuum, gas, or semiconductor is used to achieve desired effects in physical systems (Fink and Christiansen, 1989, Sec. 1). Electronic devices using liquids or solids are also employed. The particles themselves are frequently called *charge carriers*. The effects of interest include amplification, switching, control, and many others. These functions make possible computers, instrumentation for research, medicine, and industry, and entertainment systems, to mention but a few examples.

The essential physical principles for electronic devices are expressed in the principles of electromagnetism, in crystal behavior, in the principles of conduction in a vacuum or in a gas, and in basic material sciences. The charge carriers are frequently electrons, but they may be positively or negatively charged ions, or holes. A hole is the vacancy in a crystal structure that remains when an electron is removed or leaves the structure. We treat it as a positive charge in analysis, and this leads us to an understanding of the device behavior.

Most electronic devices have three or more electrical connections. (The major exception is the diode, discussed in Sec. 5). In the simplest form, the device uses two terminals for the principal charge-flow terminals or connections, and the third terminal or connection is used to control the charge flow. Because of the possibility of control, the device is enabled to amplify weak signals, to switch on or off some other device such as a light, motor, or element in a computer printer, or to effect smooth control of the control surface of an airplane or of the pen in a pen recorder attached to a computer or a device such as one that records electrocardiograms.

2. TYPES OF ELECTRONIC DEVICES

Historically, the first major electronic device, as the term is used here, was the vacuum diode (Ryder and Fink, 1984). The device that is generally considered to have started the "electronic revolution" was the three-element vacuum tube called a triode (Brittain, 1977; Ryder and Fink, 1984), which is discussed in Sec. 7.2. The vacuum diode led directly to the triode and later to vacuum tubes with many elements. In many parts of the world, vacuum tubes were called *valves.*

In 1947, the invention of a solid-state electronic device was announced. The device was known as a point-contact transistor, and the co-inventors were John Bardeen, and W. H. Brattain. This invention was followed in 1948 by the invention by William Shockley of the junction transistor, which is now possibly the most commonly used discrete electronic device. These three inventors were later honored with the Nobel Prize for Physics in 1956 (Ryder and Fink, 1984). Later, the field-effect transistor was developed, and it too has become quite important in modern electronic circuits. Transistors are discussed in the articles TRANSISTORS, BIPOLAR; TRANSISTORS, FIELD-EFFECT; TRANSISTORS, MICROWAVE; and TRANSISTORS, POWER.

In 1959, two engineers, Jack Kilby and Robert Noyce, working for competing companies, developed independently and received patents for what has become known as the *integrated circuit* (Ryder and Fink, 1984, Chap. 7). The integrated circuit is a device that puts large numbers of transistors onto a single silicon (or other material) wafer. The transistors are interconnected into a system, and as this is written, the number of transistors on a single commercially available "chip" greatly exceeds 1 million (Fink and Christiansen, 1989, Sec. 8). These integrated circuits may be best known for their applications in personal computers, but in fact they have made the wide spread of useful, reliable, and inexpensive electronic systems a reality. Integrated circuits are fully discussed in the articles VLSI—INTEGRATED CIRCUIT TECHNOLOGY and MICROELECTRONICS.

Many other electronic devices exist. To name but a few, there are the Geiger counter, the photocell, the klystron, the cyclotron, the magnetron, the tunnel diode, masers, and lasers.

3. TYPES OF ELECTRONIC CIRCUITS

Electronic circuits are so widely used that a simple classification scheme is difficult, but one possibility is a classification by the type of behavior or function that is a principal description of how a circuit operates. With this in mind, we identify digital or switching circuits, analog or quasilinear circuits, and power-control circuits. Some basic ideas are given here.

Digital or switching circuits have the characteristic that the principal charge flow is either inhibited to essentially zero or permitted to a maximum value that is controlled primarily by external elements, such as resistors and power supplies. One or more of the control terminals of the electronic device is used to inhibit or control the charge flow, usually by the voltage that is applied to the terminal.

In most cases, this process leads to a "two-state" circuit, one that operates in one of two possible conditions. In turn, this idea leads to the possibility of binary arithmetic systems, the basis of computers today. A typical computer has millions of such two-state circuits, which give it the capability that it possesses. Other switching circuits are used to provide "on–off" control of lights, motors, and communications equipment. A complete discussion of computer and switching circuits is given in the article CIRCUITS, DIGITAL.

Analog or quasilinear circuits have the characteristic that the principal charge flow is controlled smoothly between minimum and maximum values. The actual values are controlled by the voltage or other control signal that is applied to the control terminal as well as by external elements such as resistors and power supplies. Examples of such devices are amplifiers that are found in entertainment, information, medical, instrumentation, and communications systems, modulation–demodulation circuits found in communications systems, oscillators and wave-form generators, and active filters, which are discussed in Sec. 8. The other circuits, when transistor or integrated-circuit based, are discussed in the article CIRCUITS, ANALOG. An important building block for analog circuits is the operational amplifier, described in the article, AMPLIFIERS, ELECTRONIC. Analog or linear circuits based on vacuum tubes are discussed in Sec. 7 of this article.

Power-control circuits, or power-electronic circuits, have some of the characteristics of analog circuits and some of the characteristics of digital circuits. The central element is, today, a solid-state, electronic switching device that either connects an electrical source to an electrical load or disconnects the load from the source. Most of these devices conduct current in only one direction, and when conditions are such that the electronic device is switched to a conducting mode, then the amount of current that flows is determined largely by the source voltage and the load that is connected. Newell (in Fink and Christiansen, 1989, Sec. 15) describes four principal types, though other classification schemes are possible. The four types are

1. two-terminal switch, provided by a diode or diodes;
2. three-terminal switch, provided by reverse-blocking triode thyristors, or silicon-controlled rectifiers (SCRs);
3. three-terminal switches with turnoff capability, provided by turnoff thyristors or gate-controlled switches;
4. power transistors, or three-terminal switches in which control of the base signal current controls the power flow.

A power-control device known as a Triac conducts current in both directions. The Triac is, effectively, an inverse or opposing parallel connection of two thyristors. It provides ac power control with a single device, such as in a dimmer switch used in lighting.

Further discussion may be found in the article POWER ELECTRONICS.

4. OPERATING FREQUENCIES OF ELECTRONIC DEVICES

Electronic devices operate over a wide range of frequency, from fractions of a hertz (Hz) to the GHz range. The terminology is not precise, but we often divide the range into the audio-frequency, radio-frequency, microwave, and optical bands (Fink and Christiansen, 1989, Sec. 1).

The audio-frequency range is often considered to extend from dc to perhaps 200 kHz, though both extremes are outside the range of audible acoustic signals. With electronic devices, very sophisticated circuits have been built for use in this range. Examples include many of the circuits in home entertainment systems, in medical instrumentation systems, in communications systems, and in educational technology.

The radio-frequency range is usually considered to be the range from about 200 kHz to about 3 GHz, though special communications systems operate between 1.0 and 200 kHz. The principal range includes the frequencies of television broadcast, radio broadcast, cellular telephones, and many other services. Electronic circuits have always been at the heart of such systems. Modern devices and circuits have led to low-cost, versatile, and reliable systems that allow point-to-point communication anywhere in the world and that permit broadcasting of information and entertainment to large numbers of people.

The microwave band may be considered as the range from 3 to 300 GHz. Signals in this range provide line-of-sight communications and data transfer between two points and are also transmitted through waveguides and coaxial cables. Other applications include radar, some television service including satellite relaying, and microwave spectroscopy.

The optical band includes the infrared (300 GHz to 400 THz), visible (400 to 800 THz), and ultraviolet (700 to as high as 30 000 THz, depending on where the line is drawn) regions of the spectrum. Electronic devices find many applications in this range. The phrase "optical transistor" refers to a transistor in which the control is provided by an optical signal. The field is called optoelectronics (*q.v.*)

Optical frequencies are now commonly employed in high-speed communications systems. Such systems usually are used for data transfer in digital format. See OPTICAL COMMUNICATIONS.

5. POWER SUPPLIES

A common component of virtually all electronic circuits is a power supply. Electronic circuits require power for operation, and nearly always this must be delivered as a direct current or voltage. As most energy is delivered from alternating sources, means to convert ac to dc are required. Such circuits are called power supplies (Fink and Christiansen,

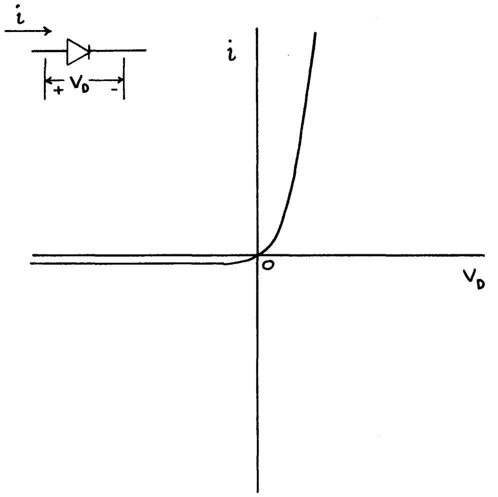

FIG. 1. Typical current-voltage characteristic for a diode.

1989, Sec. 15; Fink and Beaty, 1987, Sec. 22). Circuits that convert dc to ac are called inverters.

The essential element of a power supply is a diode, the principal two-terminal electronic device. A diode is a circuit element that allows a substantial current or charge flow in one direction and a nearly zero current flow in the opposite direction. Figure 1 shows a symbolic representation for a diode and a typical voltage–current relationship. For semiconductor diodes, the current–voltage relationship is given by the Ebers-Moll equation (Ebers and Moll, 1954).

$$i=I_0[\exp(V_D/V_T)-1], \qquad \text{(1a)}$$

where i is the diode current, I_0 is called the reverse saturation current, V_D is the diode voltage, $V_T=kT/q$, k is the Boltzmann constant, q is the electronic charge, and T is the temperature. At room temperature, kT/q is about 26 mV. In practice, it is found empirically that a correction factor is needed in the exponent, so that the Ebers-Moll equation is frequently given as

$$i=I_0[\exp(V_D/mV_T)-1], \qquad \text{(1b)}$$

where typical values of m of 1.5–2.0 are found.

When an ac source is connected in series with a resistor and a diode, as indicated symbolically in Fig. 2(a), we observe the current and voltage wave forms indicated in Fig. 2(b). Although the resulting current has a nonzero average value and thus has a dc component, it is by no means constant. This circuit is called a half-wave rectifier, and major improvements are required to make it practical for most applications.

The first improvement usually considered is to make a full-wave circuit, shown in Fig. 3(a), with the resulting wave forms in Fig. 3(b). A Fourier analysis of this wave form shows that the average value, or dc component, is doubled, and that the component at the supply or source frequency is eliminated. A figure of merit called the ripple factor is defined as the ratio of the effective value of the alternating components to the dc output (Gray, 1954). For a half-wave rectifier this figure is 1.21, while for a full-wave rectifier it is 0.48. The reduced relative magnitude and the higher frequencies involved make these components easier to separate from the desired dc component through filtering. It should be noted, however, that the zero-to-peak excursion in the output voltage is unchanged, a fact that designers of power supplies must consider in filter and rectifier design. A bridge circuit that is also a full-wave rectifier is shown in Fig 3(c). Its wave forms are similar to those of Fig. 3(b). Its main advantage is that the transformer does not require a center tap, but it requires 4 diodes.

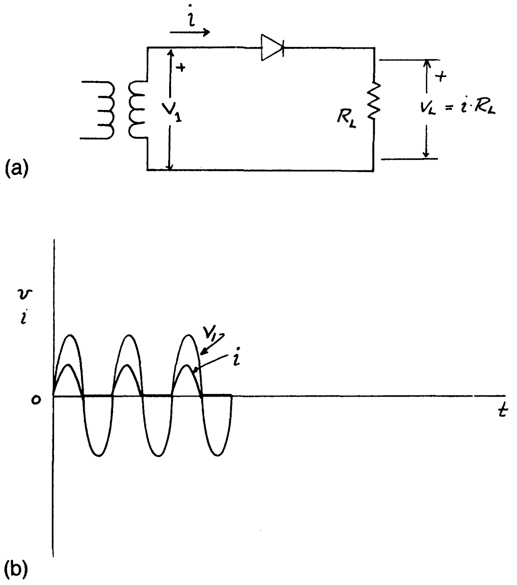

FIG. 2. (a) Half-wave rectifier circuit. (b) Current and voltage wave forms.

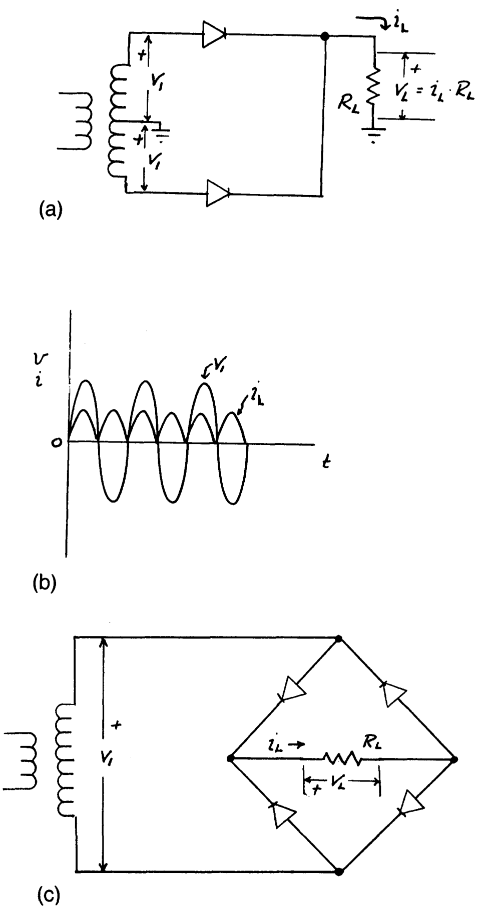

FIG. 3. (a) Full-wave rectifier circuit. (b) Current and voltage wave forms. (c) Bridge rectifier circuit.

Other improvements include the addition of filters, which are capacitors connected in parallel with the load that is using the dc power, or inductors connected in series with the load, or both. Electronic regulators have been developed over the years. These regulators reduce the ac components to very small values and maintain the dc voltage constant over a wide range of operating conditions.

Specifications for a power supply usually include the following items:

1. dc output voltage;
2. dc output current, minimum and maximum values;
3. voltage change (regulation) from no load to full load;
4. an indication of the magnitude of the ac components of the output voltage, frequently called ripple;
5. an indication of how rapidly the power supply can respond to sudden changes in the load; and
6. environmental and other operating conditions.

A wide variety of power supplies is available from many vendors. Careful selection of a power supply is crucial for operation of electronic equipment.

Many electronic devices use batteries (Fink and Christiansen, 1989, Sec. 7) because this greatly increases portability and reduces weight. Batteries are available in a wide range of sizes and shapes, voltage and current ratings, environmental operating conditions, operating and shelf lifetimes. Nickel–cadmium batteries, lead–acid cells, and nickel hydride cells are rechargeable. Most of the other commonly used batteries are not rechargeable.

6. CONSTRUCTION OF ELECTRONIC CIRCUITS

6.1 Printed Circuits

Most electronic circuits today are assembled on printed circuit boards (Fink and Christiansen, 1989, Sec. 7). This is true whether the circuits are constructed of discrete components such as resistors, transistors, and capacitors, or whether they include integrated circuits. The boards are made of laminated plastic. The material must be a good insulator. Holes are drilled in the board for mounting of components, which are then soldered to printed wiring that is plated onto the board.

The boards must be rigid and must provide protection for the circuit elements. In some cases, the components are encapsulated into resins on the board. The thickness and material choices depend on the size and on considerations of strength and stiffness. Spacing of components and of boards in an assembly is influenced by heat dissipation considerations and by voltage breakdown or insulation factors.

Frequently, a printed circuit board has a connector on one edge. The connector consists of the plated wiring brought out in a format that allows insertion of the connector into a receptacle in the overall system. An example of this is the "mother board" of a personal computer, and closely related are the expansion slots that enable the owner to customize the computer for specialized uses.

The use of printed circuit boards allows the design engineer to make changes or improvements that may be needed. It also allows the user to repair equipment by simply replacing boards and to repair the boards away from the equipment. This saves much time and improves system reliability substantially. The overall process is usually called "packaging."

6.2 Wiring

6.2.1 Wires and Wire Gauges. Wires are used to connect electrical components and systems together. The wire is made of a conducting material, usually copper, and covered with insulating materials. An assembly of two or more wires is often called a cable. Three different wire gauges for copper wire are in use. They are (Fink and Beaty, 1987, Sec. 4) the following.

6.2.1.1 American Wire Gauge (AWG). This system refers to the diameter of the wire, and divides the range of diameters from 0.0050 in. (AWG No. 36) to 0.4600 in. (AWG No. 0000, or 4/0) into 39 geometrically spaced intervals, with adjacent wire sizes having a diameter ratio of $(0.460/0.005)^{1/39} = 1.122\,932\,20$. The system has been extended down to AWG No. 50, which has a diameter of 0.0010 in. Table 1 gives an abbreviated wire table, showing sizes frequently found in electronic circuits and systems.

A useful rule of thumb is that, since the diameter ratio is very nearly equal to $2^{1/6}$, then a change of AWG numbers by 6 changes the wire diameter by a factor of 2, the area by a factor of 4, and the resistance by a factor of 4.

Table 1. Abbreviated American Wire Gauge table.

AWG size	Diameter (in.)	Area (in.^{2})	dc resistance (Ω/1000 ft) (@20 °C)
12	0.0808	0.005 13	1.64
14	0.0641	0.003 23	2.61
16	0.0508	0.002 03	4.16
18	0.0403	0.001 28	6.61
20	0.0320	0.000 804	10.5
22	0.0253	0.000 503	16.8
24	0.0201	0.000 317	26.6
26	0.0159	0.000 199	42.4
28	0.0126	0.000 125	67.6
30	0.0100	0.000 078 5	107

6.2.1.2 Metric Wire Gauge. In the systems using SI units, wire size No. 1 has a diameter of 0.1 mm, No. 2 has a diameter of 0.2 mm, etc.

6.2.1.3 British Standard Wire Gauge. This system was developed in the United Kingdom as a modification of the Birmingham Wire Gauge, which in turn was originally developed for use with soft iron wire. Other names include the New British Standard Gage, the English legal standard gage, and the Imperial wire gage. The largest diameter is 0.500 in. and is designated 7/0. The next smaller is 6/0, down to 1/0, with increasing numbers thereafter. The smallest is 0.001 in., which is designated No. 50. Thus there are 57 wire sizes. Unlike the AWG, the diameters are not geometrically spaced.

A very complete wire table may be found in Fink and Beaty (Fink and Beaty, 1987, Sec. 4, Table 4-11).

6.2.2 Cables. Cables are assemblies of 2 or more wires and usually have an outer covering in addition to the insulation on the basic wires. Often the wires are stranded, not solid, especially when there are many wires or the individual wires are large. A wide variety of cables is available to meet virtually any need. Some special-purpose cables have a mixture of wire sizes. One example is a cable that contains 2 or more relatively large wires, such as No. 14 AWG, and a large number of small wires, such as No. 22 AWG. The large wires could be used for power delivery, and the small ones for signals.

Some cables—for example, many of those used in instrumentation and audio systems—are shielded. This means that, in addition to the outer covering, there is a metallic layer enclosing all of the wires. The shield reduces problems that might arise from stray or unknown electromagnetic fields.

6.2.3 Coaxial Cables. Coaxial cables are cables made with the various conductors concentrically assembled. There is a connector in the center, one or more additional conductors separated by insulators, and, usually, a shield around the outside (though inside the final insulator). Coaxial cables are used at higher frequencies and in cases where protection from stray fields is especially important. Coaxial cable data are given by Fink and Christiansen (1989), Sec. 9 and Figs. 9-4 and 9-5.

6.2.4 Strip and Sheet Cables. Strip and sheet cables are flat cables, often used with the edge connectors found in printed circuit boards.

6.3 Connectors

Connectors are devices placed at the ends of cables or on the edges of printed circuit boards to allow electrical contact between appropriate wires or system subassemblies, with adequate mechanical properties to assure proper behavior. A wide variety of connectors for a wide variety of purposes has been developed. There are widely accepted standards that state what connectors should be used for each purpose. A look at the connectors on a personal computer will show a sample of a variety of conductors. This variety virtually eliminates any possibility of a user making incorrect connections.

Connectors must assure low-resistance electrical contacts between wires and must stay fastened regardless of mechanical problems such as vibrations. They must withstand the voltages present in a system and must perform in whatever environmental conditions are encountered.

Power-circuit connectors must handle the relatively large amounts of current involved. Signal-circuit connectors are especially vulnerable to corrosion and other problems that can increase contact resistance and lead to circuit and system failure. Special connectors have been developed for coaxial cables.

6.4 Contacts

Contacts are metallic surfaces within connectors that, when the connectors are fastened together, must touch with very low resistance to allow signals and power to be propagated from one part of a system to another without error. Contacts are susceptible to corrosion, wear, sparking in some cases, dirt, and other hazards. In critical situations, special metals are plated on the contacts to allow good performance over many years. Gold is often used for this purpose, because it does not corrode as other metals do.

6.5 Insulation

The insulation on a wire serves a number of purposes. The most important is to keep metallic wires from touching each other and causing short circuits that lead to system failure. The second is to protect the wiring itself. Insulation must meet standards of breakdown voltage and standards for vibration, bending, and other forms of mechanical motion.

7. VACUUM TUBES AND VACUUM-TUBE CIRCUITS

7.1 Historical Note

In 1884, Houston (Brittain, 1977) discussed the Edison effect, which was the observation of unilateral current flow between an incandescent element and a positively charged electrode in a vacuum. In 1897, Thomson (Ryder and Fink, 1984) identified the charge carrier as a negatively charged particle, now called an electron. This led rapidly to the development of the first vacuum tube, a two-electrode structure. The electrode that emitted the electrons was named the cathode, while the electrode that was positively charged was named the anode (a contraction of anti-cathode). The anode is also called the plate. Vacuum diodes also require a mechanism for heating the cathode. This was provided by the filament.

The vacuum triode was invented in 1906, and was the first electronic device to exhibit the control feature that has been described. de Forest (1914) discovered that by placing a meshlike control surface, called a grid, between the plate (anode) and cathode of a vacuum diode, he could control the electron flow through the mesh or grid by controlling the voltage applied to the grid. Thus he was able to achieve amplification, and his device, called the audion, was incorporated into several commercial devices. In Britain and other parts of the world, the control property gave rise to the term "valves," by which these devices are known.

Although vacuum tubes have been supplanted by transistors in most applications, many vacuum tubes are still in use. One reason is the fact that there is still a lot of useful electronic equipment built around the

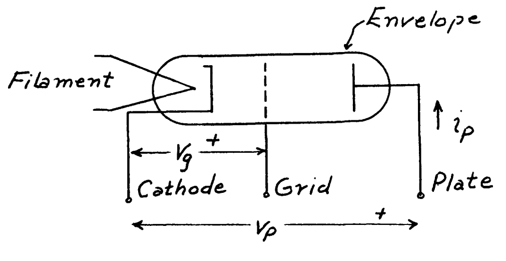

FIG. 4. Symbolic representation of a vacuum triode.

vacuum tube. A second is that in some high-power applications, the vacuum tube still has no competitor. A third reason is that the vacuum tube has some features still considered quite desirable. Some very serious high-fidelity music critics believe that the sound quality achieved in vacuum-tube amplifiers is superior to that from solid-state circuits. The distortion properties exhibited by the tube circuit when signal levels are approaching their maximum permissible limit differ substantially from the distortion properties exhibited by transistor circuits.

7.2 Tube Elements

A symbolic representation of a three-element vacuum tube, or triode, is shown in Fig. 4. The essential elements of a tube are the plate or anode, the cathode, the grid, the filament, and the (glass) envelope (Gray, 1954). The filament is heated electrically, and this heat causes the cathode to emit electrons. (In some tubes, the filament and the cathode are integrated into one unit.) When the plate voltage is positive with respect to the cathode voltage, electrons emitted by the cathode are collected by the plate. The voltage on the grid, which is usually negative with respect to the cathode, controls the electron flow from the cathode to the plate—or the current flow from the plate to the cathode. It is possible to show that, under reasonable assumptions, the voltage–current equation for a triode is given by

$$i_p = K_t[(C_{gk}/C_{pk})v_g + v_p]^{3/2}, \qquad (2)$$

where i_p is the plate current, positive charge; K_t a constant that depends on tube geometry; C_{gk} the grid–cathode capacitance; C_{pk} the plate–cathode capacitance; v_g the grid voltage; and v_p the plate voltage.

Figure 5 shows a typical appearance of these tube characteristic curves. The voltage on the plate, with respect to the cathode, is the independent variable. The voltage on the grid, with respect to the cathode, is the parameter. The plate current is the dependent variable.

As vacuum tubes developed, engineers found that the addition of additional grids to the tubes improved performance, but more importantly, led to different kinds of behavior. The pentode has very different characteristics curves. Figure 6 shows a sample set.

7.3 Vacuum-Tube Circuit Analysis

Two types of analysis are possible, and necessary, in vacuum-tube amplifier circuits. The first, called a "dc analysis," consists of finding the voltage across and the current through the tube when the signal is zero. This result is called the operating point. The sec-

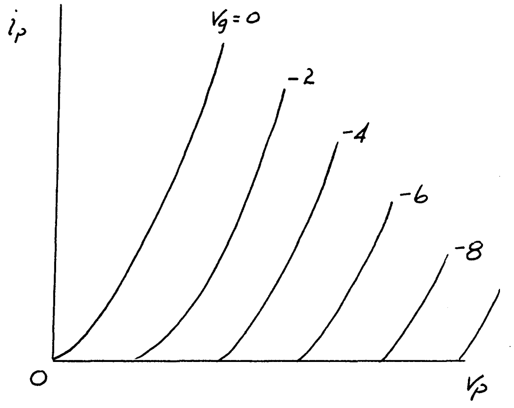

FIG. 5. Typical vacuum-triode current–voltage characteristics.

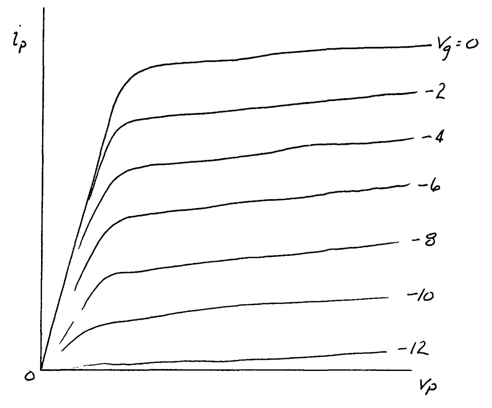

FIG. 6. Typical vacuum-pentode current–voltage characteristics.

ond, called a "small-signal analysis," consists of using equivalent-circuit parameters to find performance measures such as voltage and power gain, output resistance, and efficiency. Figure 7(a) shows a vacuum tube—a triode is chosen, but the analysis with a pentode is quite similar—with a power supply, a load resistor connected between the power supply and the plate, a second (self-bias) resistor connected between the cathode and the power supply, and a third resistor through which the grid is connected to one side of the power supply.

Figure 7(b) shows the characteristic curves with two straight lines added. Line 1 is called the "load line." Its equation is found by applying Kirchhoff's voltage law and Ohm's law to the circuit formed by the power supply, the tube, and the load and bias resistors. The second line relates the grid voltage to the plate current. Usually, the current through the grid resistor is zero, so that Eq. (4) gives the relationship between the grid voltage and the plate current. Specifically,

$$i_p = (V_{bb} - v_p)/(R_p + R_g) \qquad (3)$$

and

$$v_g = -i_p R_g \,. \qquad (4)$$

The intersection of these two lines is labeled Q, and this point tells the designer the plate current and voltage when the signal is zero. In the example shown, the plate voltage is about 150 V, the plate current is about 5.0 mA, and the grid voltage is about −5 V.

Figure 7(c) shows an equivalent circuit. It contains two elements: a voltage-controlled voltage source, μV_g, and the incremental plate resistance r_p. The voltage V_g is the small-signal voltage on the grid with respect to the cathode. The parameter μ is called the (open-circuit) voltage gain for the tube and may be determined from the characteristic curves as the ratio of a change in plate voltage caused by a change in grid voltage near the Q point. The incremental plate resistance may be determined as the slope of a line tangent to the current–voltage characteristic at the Q point.

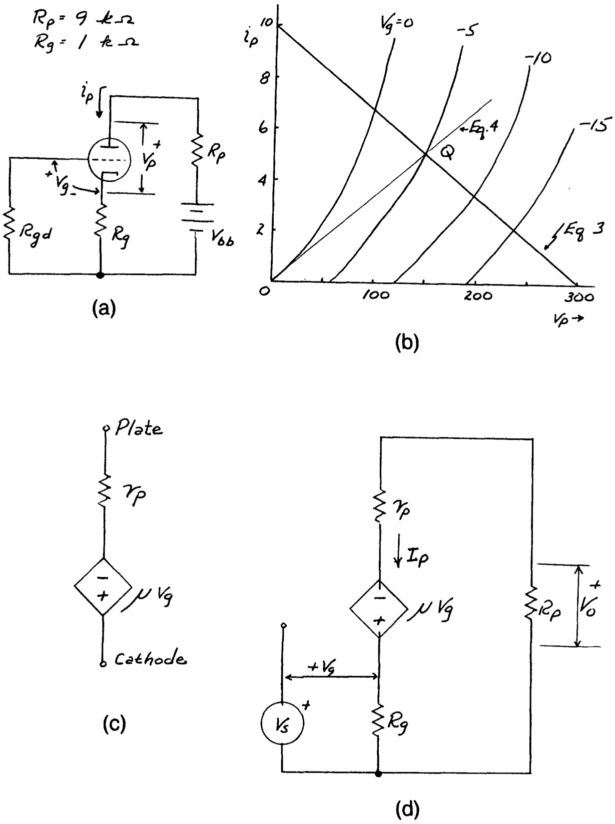

FIG. 7. Vacuum-tube analysis. (a) Circuit. (b) Load-line construction. (c) Small-signal equivalent circuit for the tube. (d) Equivalent circuit for analysis.

Figure 7(d) shows the complete equivalent circuit with external elements added. To analyze this circuit, we write the following equations:

$$I_p=\mu V_g/(R_p+r_p+R_g), \tag{5}$$

$$V_g=-I_pR_g+V_s\,, \tag{6}$$

$$V_o=-I_pR_p\,, \tag{7}$$

where V_s is the signal voltage we wish to amplify and V_o the output signal voltage. If we solve for the circuit gain, we find that

$$\frac{V_o}{V_s}=\frac{-\mu R_p}{R_p+r_p+(1+\mu)R_g}\,. \tag{8}$$

This equation, along with the operating-point analysis, shows us that the design engineer has a number of parameters to work with in the design of circuits. The negative sign means that there is a 180° phase change between input and output signals.

Many—literally thousands—of other useful circuits have been developed to use tubes over the years. A useful reference for these circuits is the book by Reich (1961).

8. ACTIVE FILTERS

8.1 Electrical Filters

One of the most important applications of electronic circuits is the process of filtering electrical and electronic signals (Huelsman and Allen, 1980; Chen, 1986; Fink and Christiansen, 1989, Sec. 12). Filtering is the process of separating desired and undesired signals based on appropriate properties. The frequency of the signal is one of the most commonly used parameters. For example, a filter in the output of a high-fidelity home entertainment system directs the low-frequency signal components to the woofer, the high-frequency signal components to the tweeter, and the remaining components to the midrange speaker. In recent years great advances have been made in this technology, with the result that the designer can now purchase a wide variety of electronic components to meet a wide variety of needs. When the filters contain electronic devices, they are usually called active filters.

8.2 Filter Design Process

In general terms, the design of a filter requires the designer to go through steps like the following set, though the details may vary depending on the situation and the experience of the designer.

8.2.1 Specifications. State the specifications that the filter must meet. These specifications would normally include some or all of amplitude and phase characteristics as functions of frequency, impedance levels at the input and output terminals, source and load characteristics, and consideration of factors such as cost, weight, reliability, sensitivity, environmental operating conditions, noise and signal levels, and other qualities deemed by the user to be important.

8.2.2 Approximation. Choose an appropriate approximation function, if one can be found, or develop a special one if necessary. The well-known approximations that follow will suffice in many situations. The approximations will be given in terms of equivalent low-pass (to be defined in the next few paragraphs) networks, and so it may be necessary to translate specifications to equivalent low-pass specifications.

8.2.3 Circuit. Choose an appropriate circuit. If a decision is being made, for whatever reason, to use an active network, then there are many circuit configurations possible, and the one that is shown to be suitable is chosen. Determine the circuit's transfer function if not already known.

8.2.4 Element Determination. From a knowledge of the transfer function required and the circuit's transfer function, determine the type and magnitude of the circuit elements. Usually they will be either resistors or capacitors, and there will not be a unique set of parameters that will meet the design criteria. Rather, there will be sets of constraint equations to be solved with additional requirements imposed by the designer, such as having two critical capacitors equal.

8.2.5 Network Conversion. If necessary, convert the network back to the required type, and scale elements in impedance level and frequency to meet the operating conditions.

8.3 Filter Types and Approximation Functions

In this section, five basic types of filter are defined, several approximations that are used in the filter design process are introduced, concepts of frequency and element scaling are developed, and one commonly used active network is developed.

8.3.1 Types of Filter. Circuit designers distinguish five basic types of electrical filter. They are as follows:

1. low-pass filter, which transmits signals whose frequency components are below some desired threshold, and attenuates signals whose frequency components are above the threshold;
2. high-pass filter, which transmits signals whose frequency components are above some desired threshold, and attenuates signals whose frequency components are below the threshold;
3. band-pass filter, which transmits signals in a range of frequencies between some required upper and lower limits, and attenuates signals lying outside this band;
4. band-stop or band-reject filter, which attenuates signals in a range of frequencies between some required upper and lower limits, and transmits frequencies lying outside this band;
5. delay filter or circuit, whose primary purpose is to correct or modify the group delay or time delay of signals from the input to the output.

8.3.2 Modern Network Synthesis. Over the years, circuit designers have developed a variety of methods for taking filter performance specifications, which are often communicated in graphical form, and approximating them analytically in a form that leads to useful network functions (see NETWORK THEORY, ELECTRICAL). The techniques to be described here are generally called "modern network synthesis." It is possible to translate high-pass, band-pass, and band-stop filter specifications to equivalent low-pass specifications, to perform the design using low-pass techniques, and to transform the resulting network back to the required type. Many methods for improving the results also exist.

8.3.3 Ideal Low-Pass Filter. An ideal low-pass filter would have a magnitude transmission characteristic of unity at frequencies from dc to the pass-band edge, and zero at frequencies above the pass-band edge [see Fig. 8(a)]. Because scaling is possible, the frequency at the pass-band edge has been scaled to 1.0 rad/s, which corresponds to a frequency of $1/2\pi$ Hz. It is shown in following sections that the specifications and the networks can be scaled and transformed in order to have the appropriate behavior at any desired freqency. Further, this scaling procedure allows computation and publication of normalized data (Zverev, 1967; Saal and Ulbrich; 1958; Weinberg, 1962; Fink and Christiansen, 1989, Sec. 12). Such tabulations are primarily for passive networks, which are not the principal focus of this article.

8.3.4 Magnitude Functions. It is not possible to achieve ideal behavior with finite networks, so it is necessary to approximate the ideal function. Two types of approximation are used—monotonic approximations and equiripple approximations. Figures 8(b) and 8(c) show these approximation types. Further, it is convenient to use magnitude-squared functions. There are two reasons for this. The first is that irrational functions are eliminated. The second is that a magnitude-squared function is easily associated with power transmission.

The process of developing a network function from the approximation requires using the mathematical process called analytic continuation to let $\omega^2 = -s^2$; finding the roots of the resulting polynomial in s, the symbol for the Laplace-transform variable usually used by electrical engineers; and finally choosing the denominator roots (function poles) in the left half of the complex plane. The reason for this choice is that it will lead to a stable network.

Although it does not arise in the first three cases to be discussed here, there are cases in which there are finite roots in the numerator also. The negative of every left–half-plane root is located in the right half-plane, and is also a root of the new function. Provided complex roots are chosen in conjugate pairs, either the left–half-plane or right–half-plane root may be chosen. The latter choice leads to nonminimum phase networks, which meet the criteria in magnitude but have additional phase

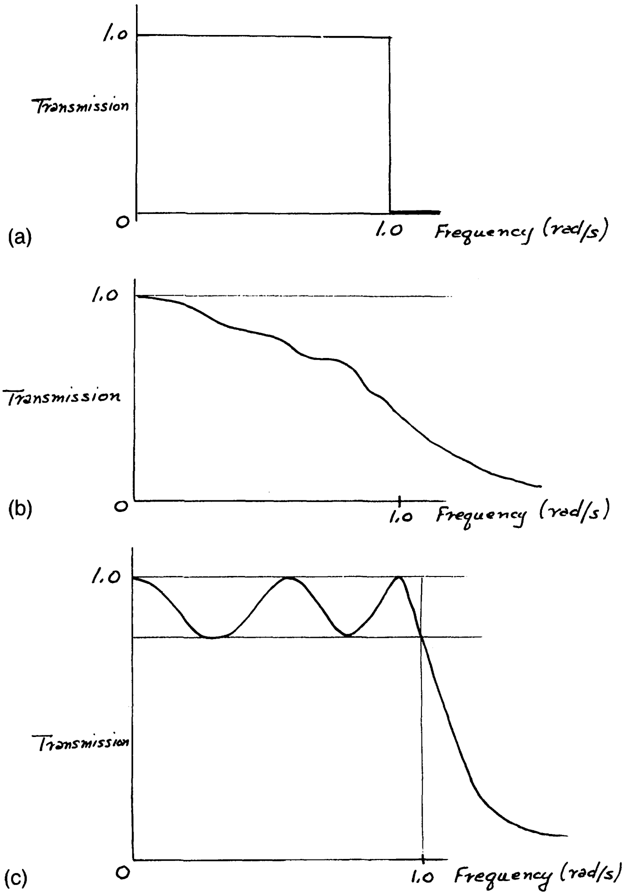

FIG. 8. (a) Ideal low-pass filter transmission characteristic. (b) Monotonic approximation. (c) Equiripple approximation.

shift, which may be an advantage in some situations and a disadvantage in others.

8.3.5 Butterworth Approximation. A useful approximation was developed by the British engineer Butterworth. Butterworth (Chen, 1986) approximated the ideal magnitude-squared function with

$$G(\omega^2)=1/(1+\omega^{2n}), \qquad (9)$$

where n is the order of the approximation. This function exhibits the monotonic behavior of Fig. 8(b), and it also has the characteristic that $2n-1$ derivatives of G are 0 at the origin. For this reason, it is also called a maximally flat monotonic approximation. All orders of this approximation take on a value of 0.5 when $\omega=1$, but higher orders of n give a better approximation to the ideal, at the expense of a more complex network.

If a designer finds that a fourth-order Butterworth response filter meets specifications, i.e., if $n=4$, then use of analytic continuation and root sorting shows that the appropriate network transfer function is

$$G(s)=\frac{1}{(s^2+0.7654s+1)(s^2+1.8478s+1)}. \qquad (10)$$

Several of the references listed at the end of this article give extensive tables for these functions (Zverev, 1967; Fink and Christiansen, 1989, Sec. 12; Weinberg, 1962).

8.3.6 Legendre Approximation. A second monotonic approximation was developed by Papoulis (1959). His goal was to find the monotonic approximation function that yields the sharpest possible discrimination at the edge of the passband. This second criterion means that the magnitude of its derivative with respect to frequency at $\omega=1$ is maximized. The approximation that meets these criteria is

$$G(\omega^2)=K/[1+L_n(\omega^2)],$$

where $L_n(\omega^2)$ is the Legendre polynomial of the first kind. Zverev (1967) and Fink and Christiansen (1989), Sec. 12, give more detail and tabulate the appropriate polynomials and roots in the form of quadratic factors.

8.3.7 Chebyshev Approximation. Chebyshev (various transliterated spellings are found in English) was a Russian engineer who studied harmonic motion, especially in steam engines, and developed the sequence of polynomials bearing his name. Cauer (1958) adapted them for use in network design. The polynomials are defined by the pair of equations

$$C_n(\omega)=\begin{cases}\cos[n\arccos(\omega)], & |\omega|\leqslant 1\\ \cosh[n\,\mathrm{arccosh}(\omega)], & |\omega|>1\end{cases}. \qquad (11)$$

It is seen that $C_0(\omega)=1$, $C_1(\omega)=\omega$. There is a recursion formula, based on trigonometric identities, that states

$$C_{n+1}(\omega)=2\omega C_n(\omega)-C_{n-1}(\omega). \qquad (12)$$

From this recursion formula, polynomials of any order can be constructed. For example, we can use the formula three times to show that

$$C_4(\omega)=8\omega^4-8\omega^2+1. \qquad (13)$$

The approximation uses the polynomials and a "ripple factor," usually denoted by the Greek letter $\epsilon\leqslant 1$, in the approximation function (Chen, 1986)

$$G(\omega^2)=1/[1+\epsilon^2C_n^2(\omega)]. \qquad (14)$$

This approximation gives a much sharper cutoff or discrimination at the edge of the passband than either the Butterworth or Legendre approximations, but the monotonic behavior is gone. Depending on whether the order n is odd or even, two differing types of equiripple approximation exist, shown in Figs. 9(a) and 9(b). It is seen that the factor ϵ controls the amount of ripple in the passband, and the order n controls the number of oscil-

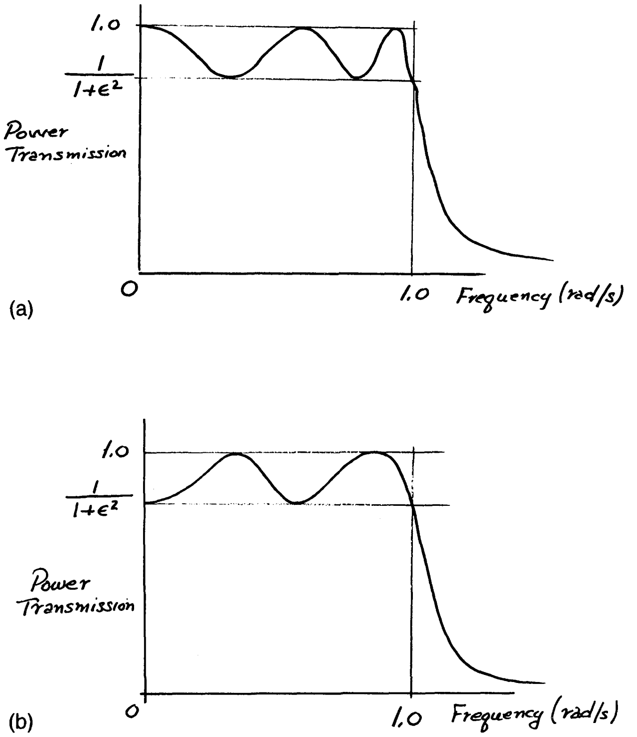

FIG. 9. (a) Chebyshev approximation for n odd. The drawing is for $n=5$. (b) Chebyshev approximation for n even. The drawing is for $n=4$.

lations. The function is monotonic in the stop band. The process of finding the quadratic polynomials in s is similar to that for Butterworth functions, but the process is more complex because of the need to consider two variables. Zverev (1967) and Fink and Christiansen (1989) Sec. 12, provide extensive lists. For example, if $\epsilon=0.3493$ and $n=4$, we find the transfer function, after using analytic continuation and root sorting, to be

$$G(s)=\frac{K}{(s^2+0.3507s+1.0635)(s^2+0.8467s+0.3564)}, \tag{15}$$

where K is a constant that can be adjusted, especially in active filters when there is a possibility of signal amplification as well as filtering.

8.3.8 Elliptic Filters. A more complex but more powerful approximation function, known variously as the Cauer-elliptic approximation, the elliptic function approximation, and the Chebyshev rational function approximation, has equiripple characteristics in both the pass band and the stop band. With elliptic functions, very sharp transitions between pass bands and stop bands are possible. These functions require three parameters for complete characterization, and as a result, the tables required are extensive. Zverev (1967) and Saal and Ulbrich (1958) give many combinations.

8.3.9 Bessel Filters. Although it is a low-pass filter, the primary use for the Bessel (also known as the Bessel-Thomson) approximation is to give a constant group or time delay for all signal frequencies below some threshold. A sequence of Bessel polynomials, not to be confused with Bessel functions, provides this approximation. The delay achieved is a maximally flat approximation to the ideal. Extensive tables of roots and other properties are provided in Zverev (1967), Weinberg (1962), and Fink and Christiansen (1989), Sec. 12.

8.4 Frequency Transformations and Scaling

The goal in this section is to show how to convert a low-pass function with a normalized band edge to a function with the values one is likely to find in practice. The first discussion will show how to scale the frequency from 1.0 rad/s to some value a. Then, transformations from low pass to high pass, band pass, and band stop will be considered. In doing this, the variable p will be substituted for s in the normalized, low-pass equations, so that s can be used in the final result.

8.4.1 Scaling. If a low-pass filter has been designed with a band edge at 1.0 rad/s, and it is desired to have the band edge at a new value of a rad/s, then the proper frequency scaling will be given by

$$p=s/a. \tag{16}$$

If we apply this to the normalized function in Eq. (10), which we rewrite as

$$G(p)=\frac{1}{(p^2+0.7654p+1)(p^2+1.8478p+1)} \tag{17}$$

and let $a=10^4$ rad/s, corresponding to a frequency of 1591.5 Hz, we get

$$G(s)=\frac{10^{16}}{(s^2+7654s+10^8)(s^2+1.8478s+10^8)}. \tag{18}$$

8.4.2 Low-Pass to High-Pass Transformation. The transformation $p=1/s$ will have the effect of inverting the frequency axis, so that the band $0\leqslant\omega\leqslant 1$ will become $1\leqslant\omega$, and the behavior that formerly existed in the low-pass region will now take place in the high-pass band. If we apply this technique to the function of Eq. (17), we get

$$G(s)=\frac{s^4}{(s^2+0.7654s+1)(s^2+18478s+1)}. \tag{19}$$

It would then be necessary to use frequency scaling on this function.

8.4.3 Low-Pass to Band-Pass Transformation. The transformation

$$p=(s^2+\omega_0^2)/Bs, \tag{20}$$

where B is the desired filter bandwidth and ω_0 is the desired frequency at the passband center, will accomplish this objective. For example, if it were desired to transform the low-pass filter of Eq. (17) to a band-pass filter having a bandwidth of 1000 Hz (6283 rad/s) and a center frequency of 8000 Hz (50 265 rad/s), then we would use the transformation

$$p=(s^2+50265^2)/6283s. \qquad (21)$$

If done without programmable calculators or computers, the arithmetic can become tedious, but it is straightforward. Alternatively, Eq. (20) can be solved for s by using the quadratic formula, and the roots of the low-pass quadratic equations can be transformed to the roots of the band-pass polynomials and the band-pass quadratic factors found without the necessity for finding roots of higher-order equations.

8.4.4 Low-Pass to Band-Stop Transformation. This transformation is the reciprocal of the low-pass to pass-band transformation. The reciprocal of Eq. (20) is used.

8.4.5 Element Magnitude Scaling. Much network design uses element value scaling, so that calculations are eased somewhat by working with a normalized load resistance of 1.0 Ω. This property also permits publication of extensive tables of element values, especially for passive networks (Zverev, 1967; Fink and Christiansen, 1989). At the end of the design, practical values are achieved by multiplying the values for inductors and resistors by the ratio of the load resistor to the normalized value, dividing the capacitance by this same value. Active network terms that have dimensions of ohms are multiplied by the same factor, terms that have dimensions of siemens (mhos) are divided by the same factor, and dimensionless terms are not changed.

8.4.6 Element Frequency Scaling. If a circuit designer has developed a network by using functions that are normalized in frequency, then the network elements can be scaled so that the desired frequency behavior occurs at a new frequency. For example, if the design has taken place at a normalized frequency of 1.0 rad/s, and the need is to translate the behavior to a frequency of 10^5 rad/s (15 915 Hz), then both capacitances and inductances are divided in magnitude by 10^5. Resistances are unaffected.

8.5 Network Realizations

8.5.1 Prototype Circuits. Once polynomials have been developed to meet the specifications, the next step is to find an electrical network. In this case it is assumed that an active or electronic circuit is desired. The number of possibilities is quite extensive, and only one will be described here. The circuit is based on the pioneering work of Sallen and Key (1955), and it uses operational amplifiers (See AMPLIFIERS, ELECTRONIC) as the central element. The circuit is usually called a multiple-feedback (MFB), infinite-gain circuit, as it depends on the very high gain achieved by the operational amplifier. Figures 10(a), 10(b), and 10(c) show the low-pass, band-pass, and

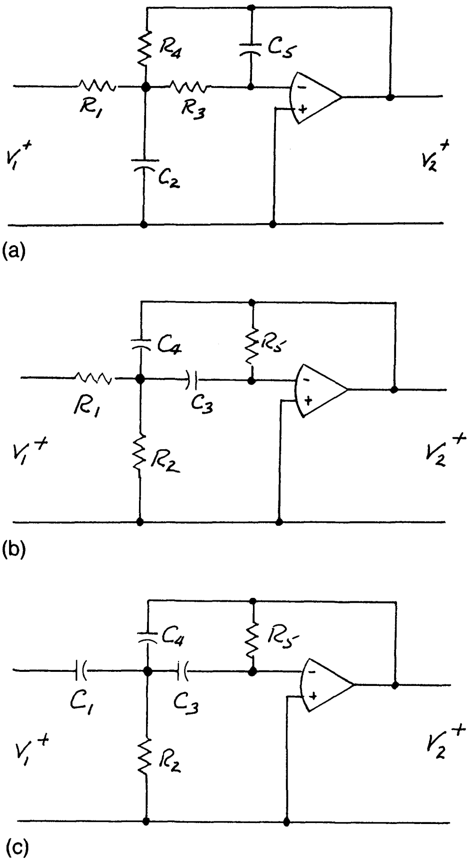

FIG. 10. Three multiple-feedback (MFB) second-order active filters. (a) Low-pass circuit. (b) Band-pass circuit. (c) High-pass circuit.

high pass configurations, respectively. A bandstop circuit is not possible with this basic circuit. The respective transfer functions for these circuits are

$$\frac{V_2}{V_1}(s) = -\frac{\dfrac{1}{R_1R_3C_2C_5}}{s^2+s\left(\dfrac{1}{C_2}\right)\left(\dfrac{1}{R_1}+\dfrac{1}{R_3}+\dfrac{1}{R_4}\right)+\dfrac{1}{R_3R_4C_2C_5}}, \tag{22}$$

$$\frac{V_2}{V_1}(s) = -\frac{\dfrac{s}{R_1C_4}}{s^2+s\left(\dfrac{1}{R_5}\right)\left(\dfrac{1}{C_3}+\dfrac{1}{C_4}\right)+\dfrac{1}{C_3C_4R_5}\left(\dfrac{1}{R_1}+\dfrac{1}{R_2}\right)}, \tag{23}$$

$$\frac{V_2}{V_1}(s) = -\frac{s^2\left(\dfrac{C_1}{C_4}\right)}{s^2+s\left(\dfrac{1}{C_3C_4R_5}\right)(C_1+C_3+C_4)+\dfrac{1}{R_2R_5C_3C_4}}. \tag{24}$$

Since the polynomials for the denominator are known in terms of quadratic factors, the designer can then choose the five element values to meet the numerical conditions. Since, in general, only three specifications must be met—two denominator coefficients and the numerator coefficient—and since five elements must be specified, the designer has two choices to make. Normally, the designer will choose these values to improve the circuit quality in some desirable sense. One possiblity, for example, is to have all capacitors equal. Another is to have a desirable ratio or equality between two resistor values. Still another is to minimize change in circuit performance caused by aging.

8.5.2 Cascading Second-Order Circuits. If a fourth-order circuit is needed, then the designer will have the option of using two of the preceding second-order circuits, connected in "cascade," as indicated in Fig. 11. With a sixth-order circuit, three such stages are needed. This works well because, under normal conditions, the stages do not interfere with or "load down" preceding stages. The ordering can be important. One good rule is to have the first or input stage realize the pair of poles farthest from the $j\omega$ axis, and then to have succeeding stages realize pole pairs progressively closer to the $j\omega$ axis.

8.5.3 Additional Active Filters. Many other techniques are available to design and build active or electronic filters. Some are similar to the circuits described earlier, in that they depend on a cascading of second-order circuits. Some do not have the negative sign, which represents a 180° phase shift that is not always acceptable.

Other techniques use combinations of operational amplifiers, resistors, and capacitors to produce devices called gyrators or frequency-dependent negative resistors (FDNRs) that replace inductors in conventional passive filter circuits (Chen, 1986).

The Huelsman-Kerwin-Newcomb (HKN) (Huelsman and Allen, 1980) filter uses operational amplifiers in a configuration that follows from state-variable descriptions of circuits. These are available commercially from a variety of sources.

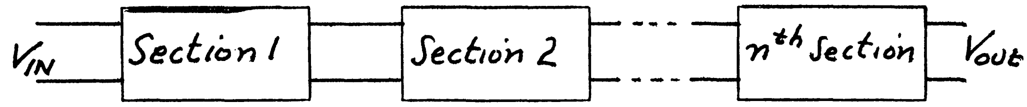

FIG. 11. Cascade of second-order active filter sections.

Two other techniques (Schauman, *et al.,* 1990; Geiger *et al.,* 1990) that are important are the switched-capacitor (SC) filter and the operational transconductance amplifier (OTA) filter. SC filters generally use the circuit topology of other active filters. However, resistors are implemented with capacitors, and the entire package is built in CMOS (complementary metal oxide semiconductor) technology. An external clock switches the capacitors between charge and discharge cycles. The circuit is tuned by adjusting the clock frequency.

While the operational amplifier is described as a voltage-controlled voltage source, the OTA is characterized as a voltage-controlled current source. The development of the OTA has led to new circuit implementation techniques, expanding the range of possibilities. Some circuits use OTAs to implement circuit elements such as resistors, though external capacitors are required in parts of the circuit.

GLOSSARY

Active Filter: An electrical filter that includes one or more electronic devices in its construction. See also **Filter**.

American Wire Gauge: A system used for designating wire sizes in the United States and elsewhere.

Bessel Approximation: A low-pass electrical filter approximation. The primary purpose of a Bessel filter is to provide a fixed time or group delay. Also known as the Bessel-Thomson approximation.

Bessel Polynomial: A sequence of polynomials, not to be confused with Bessel functions, used in the Bessel approximation.

Butterworth Approximation: A sequence of filter approximations leading to filters with maximally flat magnitude versus frequency characteristics in the pass band.

Chebyshev Approximation: A ripple type of approximation that is used in electrical filter design. It is based on the sequence of Chebyshev polynomials.

Chebyshev Polynomial: A sequence of polynomials defined by $C_n(\omega)=\cos(n \operatorname{arccos}\omega)$, $|\omega|\leqslant 1$, or by $C_n(\omega)=\cosh(n \operatorname{arccosh}\omega)$, $1\leqslant|\omega|$.

Elliptic-Function Approximation: A ripple type of filter approximation based on elliptic functions of the first kind.

Filter: An electrical circuit designed to separate components of an electrical signal based on one or more signal properties, such as frequency.

Hole: A vacancy in a crystal structure caused by the removal of an electron.

Inverter: An electrical circuit designed to convert dc to ac.

Legendre Approximation: A filter approximation that is monotonic in the pass band and that is based on Legendre polynomials.

Power Supply: In general, a component of an electrical system that provides electrical power to the system. A somewhat restricted definition is the subsystem that converts ac power to dc power.

Printed Circuit Board: A board, usually of laminated plastic, on which electrical components are mounted.

Rectifier: A circuit that converts ac to dc and that is a part of a power supply. (It also has other uses.)

Vacuum Diode: A two-terminal electrical device that has two electrodes mounted in an evacuated envelope and passes current in only one direction.

Vacuum Triode: A three-terminal electrical device that has three electrodes mounted in an evacuated envelope.

Vacuum Tube: An electrical decvice with two or more electrodes mounted in an evacuated envolope. Often the name indicates the number of electrodes. A pentode has five electrodes.

Valve: A synonym, used in Britain and elsewhere, for vacuum tube.

INTRODUCTION

The term reliability, as applied to the design and manufacture of electronic components and assemblies, is commonly defined as meeting the performance expectations of the user over the intended life of the product. The process by which reliability is achieved begins at the earliest stages of product definition and is, of necessity, a multidisciplinary evaluation of all the design, materials, manufacturing, and environmental factors that will bear on the product's performance in its intended use. The prerequisites for eliminating failures are

1. engineering evaluations that use statistical experimental methods and appropriately

digital Encyclopedia of Applied Physics

conceived and designed accelerated-life tests to uncover potential failure mechanisms,

2. failure mode analysis and laboratory experimentation that leads to scientific understanding of degradation processes, and
3. design procedures, materials selection, and manufacturing processes that avoid deficiencies responsible for failure. Stress tests that uncover root causes are best conducted during prototype development. These tests lead to reliability models that can then be used during the development of the manufacturing process to predict product reliability.

Development of high-performance, reliable electronic components and assemblies requires

1. an in-depth knowledge of the properties and interactions of materials with the surrounding world, whether it be the ambient environment or other materials;
2. scientific understanding of the behavior of electrons, photons, and atoms in the materials;
3. a detailed understanding of the effects of processing conditions on materials properties and performance;
4. robust designs that ensure the achievement of the desired properties in spite of process variability;
5. characterization of the materials and components required to manufacture the product to ensure that tolerances are being met; and
6. a scientifically based accelerated-life–test strategy that examines all functional levels of a product including semiconductor devices, discrete components, interconnection and packaging, circuit boards, modules, and entire systems.

This article describes the critical reliability issues with electronic devices and assemblies and the processes by which failures are discovered, mechanisms are understood, and prevention technologies are developed. The kinds of approaches that can be taken to ensure that performance objectives are met will be illustrated by specific examples. Failure mechanisms, accelerated testing methods, and failure prevention strategies will be considered at each level of functionality in electronic equipment, beginning with discrete components and integrated circuits and then extending to packaging, to assemblies, and finally to large mainframe computers or other systems. References with more extensive information on certain aspects of each of these functionality levels can be consulted as needed. The statistical aspects of reliability evaluation, testing, and estimation will not be described. The pertinent statistical models and methods can be found in the references.

Following this introduction is a brief history of accelerated-life testing, failure mode analysis, and reliability methodologies. The subsequent section covers reliability assurance methods for the various levels of functionality in electronic equipment. The final section considers future requirements in reliability and testing.

1. HISTORY

Since the earliest days of telephony and telegraphy, reliable performance has been essential to the proliferation of new types of electronic equipment and systems. Achieving near 100% reliability in telecommunications is now viewed as essential to the public welfare—sometimes a life-and-death concern for the general public. The same is true for computer systems used for aircraft navigation, space vehicles, and hospital monitoring systems. Laboratory-based reliability evaluations and accelerated-life testing for electronic equipment date back at least to the 1930s. At that time all components were quite large by today's standards, a large fraction of the functionality was achieved with vacuum tubes or electromechanical devices such as relays, and interconnection between components was almost entirely by wires. Faults were frequently caused by contamination at contact interfaces and tended to be intermittent rather than permanent. Tracing their source was much more difficult than in later years with transistors. The exception was vacuum tubes, the predecessor to transistors. Vacuum tubes failed permanently at rates that were many orders of magnitude higher than those for transistors in today's integrated circuits.

The earliest computers failed to operate correctly as frequently as once every few thousand cycles. Even relatively simple computations required dual calculations by identical logic units operating in a match–compare mode to ensure accurate results.

Also in the 1930s, when pollution was a major problem in metropolitan areas, corrosion and tarnishing of metals important to electronics, such as copper, copper alloys, silver, tin, and lead, became a reliability concern. Sulfide, sulfate, and nitrate corrosion products formed on these metals from exposure to sulfur dioxide, nitrogen oxides, the acids formed from these gases, and hydrogen sulfide. Accelerated corrosion tests were conducted on metal coupons to determine the maximum tolerable exposure levels that would not compromise reliability and to find alternative metallizations that could stand up to the corrosive gases.

A landmark book (Shewhart, 1939) on the use of statistical quality-control charts and quality-control methods for the manufacture of electronic equipment appeared in 1939. Through 1950, quality control through inspection and acceptance testing was the only reliability evaluation performed, with rare exception. Testing with corrosive gases and, to a minor extent, artificial dust was part of the qualification procedure that electronics manufacturing companies used for electrical contact materials in the mid-1950s. By 1960 most products underwent at least some form of wear or environmental testing, statistical techniques were frequently applied to reliability prediction, and every supplier of electronic equipment supported a substantial failure mode analysis program. The first Physics of Failure Symposium was held in 1962 and Military Standard-883 emerged in 1968 as a broadly applied standard for reliability evaluation.

By 1970 the application of reliability programs and life testing became an essential part of the development program for equipment used by governments and their military programs. More recently Deming (1982) wrote a widely read book on quality assurance and statistical process control. With the advent of the transistor in the 1950s, and later integrated circuits that coupled hundreds and thousands of transistors together on the same silicon chip, reliability requirements soared. The fact that one failed transistor could destroy an entire chip demanded unprecedented reliability and entirely new accelerated-life test methods. By the mid-1960s, electronic switching systems were able to handle all the logical steps required to transmit thousands of phone calls per day with a down time of 2 h in 40 years. The era of high reliability had clearly been born.

Standard test methods for accelerated-life testing, including military specifications and procedures adopted by professional societies, have been used by many companies and governments as part of the purchasing criteria since the late 1960s. These test methods include salt spray tests, static and cyclic temperature and humidity tests, static and cyclic temperature-humidity-voltage tests, static and cyclic mechanical test procedures, corrosive-gas tests, and dust-particle tests. Though these early tests were successful in discovering defects and led to prevention strategies for many types of failures, they also missed many failures that emerged during use of the product because they failed to activate the defects and true mechanisms responsible for field failures. Their use also caused unnecessary changes to be made because they sometimes uncovered defects that would not lead to failures in the use environment. These kinds of misleading results remain a problem today. In modern computing and telecommunication systems, the best reliability achievable in devices is not good enough and redundancy must still be built into the system design. Complicating the problem of achieving reliability even further is the rapid integration of photonic and electronic devices, components, and interconnects into the same system. Entirely new life-testing methods will be needed to unravel potential failure processes.

Today the large number of regularly scheduled meetings like the Reliability Physics Symposium and the Components, Hybrids, and Packaging Symposium sponsored by the Institute of Electrical and Electronic Engineers, the Fault Tolerant Design Symposium, and the Reliability and Corrosion of Electronic Materials and Devices Symposium sponsored by The Electrochemical Society are clear indicators of the continuing need for improved fundamental understanding of defects and failure mechanisms, advanced stress-testing methodologies, prevention technologies with broad applicability, and reliability models that include all the relevant factors in predicting the performance of mainframe computers and computer networks.

2. RELIABILITY, FAILURE MECHANISMS, AND TESTING

2.1 Passive Components

A component is a physically distinct part that encompasses a single electrical function. Passive components provide no amplification of current or voltage and are often the simplest ones in construction and in terms of reliability phenomena (Klinger *et al.*, 1990). Passive components include such devices as capacitors, resistors, inductors, transformers, and relays.

2.1.1 Capacitors. Of all the passive components, the aluminum electrolytic capacitor has the shortest useful life because of its characteristic wear-out mechanism. This capacitor has electrodes of aluminum contained in a housing or "can" with an electrolyte. A rubberlike polymer seals the can. Loss of electrolyte through the seal results in failure, with the mean time to failure varying from about 10 to 20 years. Failure rates increase with temperature and decrease with capacitor physical size. These capacitors should not be exposed to halogenated solvents since such solvents can penetrate the seal and cause internal corrosion and failure.

Another type of capacitor, commonly referred to as an electrolyte-filled ("wet") tantalum capacitor, has sometimes failed in spectacular fashion after experiencing a power surge or reversed-bias condition. Internal short circuits form, leading to excessive current, extreme heat, and possibly fire.

Other capacitor types are not prone to wear-out failures. However, care is needed in circuit design and in selecting the capacitor. Use conditions, such as temperature and humidity, must be kept in mind to avoid short- or open-circuit failures resulting from random defects.

2.1.2 Inductors, Coils, and Transformers. The most important failure mechanism in inductors, coils, and transformers is electrical breakdown of the wire insulation. The insulating properties of polymer wire insulation degrade with time and increased temperature. Eventually, a short circuit may form between windings. Local heating will then further degrade the insulation, causing more local short circuits. In a safely designed transformer, this local heating will result in an open circuit before a fire occurs. A fuse is sometimes incorporated in the design as a safety measure.

2.1.3 Relays. Relays perform a switching function and consist of one or more pairs of movable contacts. Normally a coil is energized to move one of the contacts in a pair either to open or to close the connection. Selection of the proper relay for the conditions of voltage, current, number of expected operations, and environment is essential to reliability. Important failure mechanisms include erosion of the contact metal by high-current arcs between the contacts as they open or close, and formation of insulating films or particles on the contact surfaces. These films or particles result from chemical corrosion or arc-induced formation of adherent residues from airborne organic or silicone contaminants.

2.1.4 Resistors. A resistor is a two-terminal device in which the voltage across the terminals is directly proportional to the current. Resistors dissipate power in operation, and the main reliability issues relate to the temperature rise. Proper selection for the application avoids changes in resistance value and catastrophic failure by keeping resistor temperature within allowed bounds. In applications in which high voltages are applied, the dielectric strength of the resistor must be adequate to prevent arcs.

2.2 Active Components and Integrated Circuits

Active components amplify current or voltage and, in a circuit, can be sources of current or voltage. Active components include transistors, thyristors, rectifiers, and diodes. Some of the reliability problems and failure mechanisms found in active components also apply to integrated circuits (ICs). Historically, these mechanisms were first discovered and studied in active components such as diodes and transistors, but similar failure mechanisms can occur in integrated circuits if the knowledge gathered from components is not wisely applied. Many mechanisms were not discovered until integrated circuits were produced in large volumes. These various mechanisms are grouped here according to the types of materials and their interactions.

2.2.1 Silicon Diffusion Effects. An early and important failure mechanism of diodes and transistors was related to the presence of clusters of crystal defects during the diffusion of dopants to form *p-n* junctions (Queisser, 1963). Impurities or mechanical damage at or near the surface of the silicon locally disrupts the crystal structure. When dopants are diffused into the silicon, their diffusion rates are greater at these crystalline defects. Thus, the diffusion proceeds to a greater distance, and the underlying layer width is locally reduced, as shown in Fig. 1. This width reduction can result in reduced reverse-bias voltage capability (lower breakdown voltage) or locally increased forward current resulting in a local temperature rise. In the former case, if the breakdown voltage reduction is large enough, failures will occur when the applied voltage exceeds the degraded capability. In the latter case, local heating causes more current to pass through the region (current crowding), further increasing the temperature until a runaway instability (sometimes referred to as second breakdown) takes place, possibly causing melting and catastrophic failure.

Crystal defects and impurities were eliminated or reduced by avoiding mechanical damage or contact with metallic handling tools, by incorporating highly efficient cleaning procedures in processing, and by minimizing high-temperature excursions. Also, the effects of defects and impurities are neutralized by actually introducing lattice damage to the back of wafers to getter impurities. Current crowding can be avoided by forming an array of small emitters rather than one large emitter (Stolnitz, 1965). The small emitters are connected to each other by a resistive material such that any tendency to current crowding in one emitter is negated by the forward-bias reduction in that emitter generated by the excess current. The excess current causes a voltage drop in the resistive material, tending to turn off this part of the device.

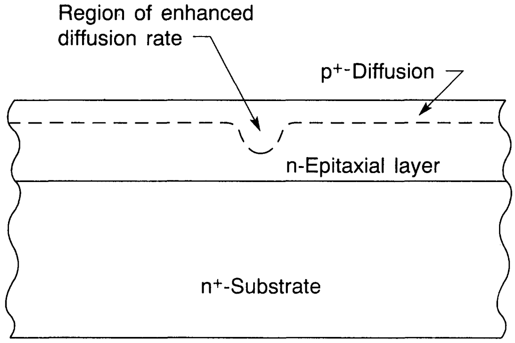

FIG. 1. Reduced breakdown voltage in diffusion-doped diodes. During diffusion of a p^+-n diode, locally enhanced diffusion rate results in a narrower *n* region. When voltage is applied, the high-field region may intersect the highly doped n^+ substrate, resulting in reduced breakdown voltage capability.

When aluminum is used as a contact material to silicon, the presence of defect clusters may cause rapid local interdiffusion of the aluminum and silicon. If the aluminum diffuses through the emitter of the transistor to the base (aluminum spiking), a short between emitter and base is formed. This short can occur during processing as a yield loss or during operating life, especially at elevated temperature. Interdiffusion can be eliminated or reduced by depositing a barrier metal, such as tungsten, between the silicon and aluminum, by doping the aluminum with silicon at deposition to reduce interdiffusion, or by minimizing processing and use temperatures.

The breakdown voltage of a reverse-biased junction may be reduced by the diffusion of copper into the silicon. The source of copper can be subtle, even ephemeral. For example, exposed copper within the cavity of a hermetically packaged transistor can react with hydrogen in the cavity atmosphere to form copper hydride vapor (Bergh, 1964). The vapor diffuses to the transistor surface where it is converted back to metallic copper. This can be avoided by sealing the device with an internal ambient that is free of hydrogen or by not having exposed copper in the package.

2.2.2 Silicon and Silicon Dioxide Interface. The strength of the electric field at the silicon surface depends on the presence of charge at the Si-SiO_2 (silicon dioxide) interface, within the SiO_2, or on the surface of the SiO_2 or other insulators. The charge in these various regions has several origins or sources (Deal, 1974). This section discusses effects related to drifting alkali ions (such as sodium) in the oxide, fixed charge at the Si–SiO_2 interface, and interface charge. Interface charge is related to traps (localized energy states that capture and release charge) and can exist in oxide traps or in traps at the Si-SiO_2 interface. The distinguishing feature of trapped charge is that the charge density depends on the number of traps filled or

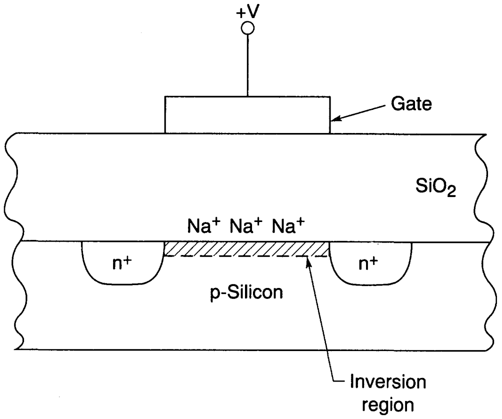

FIG. 2. Reduced threshold voltage caused by free sodium ions. During normal operation of NMOS transistors, a positive voltage on the gate turns the transistor "on." This positive voltage causes sodium ions to accumulate at the Si-SiO_2 interface. In subsequent operation, the device will turn on at lower-than-normal applied gate voltage.

empty; traps fill or empty by exchanging charge with carriers in the silicon. In contrast, the fixed charge is constant in time and location. Discussion of the effects of the charge residing on the insulator surface or at the interfaces between layered insulators is left for a later section.

The amount of charge in the oxide and the density of traps depend on impurity content, silicon crystal orientation, oxide formation conditions, annealing processes, ionizing radiation, and a number of other factors. These effects are extremely complex and are manifested by changes in a variety of electrical parameters. However, it is possible to describe briefly two of the major reliability effects related to oxide or interface charge.

Sodium ions, which have a single positive charge, are mobile in SiO_2 and move readily in the presence of an electric field, especially at elevated temperature. The numerous sources of sodium ions include dust particles; human-related contamination; impure water, solvents, acids, and other process chemicals; quartz furnace tubes used for silicon oxidation; deposited metal from contaminated sources; sodium-containing polymers that form part of the device package; and many others. Either sodium is incorporated throughout the oxide during oxide growth, as in a contaminated furnace, or it may be deposited on the surface of the oxide. In the latter case, elevated temperature causes the sodium to diffuse readily throughout the oxide.

If the sodium drift is toward the silicon, the resulting accumulation of positive charge at the Si-SiO_2 interface can affect the potential of the silicon surface. The change in potential makes the silicon less *p*-type or more *n*-type, changing the threshold voltage of MOS transistors (Fig. 2) or causing resistive short circuits between the emitter and collector of an *npn* transistor (Nicollian and Brews, 1982) (Fig. 3).

The second effect is related to the injection of electrons into SiO_2 from the silicon. In the high–electric-field region of a reverse-biased junction or a channel region in an MOS device, some conduction electrons will gain sufficient energy to leave the silicon and enter the SiO_2 (Hu *et al.*, 1985). This process, over a period of time, results in accumulation of negative charge at the interface, thereby increasing, for example, the threshold voltage of an NMOS device. This effect is minimized by altering the structure of MOS devices to decrease the peak electric fields.

2.2.3 Metal-Related Mechanism

2.2.3.1 Electromigration. Electromigration (Black, 1967) can cause failures in aluminum metal interconnection in integrated circuits and other devices. Current through the aluminum is carried by the passage of electrons. The electrons transfer a fraction of their momentum to the aluminum atoms, thus resulting in a force on the atoms. This force causes the atoms to move and to form

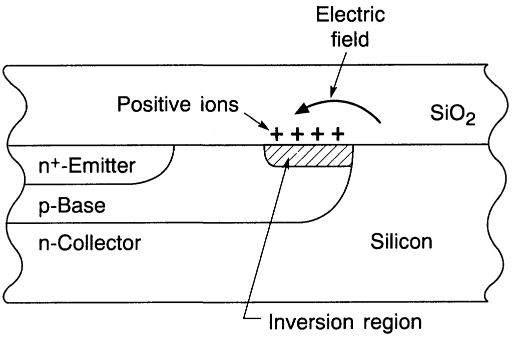

FIG. 3. Resistive shorts caused by free sodium ions. The fringing electric field at the surface of the reverse-biased collector-base junction causes sodium ions to collect at the Si-SiO_2 interface. This results in inversion of the *p* base. The fringing field moves to the left in the diagram and sweeps more sodium to the interface, resulting in an effective narrowing of the base at the interface. (From Nicollian and Brews, 1982).

voids (missing aluminum) or hillocks (accumulated aluminum). The voids can coalesce, resulting in open circuits, and the hillocks can grow until they connect to adjacent aluminum, possible resulting in a short circuit. The voids and hillocks occur principally at the intersection of three metal grains.

Electromigration is a wearout mechanism that affects many devices to some extent. The severity increases with current density in the metal line and with temperature. Factors that affect the failure rate are grain structure; constrictions in the metal arising from underlying topography, mask defects, corners, or corrosion; and hard dielectric overlayers that prevent hillock growth and, therefore, prevent void formation. For example, decreasing linewidth increases the rate of electromigration since, for a given current, the current density increases. However, for lines that are narrower than the typical grain size, the electromigration is greatly decreased. This happens since the grain structure has a "bamboo" pattern in which single grain boundaries bisect the metal line, and there are, consequently, relatively few or no junctions between three grains, as shown in Fig. 4.

Large improvements in resistance to electromigration are achieved by adding a few percent of copper to the aluminum metal (Ames *et al.,* 1970). The copper tends to segregate at the grain boundaries, inhibiting the transport of aluminum.

2.2.3.2 Mechanical Stress. Aluminum has a larger coefficient of thermal expansion than the silicon substrate and the inorganic layers deposited as interlevel dielectrics. Aluminum and dielectric deposition processes are usually performed at elevated temperature. For these two reasons, aluminum interconnections are generally in tensile stress at or near room temperature. This tensile stress results in migration of aluminum atoms from the edges of the lines to grain boundaries within the line, causing voids to appear at the edges (Yue *et al.,* 1985). For the narrow lines used in advanced device structures, these voids can cause open circuits or a reduction in metal cross section that leads to early failure by electromigration. Stress-generated voids can be minimized by using metal and dielectric deposition processes that reduce stress and by avoiding overly thick dielectric layers. Stress failures can also result from polymers used in molding device packages.

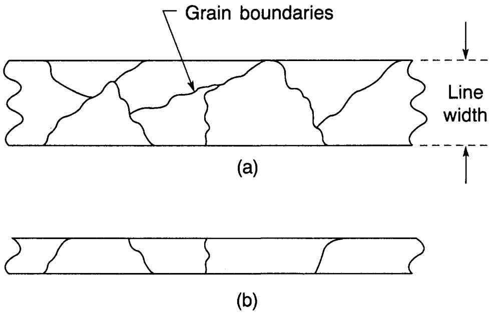

FIG. 4. Effect of grain size on electromigration. For a given aluminum grain size, a wide aluminum line (a) can have many intersections of three grains, at each of which a void can form. A narrower line (b), with the "bamboo" structure, has no intersection of three grains and electromigration is much less likely.

2.2.3.3 Corrosion. Various metals and combinations of metals are used as interconnections on monolithic and hybrid integrated circuits. The most commonly used metal is aluminum, usually alloyed with copper or silicon. Gold is sometimes used, usually in "tri-metal" combinations with a base metal, such as titanium, and a barrier metal, such as platinum or palladium. On hybrid integrated circuits, the variety of metals can be even greater and may include silver, copper, tin, lead, and others. The corrosion mechanisms depend on the metals present, contaminants, moisture, and voltage (Comizzoli *et al.,* 1986). The failure mode can be an open circuit as in the case of aluminum, or a short between interconnect lines when the soluble metal ions migrate and "plate out" at the more negative electrode to form a dendrite, as, for example, in the case of gold. In general, corrosion mechanisms are accelerated by temperature and humidity.

Dissimilar metals, e.g., gold wire bonded on aluminum pads, can corrode in the absence of an applied potential since in the presence of moisture they form an electrolytic cell with a "built-in" potential difference. This type of corrosion, called galvanic corrosion, occurs readily at bond pads in the presence of water and a contaminant such as chloride or bromide ions. Thus, plastic-packaged integrated circuits in humid environments may fail if solder fluxes containing halides penetrate to the pad area. Also, exposure of such integrated circuits to high temperature for extended time periods may decompose bromine-containing fire-retardant additives in the polymer, which subsequently results in corrosion.

Applied voltages can also cause corrosion when both electrodes are made of the same metal. Adsorbed moisture is generally required for transport of ionic species that carry current between the metal conductors. When the conductors are aluminum, both the positively biased and negatively biased conductors are susceptible to corrosion. Ionic halide contaminants destroy the protective oxide film on positively biased aluminum, exposing fresh metal that corrodes. At the negatively biased electrode, water is reduced, forming hydrogen molecules and hydroxyl ions. The latter increase the *p*H at the surface of this conductor. If the *p*H becomes sufficiently high, i.e., basic, the protective oxide and the aluminum metal will dissolve. Positively biased gold conductors are also subject to corrosion. If both adsorbed moisture and ionic halide contaminants are present, the gold conductor will corrode, forming a soluble gold halide complex. The gold complex can migrate to the negative conductor where it will be reduced to gold metal in the form of dendrites or conducting bridges that grow back toward the positive conductor. Eventually, the dendrites will short circuit the two conductors causing a failure. In the absence of halide contaminants, gold is oxidized to gold hydroxide, forming a voluminous precipitate. Failure results when this precipitate spreads across the circuit, reducing the resistance between conductors, or when the positively biased conductor has corroded through, causing an open circuit. Dendrite formation has also been observed with other metals. For example, silver dendrites have been found on ceramic chip capacitors after they were soldered using a water-soluble flux that contained halides.

Silicone polymer coatings provide excellent corrosion protection. These are applied to the chip before it is molded in epoxy. The device surface must be clean before polymer application to obtain good adhesion. If hygroscopic contamination is present at the polymer-chip interface, water absorption will occur at the contaminated interface under high humidity conditions. Corrosion of any exposed metal may then occur. Epoxy molding compounds contain some sodium and chlorine. In the late 1970s, chlorine levels of several hundred ppm were not uncommon in molding compounds. At that time, failure rates of several percent per thousand hours of 85 °C/85% relative humidity/bias were considered excellent. Now, molding compounds with chlorine contamination as low as a few tens of ppm are commercially available, and failure rates below 1% have been obtained.

Passivation layers (insulating, usually inorganic, deposited films) over the metal in nonhermetic integrated circuits greatly reduce the risk of corrosion. However, the passivation layer must be pinhole- and crack-free and adhere well in the presence of moisture and upon exposure to temperature cycling. The use of phosphorus in silicon dioxide passivation layers is beneficial on several counts, but the phosphorus content must be carefully controlled to be below 4 wt % for undensified films, to avoid leaching of phosphoric acid in the presence of moisture. This leaching has resulted in extensive corrosion of aluminum of disastrous proportions.

Corrosion rate generally increases with voltage for a given device geometry (see later discussion in Sec. 2.3.3). Power dissipation that raises chip temperature above ambient tends to reduce the incidence of corrosion, since the local relative humidity at the chip surface will be less than ambient relative humidity. Effective moisture control in hermetically packaged devices is an important factor in corrosion protection, particularly when power dissipation is low or the device operates in a reduced-temperature ambient.

2.2.4 Insulating-Layer Mechanisms. The complexity of modern semiconductor devices, hybrid integrated circuits, and advanced packaging technologies requires the use of many types of insulating layers for numerous applications such as multilevel metallization structures. For silicon integrated circuits, a thin film of silicon dioxide (SiO_2) provides the insulation layer between the gate and channel of metal oxide semiconductor (MOS) devices. An oxide layer protects the junction of bipolar circuits. Insulator films are used to isolate the different levels of metallization and also to planarize the structure for subsequent film deposition. Other insulator layers may be needed to provide stabilization or passivation, to increase breakdown voltage, or to serve as the active structure in memory devices such as metal-nitride-oxide semiconductor or floating-gate

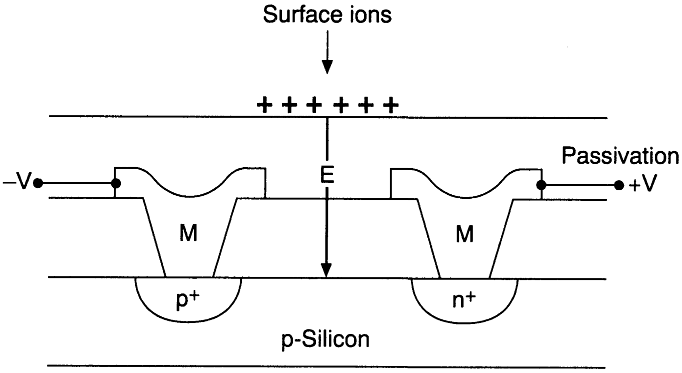

FIG. 5. Electric field in silicon caused by surface charge on insulators. Schematic cross section of an idealized diode showing the vertical electric field resulting from a net surface charge on the insulator of the device. *M*, metal; *E*, electric field vector; *V*, potential.

avalanche-effect integrated circuits. These insulating layers may include thermally grown SiO_2, SiO_2 formed by chemical vapor deposition (CVD), phosphosilicate and borophosphosilicate glass from CVD processes, silicon nitride from high-temperature CVD or low-temperature plasma-assisted CVD methods, glass layers formed by glass particle deposition and fusion, ceramics, and various polymers. Various failure mechanisms are related to these insulating layers.

2.2.4.1 Surface-Ion Failure Mechanism. Failures by this mechanism still occur, particularly in high-voltage devices, even though it was discovered and understood quite early (Atalla *et al.*, 1959).

Surface ion motion on the outermost insulating layer of a device can result in local accumulations of net ionic charge. This net charge induces a vertical electric field in the insulator and at the semiconductor surface, as shown in Fig. 5. The electric field, if large enough, can cause inversion or accumulation of the semiconductor free charge density, leading usually to increased leakage current; or it results in localized electrical breakdown in the semiconductor and reduces the device breakdown voltage below rated values.

The surface ion motion takes place on the outer layer of the device, which is normally the passivation layer in the case of an integrated circuit. A slight surface conductance, such as results when an insulator is exposed to water vapor, is sufficient to produce charge polarization. For example, at exposed metal, as exists at a bonding pad or passivation pinhole, the electric field parallel to the surface will cause ions of the same sign as that of the metal to drift away from it, as shown in Fig. 6. This ion drift tends to charge the insulator surface to the same potential as the metal, provided that the surface conductance of the insulator is much greater than its bulk conductance. By this surface-ion drift mechanism, lateral propagation of potentials to a region can result in the potential of the insulator surface being at one extreme of the potentials applied to the device, while the potential of the semiconductor (silicon) below that region is at the other extreme. In this case, the electric field in the insulator and at the silicon surface can be sufficiently large to induce the effects described above (leakage or breakdown voltage reduction). Direct deposition of charge on a device from a high-voltage source is a useful technique for studying this failure mechanism (Comizzoli and Osenbach, 1988).

A traditional method for avoiding surface-ion–induced failures is the use of a metal field plate to fix the surface potential above sensitive regions at a safe value. The distance between high-voltage nodes can also be increased within certain limits to reduce the electric field in the silicon. Oxide thickness

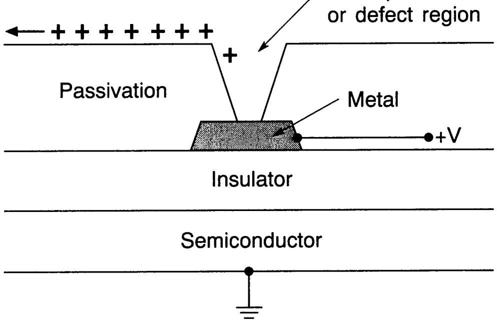

FIG. 6. Schematic cross section illustrating ion motion on the surface of an insulator near exposed metal.

can be increased, also, to reduce the electric field associated with the surface ions.

2.2.4.2 Charge Accumulation in Multilevel Insulators. Net charge can accumulate at the interfaces between insulating layers (Woods, 1974). In general, each insulator layer in a stacked structure has a different conductivity and dielectric constant. The conductivity results from ionic motion, electronic motion, or some combination of these. Initially, when voltage is applied across the insulator layers, the voltage is divided capacitively among each of the layers. Thus, the initial electric field in each layer depends on the dielectric constants and thicknesses of all of the layers. This electric field results in a current in each insulator that, in general, is not equal to the current in the other insulators. Since charge must be conserved, accumulation of net charge occurs at interfaces between insulators with unequal currents. As time progresses, the insulator system approaches a steady state in which the charge at each interface and the electric field in each insulator have attained values such that the currents resulting from the electric fields are continuous across the interfaces.

Another mechanism that can result in interface charge formation is a polarization of one of the insulators. In the applied electric field, dipoles in the insulator orient themselves parallel to the electric field. The effect is the same as that of drift of ionic or electronic charge.

If the result of the interface charge generation is an increase in the electric field at the semiconductor surface, then device operation may be degraded. The semiconductor may become inverted, resulting in excess leakage current and failure. In a high-voltage device, the excess field may result in electrical breakdown in the semiconductor at applied voltage levels below those specified. This failure mechanism can be prevented by considering the insulators' electrical properties and device design. Various structures such as field plates or shields can be used in sensitive regions.

2.2.4.3 Electrical Breakdown of Silicon Dioxide. The electrical breakdown (loss of insulation properties) of a thin insulator such as silicon dioxide (SiO_2) is one of the most difficult failure processes to understand since it is sudden and very rapid, and in general destroys the affected area by the heat generated in the breakdown event. The breakdown occurs at a highly localized region and can be induced by exceeding the breakdown electric field (field breakdown) or by maintaining a constant field for a certain time after which the insulator breaks down (time-dependent breakdown).

Much effort has been devoted to understanding breakdown effects in SiO_2. Breakdown can occur at defect sites, where the breakdown field has a wide range of values, or breakdown can be intrinsic with a value of about 1×10^7 V/cm for defect-free SiO_2. Defects that reduce breakdown voltage below the intrinsic value include thin spots, rough contours in the silicon that concentrate the electric field, and foreign material such as sodium ions, metals, and water.

Various models have been proposed to explain the time, temperature, and field dependence of SiO_2 breakdown. A model that successfully explains a wide variety of observations is the gas discharge model (Wolters and Verwey, 1986). The breakdown process in this model begins with injection of electronic charge into the oxide during the time that bias is applied. The fraction of this charge that is trapped in the oxide leads to a local increase in the electric field. When the local field is high enough, some of the trapped charge is released energetically, generating a microvoid by disruption of the SiO_2 network. In the microvoid, electrons attain much higher energies in the field so that more disruption of the structure takes place. Eventually the void structures grow and link up until a void network is formed between the electrodes. This is the breakdown event in which a surge of current passes through the SiO_2.

Various techniques are used in processing to achieve high breakdown strength. These include clean processing, growth and removal of sacrificial oxides, and complex growth and annealing processes for the oxides. Chlorine is an effective impurity getter during oxide growth and contributes to increased breakdown strength.

2.2.5 Electrical Overstress

2.2.5.1 Electrical Latch-Up. Latch-up is a purely electrical phenomenon that principally affects complementary metal oxide semiconductor (CMOS) integrated circuits. It can occur whenever four regions of alternating conductivity type, such as *npnp* or *pnpn*, exist in a structure (Schnable, 1989). In CMOS circuits, such regions occur commonly.

The series connection of *npnp* or *pnpn* forms a parasitic thyristor. This thyristor structure is not intended as part of the design, but nevertheless exists, hence the term parasitic. Thyristors switch between two states, blocking or conducting. Very little current flows across a thyristor until a certain voltage is exceeded. The device then turns on, and a large current flows at low voltage; thus the term "latch up." The parasitic thyristor functions in the same way. Thus, an overvoltage in an integrated circuit can trigger the thyristor action, and large currents will flow through the parasitic region. While the current is flowing, the device function is disrupted. If the current source has a low enough impedance, the integrated circuit may be destroyed. The thyristor action continues until the device is destroyed or the circuit is interrupted. In addition to a high voltage, latch-up can be induced by any excitation that increases the conduction carrier density in the parasitic region, such as high temperature or radiation.

2.2.5.2 Electrostatic Discharge Effects. Failures caused by electrostatic discharges (ESD) (Amerasekera and Campbell, 1987) typically occur when an electrically charged person comes into electrical contact with a device. A human being can acquire an electrical charge by contact or friction with a material such as carpeting, floor tiles, plastic seating, etc. If contact is made to a device, the charge is transferred to it. In the transfer, the device experiences a voltage surge that can cause electrical breakdown of insulators or junctions.

The approximate capacitance of a human body is 150 pF, and normal body potentials of several thousand volts can be expected from, for example, walking across a room. Under dry conditions, body potentials of more than 20,000 V are not uncommon after walking over a wool rug. If a person then touches electronic equipment, this accumulated charge is transferred to the equipment. The charge can induce large voltages on certain circuit elements, resulting in electrical breakdown of insulators or semiconductor junctions.

These electrostatic discharge effects are most severe in the production process for integrated circuits, in which the devices are exposed and can be contacted by a highly charged person. After components have been packaged, mounted on a circuit board, and assembled into an enclosure, the possibility of damage by electrostatic discharge is much smaller but can be significant if precautions are not taken.

Methods of avoiding damage include techniques to minimize charging of the human and design modifications to "harden" devices against electrostatic discharge. The former include various kinds of static-free and static-dissipative clothing and grounding straps, conductive sprays, air ionizers to discharge surfaces, and conductive floors and mats. Design modifications involve components added as part of the integrated circuit to reduce the effects of current and voltage spikes and transients. These protective circuits contain combinations of resistors and voltage-sensitive diodes or transistors. The function of the voltage-sensitive components is to switch "on," from a high-resistance state to a conducting state, when a voltage spike is applied. The electrostatic discharge voltage and current spike flow through the protective device and not through sensitive parts of the integrated circuit. Another protective device that can be fabricated as an integral part of an integrated circuit is the spark gap. This consists of a plane array of metal points with a short gap between them. When a voltage spike is applied, breakdown of the ambient gas above these points shorts out the pulse before it can damage the integrated circuit.

2.2.6 Radiation Effects. The effects of ionizing radiation are particularly important in satellite or military applications. There are both immediate and long-term effects on devices (Braunig and Fahrner, 1986). For example, in a nuclear blast, an intense radiation flux immediately passes through an integrated circuit, generating a high density of charge carriers in insulators and semiconductors alike. For a time, the device is nonfunctional since all parts of it are conducting. Long-term effects occur even for the levels of radiation occurring naturally in outer space. For example, high levels of proton or electron flux, depending on altitude, are found in the Van Allen belts. This radiation can increase the charge at the Si-SiO$_2$ interface and cause failures in metal oxide semiconductor (MOS) devices. Crystal structure damage can also occur as a result of particle flux, which can change the gain of bipolar resistors.

Radiation associated with metals and ceramics used in integrated circuit packaging can cause "soft" or "single-event upset" errors. α particles are emitted by certain nuclei in, for example, alumina device packages. An α particle generates a large number of electron-hole pairs when it passes through silicon. If the path is through a memory cell in a dynamic random access memory (DRAM), the generated carriers result in sufficient conductivity to change the state of the memory cell. These effects are eliminated by carefully selecting packaging materials and by using an α-particle shield over the surface of the integrated circuit.

2.3 Enclosures For Integrated Circuits

Once an integrated circuit has been manufactured it must be surrounded by a package or enclosure that provides some degree of protection from the environment and a means to interconnect the functional capability of the chip to the rest of the electronic system. It is essential that the materials used to achieve protection from environmental contaminants do not contribute harmful contamination at the chip surface. These subjects have been discussed in more detail by Comizzoli *et al.* (1986). Before considering the various methods for enclosure, the environmental constituents of concern will be discussed.

2.3.1 Environmental Factors and Manufacturing Contamination. Because of the importance of environmental effects, the constituents that cause corrosion and short circuits in electrical devices need to be considered when reliability tests are planned (Sinclair, 1988). These tests should take into account the severity of the environment that the product will see. The constituents of greatest concern are water-soluble ionic contaminants. These are ubiquitous components of the environment and include sea-salt particles, particles derived from fossil-fuel combustion or the incineration of municipal waste, commercial and residential fertilizers, soil dust, and salts used to melt ice and snow. The indoor concentrations of these substances typically range from 10% to 80% of their outdoor concentrations, with office environments usually at the low end of the range and factories at the high end.

Particles in the environment exist in two distinct size regions:

Coarse particles ($>2\ \mu$m diameter) consist largely of natural materials derived from soil and rocks, especially in the outdoor environment. In the manufacturing environment, a variable fraction of these particles may be process related. Air-filtration systems in office buildings and manufacturing environments are typically (30–95)% efficient in removing coarse particles from the incoming air.

Fine particles ($<2\ \mu$m diameter) typically result from fossil-fuel combustion, but they may also be process-related in manufacturing environments. Because combustion-derived particles contain larger concentrations of water-soluble ionic substances, they tend to be more corrosive than natural particles. Air-filtration systems are less effective in removing fine particles than coarse particles.

Sulfate, typically as ammonium acid sulfate, is usually the most abundant anion in fine particles indoors and outdoors. Indoor concentrations of sulfate are typically (40–75)% of the outdoor concentrations and correlate over time with the outdoor levels.

Ionic contaminants are also present in processing chemicals, which include electroplating salts, gases or liquids used for wet or dry etches, solder fluxes, acids and bases, and some cleaning solutions. These processing sources can cause contamination by direct contact. They can also raise the airborne concentrations of specific ionic compounds to levels several times higher than outdoor concentrations. These airborne contaminants may be transferred by air currents to sensitive electronic components in other parts of the surroundings.

In the presence of sufficient humidity, ionic contaminants acquire moisture and form thin films of electrically conducting solutions. The result may be enough current leakage to cause crosstalk (extraneous signals) or soft errors. The same types of moisture-related failure processes described previously for integrated circuits also apply to circuit boards and hybrid integrated circuits. When high electric fields are present, component-damaging electrical arcs can also occur.

Ionic contaminants may be deposited on sensitive surfaces during manufacture before protective coatings are applied. These contaminants, combined with exposure to atmospheric moisture, allow leakage currents to flow under the coating. Ionic contamination deposited in the field allows leakage currents to flow over the top surface of the coating between exposed bond pads or leads.

The increasing use of forced-air cooling to carry away the heat generated by high–power-density circuits can greatly accelerate the deposition of atmospheric dust particles if enhanced filtration is not provided on the incoming air stream.

2.3.2 Package Types, Wire Bonding, and Chip Mounting. The three most predominant types of packaging (plastic packages, ceramic packages, and flip-chip encapsulated devices) and the methods of connecting device leads to substrate metallizations are depicted in their simplest forms in Fig. 7–10. The metal leads extending from the plastic and ceramic (hermetic) packages in Figs. 7 and 8 are one of three common designs for connecting the package to a circuit board or hybrid integrated circuit. In this case the leads are placed in "via" holes drilled in the substrate and then soldered permanently in place, as shown in Fig. 9. In another method the leads may be plugged into a "socket," which has previously been attached to the substrate through a soldered interconnection. A third method is to "surface-mount" the package directly to the circuit board. This method of attachment is also depicted in Fig. 9. In this case the leads extending from the package are oriented parallel to the substrate surface and are connected to "bond pads" on the mounting surface, again using solder.

For plastic or ceramic packages, the silicon chip inside the package must be connected to the leads that extend out of the package. This connection is usually accomplished through gold wire bonds that are attached to the aluminum metallization of the silicon chip and to the lead metal (usually copper) by ultrasonic or thermocompression bonding. A wire bond connection is shown in Fig. 7.

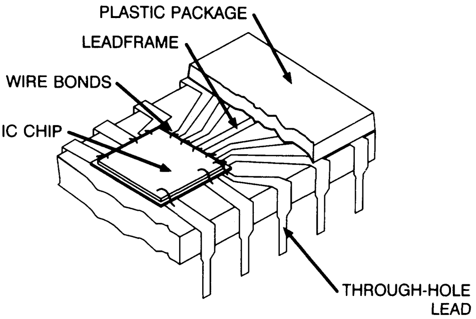

FIG. 7. Plastic package.

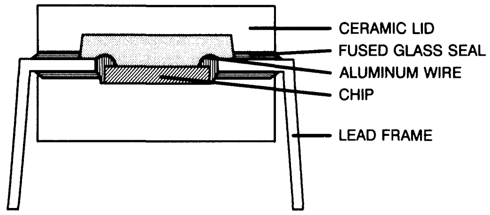

FIG. 8. Ceramic package.

In the case of flip-chip encapsulated devices, bond pads on the active side of the silicon chip are placed directly over solder bumps on bond pads on the substrate. Attachment takes place when the solder bumps are reflowed. The attached chip is then protected from the environment by encapsulation with a rubbery polymer (elastomer), which is usually a silicone. This method is illustrated in Fig. 10.

2.3.3 Plastic Packages and Flip-Chip Encapsulated Devices. Reliability issues that must be considered in the use of plastic packages and flip-chip encapsulated devices include chemical and electrochemical degradation, e.g., corrosion processes caused by moisture and other contaminants, and me-

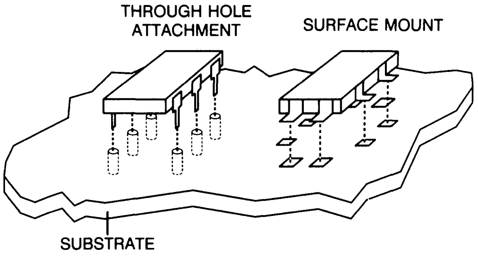

FIG. 9. Comparison of through-hole and surface-mount attachment. For through-hole attachment, the leads from the device are placed in holes that are previously drilled in the substrate. A permanent connection is made by exposing the underside of the board to molten solder. For surface-mount attachment, solder paste is applied to bond pads on the substrate, the device is then positioned on the substrate so that the bond pads and leads align, and the solder paste is flowed by hot air or infrared heating.

chanical stresses caused by temperature fluctuations, vibration, or shock.

Most chemical and electrochemical degradation processes involving contamination require the presence of moisture. Prevention of ionic contamination and moisture condensation inside the package is the most important function of the plastic package or encapsulation surrounding the chip. All polymeric materials that are used to protect chips are permeable to moisture to some degree. The best polymers available for electronic applications (polyimides and Novolac epoxies) typically acquire (0.1–3)% of their dry weight in moisture at saturation. While equilibration with the external humidity level is rapid (hours to days), condensation of moisture is prevented as long as the polymer tightly adheres to the active surface of the chip. Moisture-related failures are usually associated with loss of polymer adhesion to metal conductors. Ionic contamination is frequently found at the ruptured interface, though the contamination is not necessarily the cause of adhesion loss or device failure. Once delamination occurs and moisture condenses on exposed circuit elements, the electrical bias in typical integrated circuits is more than sufficient to initiate electrolytic corrosion, as illustrated in Fig. 11. The electrical malfunction associated with electrolytic corrosion can take one of several forms including leakage currents due to ion current in the condensed moisture film, electrical open circuits caused by consumption of the conductor, and electrical shorts caused by metal bridges between conductors. These are illustrated schematically in Fig. 12. The susceptibility of devices to failure by these processes increases dramatically as the minimum conductor linewidth decreases for integrated

E_{anode} and $E_{cathode}$ are the electrode potentials, which take into account the concentration-mediated thermodynamic potential for the reaction at each electrode and kinetic factors. All the remaining voltage between the conductors must be dissipated in the *I-R* drop (*I* is current and *R* is resistance). Corrosion is minimized by maximizing *R*, which is accomplished by lowering relative humidity, minimizing contamination, and use of high-resistance coatings. Bottom: illustration showing that a large fraction of the voltage applied to an integrated circuit (5 V) is dissipated in the *I-R* drop, illustrating the importance of high insulation resistance. The electrode potentials used for this illustration are rough approximations.

FIG. 12. Moisture/contamination failures on substrates. The three most common types of failures that can occur when contamination and moisture allow leakage currents to flow. (a) The simplest failure, a shift of the electrical parameters of a circuit out of specification. The shift is caused by the current flow associated with migration of positive and negative ions from contaminants. (b) The leakage current associated with ion migration, which may not be sufficient to cause a failure by itself, but may lead to oxidation of the anodic conductor with the formation of metal ions. These ions can migrate to the cathode. Upon reaching the cathode, the ions are reduced to the metallic state. As this process proceeds, dendritic filaments of metal grow back toward the anode. Eventually the gap between conductors is bridged, forming a short circuit. (c) Similar to (b), in that metal ions oxidized at the anode migrate to the cathode. In some cases, the important reaction at the cathode is the reduction of water to form hydroxyl ions. The hydroxyl ions and metal ions react to form an insoluble precipitate, usually near the cathode. An open circuit eventually develops at the anode when sufficient metal has oxidized to open up the conductor line. The time to failure in this case is a direct function of the cross-sectional area of the conductor and the leakage current (see Fig. 13).

circuits, the interconnecting conductors in the packages that contain them, and the printed wiring on the circuit boards on which they are mounted. This trend is illustrated in Fig. 13 for electrical open circuits caused by consumption of conductors. This figure shows that the maximum tolerable leakage current per corrosion site for a 10-year lifetime, assuming

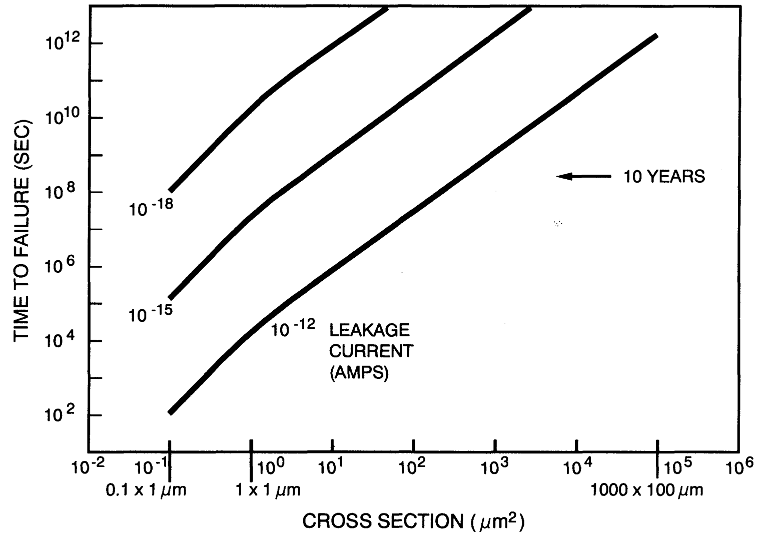

FIG. 13. Time to failure versus cross section. The time to failure, when electrical leakage currents that flow between conductors lead to corrosion of the anode or cathode, depends on the current and the cross-sectional area of the conductor. For circuit-board conductors with typical linewidths of 100–1000 μm, the time to failure is > 10 years for a leakage current of 10^{-12} A per corrosion site, which is the optimum level typically achieved for circuit boards in ordinary environments. However, for integrated circuits with linewidths of 0.1 μm, which are expected to be commercially available around the year 2000, a 10-year lifetime requires leakage currents of no more than 10^{-18} A per corrosion site.

that the current efficiency for corrosion of metal is 100%, decreases by more than 6 orders of magnitude as feature size changes from 150 to 0.5 μm (typical of circuit boards and integrated circuits, respectively, in the early 1990s).

The leakage current across insulators typically shows an exponential dependence on relative humidity. The concept of a critical relative humidity below which moisture-related failures do not occur follows from the exponential dependence. The critical relative humidity is usually in the range of (55–70)%, which roughly corresponds to the humidity at which ionic pollutants associated with fossil-fuel combustion show a large increase in hygroscopicity (moisture pickup capacity) as humidity increases. None of the failure processes ascribed to electrolytic corrosion will occur in the absence of moisture. As discussed, prevention requires highly adherent polymer coatings or packages. Controlling ionic contamination on chip surfaces well below 10^{13} ions/cm^2, and controlling bulk ionic contamination in polymers to < 5 ppm, also minimize the risk of failure.

The appropriate testing strategy is to expose the chip package to moisture stresses and ionic contamination. Three different thermal/moisture stress tests are in common use. The steam bomb test conducted at temperatures > 100 °C is the harshest but is used infrequently because it tends to produce some defects that are not observed in the field. A gentler test exposes chip packages to 85 °C/85% relative humidity with imposed electrical bias in the range of 5–30 V. The test is usually run for 1000–2000 h. Electrical testing of the devices is frequently conducted *in situ*. While the validity of this test in duplicating field experience is rarely established conclusively, years of experience have shown that devices that survive this test have a high probability of not failing in the field. In recent years, the highly accelerated stress test (HAST) has sometimes been used when rapid reliability data are needed by designers and process engineers. The typical conditions for this test are 100–160 °C and (50–100)% relative humidity, with or without bias. The duration is usually 24–48 h. The acceleration factor for a test at 120 °C/95% relative humidity is typically 10–20 times that for the 85 °C/85% relative humidity test.

Strategies to prevent moisture-related problems are not limited to providing impenetrable packages or highly adherent coatings. In some cases the humidity in the use environment can be controlled at levels below which degradation is largely eliminated. Many computer installations require that the relative humidity be kept under (50–60)% for just this reason. Other strategies include selecting metal conductors that are less susceptible to corrosion (gold is better than copper or tin-lead alloys in many situations) or designing circuitry to minimize electric fields. As feature size decreases, design engineers consider all of these options when high reliability is required.

With surface-mount plastic packages and flip-chip technology, moisture effects are not limited to electrochemical phenomena. Absorption of moisture by encapsulants can also affect the mechanical integrity of devices, depending on stresses at the encapsulant-device interface. New polymers with at least an order of magnitude lower capacity for moisture absorption will be required to eliminate the need to ensure that packages are completely dry when undergoing solder attachment. Stress concentration can cause cracking or shearing of metal conductors or wire bonds on devices or delamination of metals from insulators. Sudden temperature changes, such as those experienced during solder reflow, can cause cracking of plastics and metals due to pressure buildup at interface voids associated with rapid moisture evaporation. Solder joints can also be fractured by combined moisture/thermal effects, especially when attachment is through an array of solder joints.

Prevention of these degradation processes requires selection of plastics that are screened to be mechanically stable over a wide range of relative humidity; design of packages, solder interconnect schemes, and encapsulants to minimize stress concentration, particularly at solder joints; and environmental stress testing that combines cyclical application of thermal, mechanical, and humidity stresses to the packaged devices.

2.3.4 Ceramic Packages. When the highest level of reliability is required (military and space applications, implanted medical devices, undersea transmission systems for telecommunications), integrated circuit chips are usually enclosed in hermetic ceramic packages. These packages are typically several times more expensive than plastic packages. In recent years many reliability engineers, looking for ways to reduce cost, have questioned the need for hermeticity. As the concentration of ionic impurities in polymers continues to be lowered, as adhesion is improved, and as molding engineers continue learning how to manage stress in packages, reliability of plastic packages has improved. The need for ceramic packages may eventually be eliminated. Until then, designers need to be aware of the reliability issues for ceramic packages. The sealed character of ceramic packages ensures that there will be no influence on the device from the external environment, contaminants, or moisture, but it also ensures that any contamination or moisture contained within the device will not escape. As long as the cavity is completely dry and free of contamination and all of the materials within the cavity are free of trapped moisture that can outgas at elevated temperature, reliable operation can be expected. If moisture outgasses at elevated temperature and subsequently condenses on device surfaces at cooler temperatures, the same electrochemical phenomena described for plastic packages can occur. The appropriate screening test is a cyclical thermal test (−40 °C to 100 °C) on an operational device. Various screening tests are employed to evaluate the seal integrity, such as dye penetration, observation of escaping gas as bubbles in a liquid, and pressurization with radioactive tracer gas. Most hermetic devices are sealed in an inert-gas atmosphere. Mass spectrometry or weight change can be used to monitor the escape of the inert gas. Attention to proper manufacturing procedures eliminates most reliability problems with ceramic packages.

Surface attachment of ceramic packages with leads mounted through via holes in substrates can be accomplished with high reliability using commonly practiced assembly methods. For surface-mount attachment, mechanical stresses on solder joints and on ceramic materials can be severe. Temperature/time profiles for the substrate and package must be carefully examined to minimize residual stress when the package and substrate return to room temperature following attachment. Since solder is well known to slowly creep and recrystallize to relieve stress (even at room temperature), a surface-mount process for ceramic packages should be subjected to static and cyclic thermal stress and mechanical loads to establish the design reliability.

2.4 Assemblies

2.4.1 Interconnection of Components and Integrated Circuits

2.4.1.1 Circuit Boards. The most common type of circuit board consists of multiple layers of metal networks that are separated by a dielectric material and interconnected by metal-filled holes in the dielectric layer. The dielectric material is typically a composite of epoxy and layered sheets of woven glass fibers. Copper metallization layers are typically produced by laminating a thin foil of copper on the epoxy-glass substrate, then patterning the desired metal network by photolithographic methods, and finally thickening the metal conductor lines by electroplating copper. For many applications, ten or more of these layers are laminated together. For less demanding applications, only one epoxy/glass layer may be required, which may have the metallization printed on both sides. For single-layer boards, phenol fiber or molded plastics are also sometimes used in place of the epoxy glass. In some applications the molded plastic may be sufficiently thin to enable the circuit board to be flexed without causing damage. For most types of circuit boards, the final manufacturing step is to coat the copper with solder. An appropriately patterned solder mask covercoat is applied to the board, which is then dipped into molten solder. The solder overcoat ensures subsequent solderability of components to the board. Without this coating, the natural oxide that grows on copper would inhibit soldering. In some cases, a corrosion inhibitor that adsorbs onto the copper surface, such as benzotriazole, is used instead of solder to preserve solderability. At this point the circuit board is ready for component and connector attachment, which is usually accomplished by a soldering process, though metal-filled conductive adhesives may be used for low-cost products. In the early 1990s, the typical metal linewidth is 100–200 μm with state of the art being 25 μm for a 40-layer board. The linewidths will necessarily decrease as feature sizes for integrated circuits decrease.

Several potential failure mechanisms must be considered in evaluating the reliability of circuit boards. These are listed in Table 1. Here only multilayered epoxy/glass circuit boards will be considered, but many of the issues are common to all types. Also listed in the table are appropriate stresses, specific stress tests for bringing out these failure processes, and special considerations.

In the manufacturing process for multilayer boards, two critical issues with respect to achieving high yield and long-term reliability are the adhesion and the accuracy of registration between layers. Thermal, vibration, and shock stresses are effective in uncovering defects associated with inadequate adhesion or poor registration. Another process issue with all types of circuit boards is ionic contamination that may be derived from electroplating or solder flux residues, or from exposure to gaseous and particle contamination in the environment. During manufacturing, cleaning steps remove harmful ionic contaminants at sensitive stages of the process. A commonly used specification for cleanliness of circuit boards is that the residual water-soluble ionic residue must not exceed 1 μg/cm^2 sodium chloride or its equivalent in ionic contamination. Contamination can also occur as a discrete event or continuously during the life of the product in the field. Because of the importance of environmental effects, the environmental constituents that cause corrosion and electrical defects in devices should be considered in planning of environmental tests.

2.4.1.2 Failure Processes and Stress Tests. The typical failure process caused by contamination is corrosion of conductor lines, leading to open or short circuits. The electrical leakage currents associated with the corrosion process may also cause failure due to device parameter shifts in components or devices. In either case, the high surface conductance brought about by the combined effects of contamination and surface moisture is responsible for the failure.

Humidity coupled with electrical bias is an effective stress for uncovering these failure processes. The 85 °C/85% relatively humidity/bias test used for accelerated testing of device packages or encapsulation is also used for circuit-board and hybrid integrated-circuit evaluations. The electrical bias used to test circuit boards is usually much higher (100–300 V).

Since it is inevitable that contamination will occur over the life of the product, it is essential that the circuit board be protected with a reliable covercoat. In many cases the

Table 1. Failure processes and stress tests for circuit boards.

Degradation process	Stresses causing failure	Typical tests	Special considerations
Cracks in metal caused by differential thermal expansion of metals and insulators	Thermal	Thermal cycling (−40 °C to 100 °C), thermal shock, high temperature (> 100 °C)	
Corrosion of metallization leading to electrical open circuits in conductors and reduced insulation resistance or electrical shorts between conductors	Humidity with electrical bias, thermal, ionic contamination from particles, and corrosive gases	Exposure to elevated relative humidity (> 85%), elevated temperature (85 °C), bias, and possibly corrosive gas, e.g., $(10^{-5}$–$10^{-4})$% sulfur dioxide, nitrogen oxides, hydrogen sulfide, or hydrochloric acid, and corrosive particles, e.g., 50–100 μm/m^3 of test dust applied by forced airflow	At sufficiently high humidity, no contamination is required; contamination enhances failures by increasing the amount of surface moisture and the surface conductance
Fracture or displacement of materials caused by mechanical factors	Vibration, shock	Exposure to vibrations with variable amplitude and frequency, centrifuge (constant acceleration), thermal shock, dropping, sudden acceleration with acoustic monitoring	
Fracture of solder joints as a result of creep or fatigue	Thermal shock, mechanical stress	Thermal cycling, thermal shock, cyclic or static mechanical load	

solder mask may be a suitable covercoat. The solder mask is applied prior to component and connector attachment. For some applications it may be necessary to apply a supplemental covercoat after all solder connections are made. If the solder mask or other covercoat on a circuit board has defects such as pinholes, a leakage current may flow between the normally covered components or metal lines, which are now under a defect, and a nearby metallic conductor. Sometimes a component-damaging arc may occur (see Fig. 14). Severe arcing can pyrolyze circuit boards to form conducting carbon bridges.

Whatever method is used to provide protection from contamination, the susceptibility of the fully assembled circuit board to failure should be evaluated by a combination of corrosive-gas tests, corrosive-particle tests, and humidity/bias tests. An example is shown in Fig. 15. A synthetic dust representative of particulate pollutants is applied onto a test circuit that has been previously protected with an covercoat. A drop of water is applied, and an electrode is inserted in the water. A variable electrical bias is applied between the electrode and the conductor lines on the test structure, and the breakdown voltage is recorded. A faulty covercoat with pinholes or low dielectric strength will show low and variable breakdown voltages, while a high-quality covercoat will only break down at a voltage well in excess of any that might be encountered in the field, as illustrated in the figure.

2.4.2 Interconnection of Circuit Boards

2.4.2.1 Connectors and Backplanes. Connection of the circuit board to the rest of an electronic assembly is accomplished through plug-in and receptacle connectors. One member of the connector pair is attached to the circuit board, and its mate is part of the "backplane" network that enables tens to thousands of circuit boards to be interconnected. For small computers, the backplane is com-

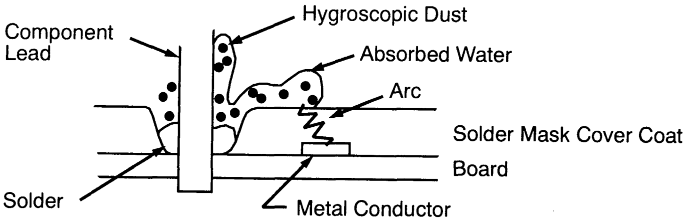

FIG. 14. Arcing failure mechanism. In this failure process, contamination that accumulates on the covercoat absorbs sufficient moisture above its critical relative humidity to extend the voltage present at the component lead over the covercoat. If a defect exists in the covercoat above a grounded metal conductor on the substrate, an arc may occur. The resulting high-voltage pulse may burn out devices anywhere in the circuit.

monly referred to as the mother board. For larger systems it can be a large array of connectors that are themselves interconnected by wires or elaborate printed wiring networks much like those on circuit boards.

2.4.2.2 Failure Processes and Stress Tests. Backplanes are susceptible to the same kinds of failure processes as circuit boards. However, the connectors require special consideration. It should also be noted that components are sometimes attached to circuit boards through standard plug-in connections rather than by solder attachment. Plug-in component attachment also requires special consideration. The critical issue with all plug-in connections is how successfully low contact resistance can be maintained over the life of the product. Corrosion films, dust particles, and wear of the contact metal can all lead to high-resistance failures through the connection. For the highest reliability applications, the contact metallization over the underlying copper is typically an electroplate of gold over nickel. The most important reliability concern is the porosity of the gold. If the gold is sufficiently porous, the underlying nickel and copper may corrode, especially in environments with high concentrations of hydrogen sulfide, e.g., near oil fields, oil refineries, or pulp mills. If corrosion occurs, the corrosion products slowly migrate across the gold surface to form a highly insulating, tenaciously adhering film. Two approaches to evaluating this potential failure process are in common use. One is to measure the porosity of the gold electroplate immediately after plating by exposing the electroplate to a corrodant and then counting the pore density revealed by corrosion spots for pores larger than a given diameter. A density greater than a set standard indicates a high susceptibility to field failure by hydrogen sulfide–induced corrosion. An alternative test is exposure of the connectors to a corrosive-gas environment, as

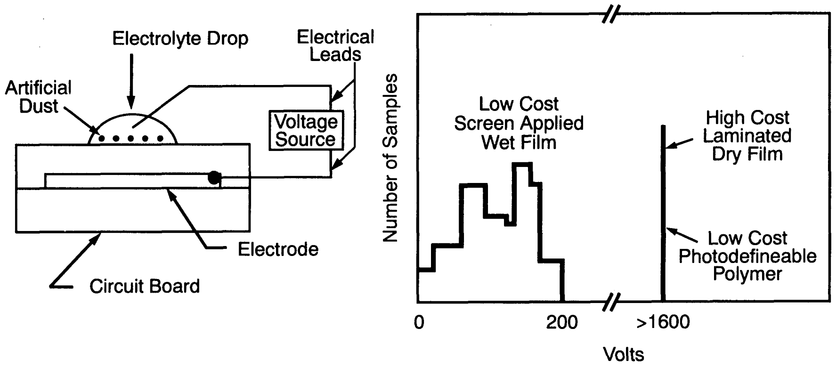

FIG. 15. Test apparatus and selected data for measurement of breakdown voltage of polymeric dielectrics. Left: The apparatus for measuring breakdown voltage. A test pattern on a circuit board is coated with a polymeric material. A hygroscopic contaminant, such as synthetic dust, is placed on the polymer followed by a drop of water. Voltage is then applied across the polymer by connecting one lead to the conductor and placing the other in the drop of water. Right: Results for three different polymeric covercoats. The screen-applied wet film shows erratic breakdown voltages well below the 1600-V design criterion for many applications. Screen-applied films typically have pinhole defects that cause low breakdown voltage.

described in Table 1, followed by evaluation of the contact resistance by electrical measurements. For most computer applications the resistance should be <20 mΩ.

Tin or a tin-lead alloy is sometimes used for plug-in connections, especially for components attached to circuit boards. The most common failure process associated with these metals, when used for connectors, is fretting corrosion leading to a high contact resistance (see Fig. 16). Fretting corrosion is typically caused by the micromotion between connector pairs associated with ordinary vibrations. Such failures have sometimes been attributed to the vibrations caused by motors for cooling fans. The vibrations disrupt the native oxide on the metal, leading to further oxidation and fretting. As the oxide debris builds up, the contact resistance increases. The appropriate stress test for evaluating susceptibility to fretting corrosion is exposure to vibrations with variable amplitude and frequency.

3. FUTURE REQUIREMENTS IN RELIABILITY AND TESTING

Several driving forces will affect not only the kinds of phenomena that are likely to be important in the future reliability of electronics, but also the way in which reliability practitioners carry out their mission (Crook, 1990). These driving forces include

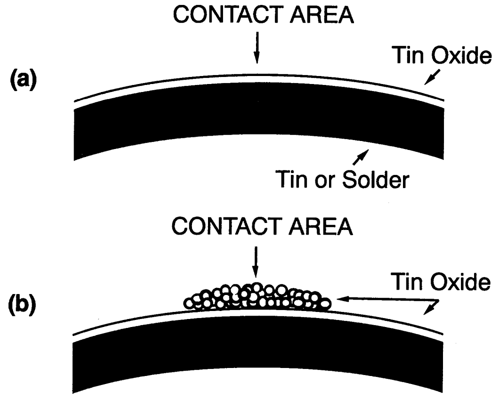

FIG. 16. Fretting corrosion of connector contacts. Motion from ordinary vibrations can produce enough oxide debris (fretting) to cause contact failure. (a) Cross section of a connector contact surface with an oxide layer over the tin or tin-lead alloy. (b) The same surface after fretting has generated tin-oxide particles that prevent intimate contact with the opposing contact surface (which is not shown).

1. the increasing density and shrinking feature sizes of integrated-circuit components;
2. the growing complexity of systems that use integrated circuits and other electronic components; and
3. the increasing critical demand for reliability from the customer.

Item **1**, as will be discussed, continually decreases the reliability margin (inherent reliability minus needed reliability) by decreasing the inherent reliability, while items **2** and **3** result in continuing pressure for an increase in the reliability level, further decreasing the available margin. Since margin cannot decrease to zero without annoying the customer, the practitioner must seek to increase the inherent reliability of the device by introducing process and design improvements as the circuit density increases.

3.1 Integrated Circuits—Shrinking Dimensions

3.1.1 Device Scaling. As feature size decreases, "scaling laws" show that the expected lifetime of a circuit may decrease drastically (Woods, 1986). These scaling laws consider the effect of shrinking dimensions on the time to failure expected for various wearout mechanisms. As dimensions decrease, wearout mechanisms are accelerated by the changes in relative dimensions. This can be illustrated for the case of electromigration failure. Assume that the thickness and width of the aluminum line decrease by the same factor K. Then the cross-sectional area of the metal line will decrease by a factor K^2. If gate oxide thickness is scaled but device voltage is not (as is often the case), the device conductance and, therefore, current increase linearly with the scale factor. Thus, the effect of scaling increases current density by K^3 for geometric factors. Additional considerations related to metal line cross sections at topological steps increase the exponent to four. Since the lifetime for electromigration failure is inversely proportional to the square of the current density, the lifetime decreases by the eighth power of the scaling factor.(Fortunately, in the case of electromigration, narrow lines benefit from the "bamboo effect" discussed in Sec. 2.2.3.1) Similar considerations apply to oxide wearout and breakdown and result in shorter mean time to failure for reduced oxide thickness. By these and other scaling effects, the ultimate reliability decreases and approaches the advertised value.

3.1.2 Particle Effects. Airborne particles that land on integrated circuits during manufacturing can affect both device yield and reliability, especially in the short term (infant mortality). The particles can interfere with photolithographic processes and cause shorts between conductors or opens in conductor lines, resulting in yield loss. Or the lithographic defects may be partial in nature, so that insulator thickness or metal width is reduced locally, increasing failures. Particle contamination can also affect breakdown voltage and leakage current.

For a given feature size, only particles that are larger than about one-tenth of the characteristic feature dimension are expected to have an effect. As feature sizes decrease with advanced device technologies, the size of particles expected to result in failures also decreases. The volume density of airborne particles increases dramatically with decreasing particle size. Thus, ever more stringent filtration requirements for manufacturing areas can be expected along with more effective protective methods and cleaning processes.

3.1.3 Advanced Packaging. Increased component density tends to result in greater power dissipation per unit area of integrated circuit. The parallel trend to greater system speed and density is driving new interconnect technologies, such as solder connection of flip chips instead of wire bonds. The requirements for denser interconnections and increased power dissipation are met with more complicated combinations of materials. Complex metal structures may be more susceptible to interdiffusion and formation of intermetallic compounds, especially at elevated operating temperatures. The reliability will depend on the quality of the selected barrier metals. Combinations of metals also increase the probability of galvanic reactions. However, the increase in device operating temperature and the correspondingly reduced humidity tends to mitigate against these and other corrosion reactions. Electromigration effects, on the other hand, will be amplified by the higher temperature.

3.2 Reliability Verification and Improvement

As the trend to higher density and decreasing feature size reduces the reliability margin of devices, the electronics industry at the same time demands greater reliability. The demand for greater reliability arises not merely because of our normal expectation that products should improve but because of the greater complexity and criticality of systems. For example, the consequences of a failure in an aircraft navigation system are much greater than those of television set failure. Even more important is the effect of a defect in a computerized aircraft landing system.

On the basis of historical trends, the expected failure rates for complex devices in the year 2000 will be approximately one failure in 10^8 device-hours (Crooks, 1990). Our present methods of assessing failure rates, by using highly accelerated stress tests and screens, will be inadequate for assessing this level of reliability. The testing requirements (number of devices and test duration) will make these kinds of tests impractical for verifying attainment of these reliability goals. Wafer-level reliability testing, a current popular method, for assessing base-line reliability of a process, will also be inadequate. This technique applies highly accelerated stresses to devices in wafer form to assess inherent reliability. Such tests have found extensive use, particularly for electromigration and oxide breakdown assessment. Wafer-level testing can give a false satisfactory result when several process parameters are out of specification in a way that the process variations cancel each other's effect. For example, a particular lot of devices may have aluminum thickness, linewidth, and steepness of step contours all out of control; but overly steep step contours, which reduce electromigration life time, may be compensated by excessive linewidth and metal thickness. If the implications of this example are extended to the full complexity of process parameters involved in electromigration reliability, it is clear that wafer-level testing on a wafer from an out-of-control process could give a satisfactory result even though actual reliability in the field will be unsatisfactory.

Since reliability screens, accelerated-life tests, and wafer-level stressing are all expected to be inadequate for the very stringent reliability demands of the future, statistical process control must become sufficiently precise and device design sufficiently robust that high reliability can be guaranteed without testing. Reliability practitioners will spend less time understanding the effect of a failure mechanism on actual field reliability and more time on understanding the effects of physical and chemical processes on material and structural variation and designing controls to monitor these processes. Improvements in reliability will be achieved by greater understanding of the degradation mechanisms of materials and their relation to processing, and the development of analytical tools and techniques to monitor the relevant parameters in a way that continuously decreases process variations.

GLOSSARY

Acceleration Factor: The inverse ratio of the time to failure of a product undergoing accelerated-life testing to its time to failure by the same mechanism in normal field service.

Active Components: Electronic devices that amplify or are sources of current or voltage. Active components include transistors, thyristors, rectifiers, and diodes.

Bonding Pads: Areas of metal on substrates, components, or integrated circuits that serve as input or output points for connecting to other substrates, components, or integrated circuits through solder joints or wire bonds.

Breakdown Voltage: Minimum voltage applied across an insulator or semiconductor that results in sudden loss of insulating properties and simultaneous current flow.

Circuit Board: A functional unit consisting of a printed wiring board with attached components and an edge-mounted connector for plugging the unit into an assembly.

Covercoat: A thin coating, usually polymeric, applied to a printed wiring board or other substrate to inhibit degradation processes caused by interaction of the printed wiring board with the environment, especially ionic contaminants and moisture.

Encapsulant: A thick coating applied to a component or device to inhibit interaction of the functional elements with the environment.

Electromigration: The degradation of aluminum or other metal conductors when subjected to high current density, due to momentum transfer from electrons to metal atoms. The momentum transfer causes atoms to move, eventually leading to open circuits.

Failure Mode Analysis: The process of characterizing a failed device or assembly by analytical techniques and electrical measurement to ascertain the cause of failure.

Field Plates: Metal plates or structures in an integrated circuit or component that are connected to a reference voltage and fix, at a specified value, the electric field below them. They stabilize the breakdown voltage of the device.

Hermetic Package: An enclosure, usually ceramic with a ceramic or metal lid, that provides electrical connections and prevents interaction of an enclosed component with the external environment.

Interconnect: A network of metal conducting pathways that connects components on or between circuit boards or other substrates or connects transistors or other elements on integrated-circuit chips.

Passivation (Passivation Layers): The surface coating on an integrated circuit or component that provides mechanical and environmental protection. Typical passivation layers are silicon nitride and silicon dioxide doped with phosphorus.

Passive Components: Electronic devices that alter a current or voltage without providing amplification. Passive components include capacitors, resistors, inductors, transformers, and relays.

Printed Wiring Board: A sheet of dielectric material with a metallization pattern on its surface, frequently packaged in multiple layers, that serves as the substrate on which components are mounted to make a circuit board.

Root Cause: The original error in judgment, process function, or product design that ultimately leads to product failure.

Sacrificial Oxides: Oxides that are grown on silicon and then removed by etching to increase the near-surface purity of the silicon.

Solder Reflow: Process of remelting solder that has been previously fused to a substrate or integrated circuit so that a component or integrated circuit can be bonded to the substrate.

Statistical Quality Control: Use of statistical techniques to pinpoint and eliminate the sources of variation in product quality.

Surface Ions: Ions on the surface of insulating materials that migrate in the presence of electric fields and may alter device function.

Undensified Film: A film, usually an insulating oxide, that is deposited at a relatively low temperature and has a density lower than that of the bulk material. Such films are mechanically weaker and less durable chemically, and provide for more rapid diffusion of impurities, than the corresponding densified material. Undensified films may be densified by heat treatments.

INTRODUCTION

Much of the original insight into the quantum-mechanical nature of the electronic structure of atoms and molecules came from spectroscopy. This early experimental approach together with an increasingly complex array of scattering and resonance techniques has led to a wealth of experimental data, which can be interpreted using models of atomic and molecular structure. From the earliest years following the development of quantum mechanics, empirical models have been used that enable us to correlate and codify our knowledge and to predict the results of further experiments.

As mathematical and computational techniques have developed, electronic-structure theory has established itself as an independent branch of science. While the success of any theory depends upon its ability to reproduce the results of experiments, the nonrelativistic theory can still be formulated as a scheme for obtaining approximate solutions of the Schrödinger equation. The corresponding first-principles formulation of the relativistic theory is presently being rapidly developed. It would take many different kinds of spectroscopy and scattering experiments to gain as much knowledge about the structure and properties of an atom or molecule as can be obtained nowadays by a good *ab initio* calculation. *Ab initio* literally means "from the beginning" and implies a theoretical study based on quantum mechanics, without the input of experimental data specific to the system being studied. The power of many types of theoretical calculations comes from obtaining a wave function that can subsequently be used to calculate different physical properties. In this article, we shall develop from first principles the theoretical models that play an important role in this vast area of research.

While there are many obvious similarities between atoms and molecules, there are also important differences. For atoms, highly charged ions can be produced in the laboratory, and this makes it possible to study isoelectronic sequences over a wide range of possible ionization states. In this way, the nuclear charge of an electronic state can be turned up to quite high values. This provides a good setting for testing quantum electrodynamics and the models for applying relativistic quantum mechanics to many-electron systems. On the other hand, the various molecular phenomena associated with the relative motion of the nuclei, such as dissociation and the formation of chemical bonds, do not arise when we consider atomic structure. Apart from the effects of the hyperfine interaction, the physical and optical properties of atoms are due entirely to their electronic structure, whereas for molecules, the description of their electronic structure is only the first part of a complex and multifaceted problem.

The purpose of this article is to give an integrated account of the electronic structure of atoms and molecules. The article begins with a review of the most essential aspects of the theory of the hydrogen atom, and then gives a brief description of the independent-particle and Hartree-Fock models, which provide an intuitively satisfying framework for obtaining approximate solutions of the Schrödinger equations for atoms and molecules.

1. THE HYDROGEN ATOM

The hydrogen atom consists of a proton and an electron. Without introducing any difficulty, however, the problem can be generalized to include a nucleus of charge Ze in place of the proton. The nuclear mass will be denoted by M and the charge and mass of the electron by $-e$ and m_0. The only interaction between the nucleus and the electron that will be considered at this time is the electrostatic interaction described by the Coulomb potential $u(r) = -Ze^2/4\pi\epsilon_0 r$. As we shall see, the central nature of the potential simplifies considerably this one-electron problem. The time-independent Schrödinger equation for the relative motion may be written

$$H\Psi = E\Psi, \tag{1}$$

where Ψ is the wave function and the Hamiltonian H is given by the expression

$$H=(-\hbar^2/2m)\nabla^2+u(r). \tag{2}$$

Here m is the reduced mass of the electron–nuclear system, $m=m_0M/(m_0+M)$. The first term on the right-hand side of Eq. (2) represents the kinetic energy of the electron, and the second term corresponds to the attractive potential of the nucleus. In what follows, we shall use atomic units, for which $\hbar$, $4\pi\epsilon_0$, the mass and charge of the electron, and the Bohr radius a_0 all have the value 1. (The value of a_0 is approximately equal to 0.5292×10^{-10} m.)

The quantum-mechanical angular-momentum operator is

$$\mathbf{l}=-i\mathbf{r}\times\nabla. \tag{3}$$

The components l_k may be shown to commute with the central-field Hamiltonian and hence correspond to constants of the motion. This is the underlying reason for the importance of angular momentum to atomic physics, and it forms the basis for the shell structure of atoms.

The components of the angular momentum also commute with $\mathbf{l}^2$. It follows that H, $\mathbf{l}^2$, and l_z (for instance) are a set of mutually commuting operators and that they possess a complete set of simultaneous eigenstates. The simultaneous eigenfunctions of $\mathbf{l}^2$ and l_z are the spherical harmonics $Y_{lm}(\theta,\phi)$, where θ and ϕ are ordinary polar coordinates.

The spherical harmonic for $l=0$ is spherically symmetric, while the function $Y_{lm}(\theta,\phi)$ for $l=1$ and $m=0$ is directed along the z axis. Similarly, there are linear combinations of the spherical harmonic for $l=1$, $m=1$ and $l=1$, $m=-1$ that are directed along the x and y axes. For atoms, it is customary to use the spectroscopic notation to denote the orbital angular momentum of the electrons. In this notation, the letters *s,p,d,f,g,h,i,...* stand for the l values 0,1,2,... .

The wave function of a particle moving in a central field can be written as the product of a radial function, a spherical harmonic Y_{lm_l}, and a spin function χ_{m_s}. It is generally written

$$\Psi=\frac{P(r)}{r}\,Y_{lm_l}(\theta,\phi)\chi_{m_s}. \tag{4}$$

The two possible spin states of a single electron, for which $s=\frac{1}{2}$ and $m_s=\pm\frac{1}{2}$, are usually denoted α and β. Since the spherical harmonic Y_{lm_l}, which describes the angular dependence of the wave function Ψ, is an eigenfunction of $\mathbf{l}^2$ and l_z corresponding to the eigenvalues $l(l+1)$ and m_l, the single-particle wave function itself also has this property. Requiring that Ψ be an eigenfunction of the central-field Hamiltonian corresponding to the eigenvalue E leads to the radial equation

$$\left(-\frac{1}{2}\frac{d^2}{dr^2}+\frac{l(l+1)}{2r^2}+u(r)\right)P(r)=EP(r). \tag{5}$$

The first term in the equation corresponds to the radial part of the kinetic energy of the electron, the second term corresponds to the angular or centrifugal part of the kinetic energy, and the third term corresponds to the interaction of the electron with the central field. The centrifugal term tends to push the maxima and nodes of the higher angular momentum states away from the nucleus. For one-electron atoms, the central potential (in atomic units) is simply $u(r)=-Z/r$.

For the wave function to be finite at the origin, it is necessary for $P(r)\to0$ as $r\to0$. Furthermore, for Ψ to be normalizable, it must be true that $P(r)\to0$ as $r\to\infty$. The values of E for which there exist solutions of the radial equation satisfying the boundary conditions are the possible energies of an electron moving in a central potential. These solutions may be distinguished by the value of l to which they correspond and the number of nodes of the radial function. The principal quantum number is related to the number of nodes ν: $n=l+\nu+1$. The radial functions $P(r)$ for several states are shown in Fig. 1. The wave function of the ground state of the hydrogenic atom is

$$\psi=(Z^3\pi)^{-1/2}\exp(-Zr). \tag{6}$$

2. THE INDEPENDENT-PARTICLE MODEL

A useful first approximation of more complex atoms and molecules is obtained by assuming that each electron moves independently of the other electrons in an average field due to the nuclei and the other electrons. This assumption leads to the independent-particle model, which provides an approximate description of atomic and molecular

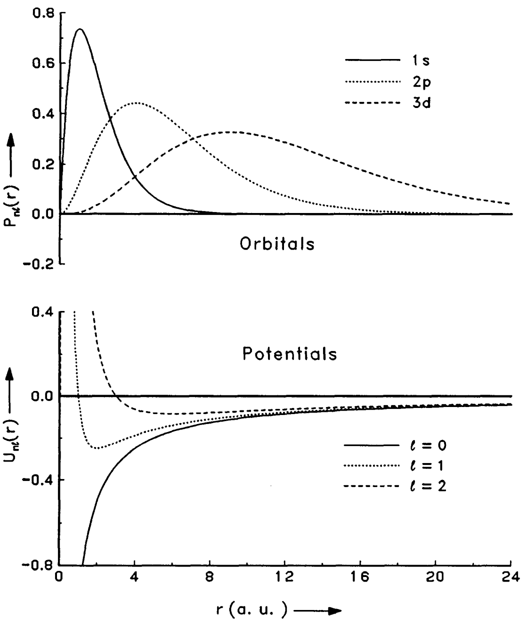

FIG. 1. Radial wave functions and potentials for the hydrogen atom. Potentials include the centrifugal repulsion term arising from the kinetic energy operator.

systems and also serves as the starting point of more accurate calculations.

The simplest wave function that describes a system of N electrons moving in an average potential is the product function

$$\Psi = \varphi_{a_1}(1)\varphi_{a_2}(2)\cdots\varphi_{a_N}(N). \tag{7}$$

Here $a_1, a_2, \ldots$ refer to the quantum numbers necessary to specify the single-electron states, and 1,2,... refer to the coordinates of the electrons. Any permutation of the electrons among the single-particle wave functions also leads to wave functions that describe this system of electrons. One may ensure that the Pauli exclusion principle is satisfied by forming an antisymmetric linear combination of the product functions:

$$\Phi = \left(\frac{1}{N!}\right)^{1/2} \sum_{P} (-1)^{p} P \times [\varphi_{a_1}(1)\varphi_{a_2}(2)\cdots\varphi_{a_N}(N)]. \tag{8}$$

The sum extends over all permutations P of the electrons among the single-particle states, and p is the parity of the permutation. The state Φ can be written in the following way:

$$\Phi = \left(\frac{1}{N!}\right)^{1/2} \begin{vmatrix} \varphi_{a_1}(1) & \varphi_{a_1}(2) & \cdots & \varphi_{a_1}(N) \\ \varphi_{a_2}(1) & \varphi_{a_2}(2) & \cdots & \varphi_{a_2}(N) \\ \cdots & \cdots & \cdots & \cdots \\ \varphi_{a_N}(1) & \varphi_{a_N}(2) & \cdots & \varphi_{a_N}(N) \end{vmatrix}. \tag{9}$$

Such a state is called a determinantal product state or a *Slater determinant.* An interchange of the coordinates of any two of the electrons leads to the interchange of two columns of the determinant, and this will cause a sign change. If any two of the single-particle states are the same, two rows of the determinant will be equal, and the determinant will vanish. Thus the Pauli exclusion principle is automatically satisfied. Determinant states of this kind provide a useful basis for atomic and molecular calculations

Simple formulas are available for evaluating the matrix elements of one- and two-particle operators between determinantal states. The diagonal matrix elements of a general single-particle operator, $F = \Sigma_i f(i)$, are given by the formula

$$\langle \Phi | F | \Phi \rangle = \sum_{a} \langle a | f | a \rangle. \tag{10}$$

Here the letter a stands for the orbital φ_a specified by that set of quantum numbers. For this formula to apply, the orbitals must be orthonormal. The corresponding formula for the matrix element of the two-particle operator

$$G = \sum_{i<j} g(i,j) \tag{11}$$

is

$$\langle \Phi | G | \Phi \rangle = \sum_{a<b} [\langle ab | g | ab \rangle - \langle ab | g | ba \rangle]. \tag{12}$$

In the integrations implied by the matrix element $\langle ab | g | ab \rangle$, for instance, the functions φ_a on the left and right correspond to the first variable and the functions φ_b to the second. The sums over a and b include all orbitals that are occupied in the determinantal state. There are similar formulas for evaluating the off-diagonal matrix elements.

In order to construct a determinantal state Φ, it is necessary to know how the single-electron states are ordered within the determinant. This information may be provided by writing

$$\Phi=(N!)^{-1/2}|\varphi_{a_1}\varphi_{a_2}\cdots\varphi_{a_N}|. \tag{13}$$

3. THE HARTREE-FOCK APPROACH

3.1 Operator Formulation

In the previous section, the many-body wave function was approximated by determinantal product functions. For a closed-shell atom or molecule, the Hartree-Fock wave function is the variationally optimized single determinant of doubly occupied orbitals

$$\Psi=(2n!)^{-1/2}|\varphi_1\alpha(1)\varphi_1\beta(2)\varphi_2\alpha(3) \times\cdots\varphi_n\alpha(2n-1)\varphi_n\,\beta(2n)|. \tag{14}$$

One usually assumes that the orbitals are orthonormal,

$$\langle\varphi_i|\varphi_j\rangle=\delta_{ij}\,. \tag{15}$$

At this point, we will leave unspecified the symmetry and coordinate system, so that all that follows applies equally to the electronic structure of an arbitrary molecule as well as an atom. Using the formula from Sec. 2 for the diagonal matrix elements of one- and two-particle operators between determinantal states, the total-energy expression for such a wave function can be written

$$E=\langle\Psi|\mathscr{H}|\Psi\rangle =2\sum_i\langle\varphi_i|h|\varphi_i\rangle+\sum_{i,j}\left(2\left\langle\varphi_i\,\varphi_j\left|\frac{1}{r_{ij}}\right|\varphi_i\,\varphi_j\right\rangle -\left\langle\varphi_i\,\varphi_j\left|\frac{1}{r_{ij}}\right|\varphi_j\,\varphi_i\right\rangle\right), \tag{16}$$

where h is the single-particle Hamiltonian,

$$h=-(\nabla^2/2)-\sum_a(Z_a/r_a). \tag{17}$$

Here Z_a denotes the charges of the nuclei of the molecular system. The expression for the energy may be written more simply by introducing Coulomb and exchange operators, J_j and K_j, defined by the equations

$$J_j(1)\varphi(1)=\left(\int dV_2[\varphi_j(2)]^2\frac{1}{r_{12}}\right)\varphi(1), \tag{18}$$

$$K_j(1)\varphi(1)=\left(\int dV_2\varphi_j(2)\varphi(2)\frac{1}{r_{12}}\right)\varphi_j(1), \tag{19}$$

where φ is an arbitrary function. Using these equations, the expression for the total energy can be written

$$E=\langle\Psi|\mathscr{H}|\Psi\rangle =2\sum_i\langle\varphi_i|h|\varphi_i\rangle\sum_{i,j}\langle\varphi_i|2J_j-K_j|\varphi_i\rangle. \tag{20}$$

We require that the energy be stationary,

$$\delta E=0, \tag{21}$$

for small changes in the single-electron wave functions that are consistent with the orthogonality constraints. Multiplying the variation of each orthogonality constraint by a Lagrange multiplier and subtracting the result from the variation of the total energy gives

$$\delta E'=\delta E-\sum_{i,j}4\epsilon_{ij}\langle\delta\varphi_i|\varphi_j\rangle, =4\sum_i\left\langle\delta\varphi_i\left|\left(h+\sum_j(2J_j-K_j)\right)\varphi_i -\sum_j\epsilon_{ij}\,\varphi_j\right.\right\rangle. \tag{22}$$

Each integrand in Eq. (22) must vanish for any variation of the orbitals with appropriate values of the Lagrange multipliers. This condition will be satisfied only if each term vanishes identically:

$$\left(h+\sum_j(2J_j-K_j)\right)\varphi_i=\mathscr{F}\varphi_i=\sum_j\epsilon_{ij}\,\varphi_j\,. \tag{23}$$

Here $\mathscr{F}$ is called the Fock operator, and Eqs. (23) are called the Hartree-Fock equations. The matrix of Lagrange multipliers, ϵ_{ij}, is symmetric as are the orthogonality constraints themselves. For closed-shell systems, it is possible to show that the Hartree-Fock equations are covariant under unitary transformations of the orbitals and that the determinantal wave function itself is invariant under such unitary transformations. If we solve the equations for the unitary transformation that diagonalizes the matrix of Lagrange multipliers, the Hartree-Fock equations take the canonical form of single-particle eigenvalue equations,

$$\mathscr{F}\varphi_i=\left(h+\sum_j(2J_j-K_j)\right)\varphi_i=\epsilon_i\varphi_i\,. \tag{24}$$

Since the operators $2J_i-K_i$ that describe the potential field are themselves functions of the solutions, the equations must be solved iteratively until self-consistency is achieved. For this reason, the Hartree-Fock equations are often referred to as the self-consistent-field (SCF) equations.

Although the sum over j in the Hartree-Fock equations runs over all of the occupied orbitals, the definitions of the Coulomb and exchange operators may be used to show that the self-interaction term vanishes identically:

$$(J_i-K_i)\varphi_i\equiv 0. \tag{25}$$

Using this result and the definition of the exchange operator, the Hartree-Fock equations can be cast in a form in which the inhomogeneous character of these equations is apparent:

$$\left(h+2\sum_{j\neq i} J_j+J_i\right)\varphi_i = \epsilon_i\,\varphi_i+\sum_{j\neq i}\left(\int dV\,\varphi_j\varphi_i\frac{1}{r_{12}}\right)\varphi_j. \tag{26}$$

The eigenvalue of the Hartree-Fock equation may be shown to be equal to the "frozen-orbital" ionization energy, i.e., the ionization energy obtained by assuming the orbitals do not relax upon removal of one electron. These eigenvalues have therefore come to be called the orbital energies. This result, which is referred to as Koopmans's theorem, provides the final touch that enables one to interpret the variational self-consistent-field equations as a set of Schrödinger's equations for a single electron moving in the effective field of all the other electrons of the atom or molecule.

3.2 Expansion Method

The expansion method represents an alternative formulation of the Hartree-Fock scheme that is, in principle, entirely equivalent to the original methodology and particularly attractive for molecular calculations. One writes the orbitals as an expansion in a set of analytical *basis functions,*

$$\varphi_i=\sum_p c_{ip}\chi_p\,. \tag{27}$$

The central idea here is to "fit" the unknown Hartree-Fock functions with a set of analytical functions, using the variational principle to determine the fitting coefficients.

Inserting the expansion for the orbitals into the expression for the total energy gives the energy as a function of matrix elements and coefficient vectors,

$$E=2\sum_i \mathbf{c}_i^\dagger\mathbf{H}\mathbf{c}_i+\sum_{i,j}\mathbf{c}_i^\dagger\mathbf{G}_j\mathbf{c}_i\,. \tag{28}$$

The matrices **H** and **G** are given by

$$(\mathbf{H})_{pg}=\langle\chi_p|h|\chi_q\rangle, \tag{29}$$

$$(\mathbf{G}_j)_{pq}=\sum_{s,t} c_{js}c_{jt}[2(pq|st)-(ps|qt)]; \tag{30}$$

where

$$(pq|st)=\int dV_1dV_2\chi_p(1)\chi_q(1)\frac{1}{r_{12}}\chi_s(2)\chi_t(2) \tag{31}$$

are the two-electron repulsion integrals over the basis functions from which *both* the Coulomb and exchange integrals are constructed. The orthonormality constraints then take the form

$$\mathbf{c}_i^\dagger\mathbf{S}\mathbf{c}_j=\delta_{ij}\,, \tag{32}$$

where

$$(\mathbf{S})_{pq}=\langle\chi_p|\chi_q\rangle \tag{33}$$

is the basis-function overlap matrix, which is not generally diagonal.

The variational principle with the constraints included then requires that

$$\delta E'=4\sum_i \delta\mathbf{c}_i^\dagger\left(\mathbf{H}\mathbf{c}_i+\sum_j \mathbf{G}_j\,\mathbf{c}_i-\sum_j \epsilon_{ij}\,\mathbf{S}\mathbf{c}_j\right)=0 \tag{34}$$

for any arbitrary variation of the coefficient vectors $\mathbf{c}_i$. This leads to the matrix self-consistent-field equations,

$$\mathbf{F}\mathbf{c}_i=\left(\mathbf{H}+\sum_j \mathbf{G}_j\right)\mathbf{c}_i=\epsilon_i\mathbf{S}\mathbf{c}_i\,, \tag{35}$$

where we have again transformed the matrix of Lagrange multipliers to diagonal form. Because exchange has been included in the Coulomb interaction matrix $\mathbf{G}_j$, the expansion-method equations are true homogeneous equations. Just as in the operator formulation, they must be solved iteratively, the interaction matrix being a function of the expansion coefficients.

Some writers prefer to express the Fock matrix in terms of the density matrix **D**, defined by the equation

$$(\mathbf{D})_{pq}=\sum_{i}^{n} c_{ip}c_{iq}\,. \qquad (36)$$

Using the density matrix, the Fock matrix may be written

$$(\mathbf{F})_{pq}=(\mathbf{h})_{pq}+\sum_{s,t}(\mathbf{D})_{st} \times[2(pq|st)-(ps|qt)]. \qquad (37)$$

The main problem in implementing the expansion method centers around the selection of the basis set. For atomic calculations, the most commonly used basis sets consist of Slater-type orbitals,

$$\chi_{plm}^{S}(\zeta)=N_s r^p e^{-\zeta r} Y_{lm}(\theta,\varphi). \qquad (38)$$

The exponential parameter here is used as an additional variational parameter to enhance the expansion-method "fitting process."

4. ATOMIC STRUCTURE

4.1 Central-Field Model

In the previous two sections, we considered the independent-particle model in which the electrons are assumed to move independently of each other in an average field due to the nuclei and the other electrons. This assumption reduces the many-electron problem to a number of independent single-electron problems. For atoms, we can generally make the additional assumption that the potential is spherically symmetric. As we have seen previously for the hydrogen atom, the single-electron orbitals can then be written as a product of a radial function, a spherical harmonic, and a spin function.

All of the orbitals of a single electron in a central field that have the same values of n and l are said to form an atomic subshell. These orbitals are all described by the same radial function, and they all have the same energy. The state of the many-electron system can be specified by saying which of these single-electron states are occupied. This specification of an atomic state is called the electronic configuration, and it is usually denoted using the spectroscopic notation given in Sec. 1. For instance, $1s^2 2s^2 2p^3$ means that there are two electrons each in the $1s$ and $2s$ shells and three electrons in the $2p$ shell.

4.2 The "Building-Up" Principle

According to the exclusion principle, there can be at most $2(2l+1)$ electrons in each shell nl. A shell for which all of the single-electron states is occupied is said to be filled or closed. A partially filled shell is said to be open.

For a particular atom, one would expect to get the lowest energy by successively filling the lowest-lying electron shells. The configuration for the ground state would thus consist of a certain number of filled shells and at most one open shell. This leads to the historically important "building-up" or *Aufbau* principle, which was originally suggested by Bohr to explain the periodic table.

There are a number of departures from this simple description. As more electrons are added, the central field changes, and also the electron–electron interaction for particular electronic states causes deviations from the central-field description that are sufficiently large to lead to irregularities in the filling of the electron shells. There are atoms having two open shells in the ground configuration. This occurs for some of the transition elements for which a d shell is being filled, and for the rare-earth and actinide elements for which an f shell is being filled. In such cases, two open shells may have orbital energies that lie so close to each other that small departures from the central-field model can be sufficient to change the order in which the shells are filled.

4.3 Russell-Saunders Coupling

The central-field model leads to highly degenerate energy levels. For light and medium-size atoms, this degeneracy is removed mainly by the Coulomb interaction among the electrons, which splits the states of an electronic configuration into levels characterized by the quantum numbers of the total spin and orbital angular momentum. An illustration of the electrostatic splitting of an electronic configuration is given in Fig. 2, which shows the energy levels of an np^2 configuration. Each of the levels corresponds to definite values of the total angular-momentum quantum numbers S and L. The lowest level, which is denoted ${}^3P$, has a total spin quantum number $S=1$ and a quantum number of the total orbital angular momentum $L=1$. As is customary, the value of $2S+1$ is given for this level rather than the

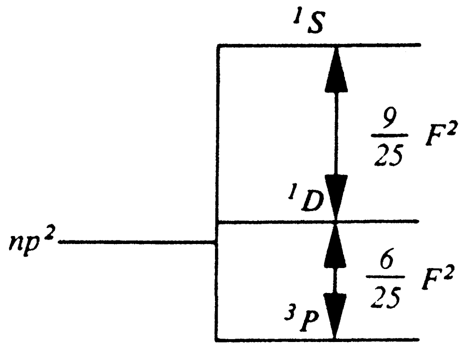

FIG. 2. Electrostatic splitting of an np^2 configuration. The quantity F^2 is defined in Sec. 4.4.

spin quantum number itself. The next higher level in Fig. 2, which is denoted ^1D, has total spin and orbital quantum numbers $S=0$ and $L=2$, while for the ^1S level, $S=0$ and $L=0$.

In order to form states that have definite values of the total angular momenta, it is generally necessary to form linear combinations of product functions or of Slater determinants. This process of forming eigenstates of the total-angular-momentum operators is referred to as addition or coupling of angular momenta. In order to discuss angular-momentum coupling in general terms, we consider now a system composed of two subsystems that are described by the states $|j_1m_1\rangle$ and $|j_2m_2\rangle$. For a composite system of this kind, the total-angular-momentum operator $\mathbf{J}$ can be written $\mathbf{J}=\mathbf{j}(1)+\mathbf{j}(2)$, and the eigenfunctions of $\mathbf{J}^2$ can be expressed as linear combinations of the product functions:

$$|(j_1j_2)JM\rangle=\sum_{m_1,m_2}|j_1m_1,j_2m_2\rangle \times\langle j_1m_1,j_2m_2|JM\rangle, \qquad (39)$$

where j_1m_1 and j_2m_2 are the angular-momentum quantum numbers of the individual states. The coefficients $\langle j_1m_1,j_2m_2|JM\rangle$ are known as the Clebsch-Gordan or vector-coupling coefficients.

The angular momenta of the electrons can be coupled together in various ways. The coupling scheme illustrated in Fig. 2, for which the spin angular momenta of the electrons are coupled together to form a total S and the orbital angular momenta are coupled to form a total L, is called LS or Russell-Saunders coupling. The total spin and orbital angular momenta are then coupled together to form the total angular momentum J.

4.4 Partial-Wave Expansion of the Coulomb Interaction

As we have seen, the spatial part of the wave function of an electron moving in a central field can be written as a product of a radial function and a function of the polar angles. In order to take advantage of this, we use the result from classical physics that $1/r_{12}$ can be expanded in partial waves as

$$\frac{1}{r_{12}}=\sum_k \frac{r_<^k}{r_>^{k+1}}P_k(\cos\omega). \qquad (40)$$

Here $r_<$ denotes the lesser and $r_>$ the greater of the two radial distances r_1 and r_2. The coordinates of a two-electron system are shown schematically in Fig. 3. In this figure, the positions of the electrons are represented by the coordinate vectors $\mathbf{r}_1$ and $\mathbf{r}_2$, which are separated by an angle ω.

The partial-wave expansion can be written in a particularly simple form using spherical tensors. For tensor operator methods the reader is referred to the book by Lindgren and Morrison (1986). Defining a tensor C with components

$$C_q^k=\left(\frac{4\pi}{(2k+1)}\right)^{1/2}Y_{kq}(\theta,\varphi) \qquad (41)$$

and using elementary properties of the spherical harmonics, the Legendre polynomial $P_k(\cos\omega)$ can be written

$$P_k(\cos\omega)=\mathbf{C}^k(1)\cdot\mathbf{C}^k(2). \qquad (42)$$

Equation (40) then becomes

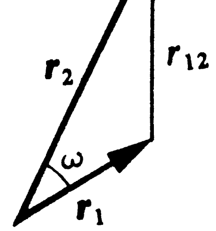

FIG. 3. The coordinate vectors of a two-electron system.

$$\frac{1}{r_{12}} = \sum_k \frac{r_<^k}{r_>^{k+1}} \mathbf{C}^k(1)\cdot\mathbf{C}^k(2). \tag{43}$$

Each term that appears in this expansion has a radial part that is represented by $r_<^k/r_>^{k+1}$ and an angular part that is represented by the scalar product of two spherical tensors. The fact that the two tensor operators are coupled together to form a scalar corresponds to the fact that the Coulomb interaction is invariant with respect to a simultaneous rotation of the coordinates of the two electrons.

As we have seen in Sec. 1, the wave functions for electrons moving in a central field also have separate radial and angular parts. For this reason, the terms in the partial-wave expansion of the Coulomb matrix elements for a two-electron system can be expressed as a product of a radial integral called a Slater integral and an angular term, which is the matrix element of the scalar product of two spherical tensor operators:

$$\begin{aligned}\left\langle n_a l_a m_s^a m_l^a, n_b l_b m_s^b m_l^b \right| \frac{1}{r_{12}} & \\ \times \left| n_c l_c m_s^c m_l^c, n_d l_d m_s^d m_l^d \right\rangle & \\ = \sum_k R^k(ab,cd)\,\delta(m_s^a,m_s^c)\,\delta(m_s^b,m_s^d) & \\ \times \langle l_a m_l^a, l_b m_l^b | \mathbf{C}^k(1)\cdot\mathbf{C}^k(2) | l_c m_l^c, l_d m_l^d \rangle. &\end{aligned} \tag{44}$$

Using our previous notation for the wave function of a particle moving in a central field, the two-electron Slater integral is defined as

$$R^k(ab,cd) = \int P_a(r_1)P_b(r_2) \times \frac{r_<^k}{r_>^{k+1}} P_c(r_1)P_d(r_2)\,dr_1dr_2. \tag{45}$$

For the special cases in which the radial wave functions of the two states on the right are the same as the two states on the left, it is convenient to define direct and exchange integrals

$$F^k(a,b) = R^k(ab,ab), \tag{46}$$

$$G^k(a,b) = R^k(ab,ba). \tag{47}$$

4.5 Antisymmetric Wave Functions for Two Electrons in *LS* Coupling

For two electrons with quantum numbers nl and $n'l'$, the antisymmetric wave function in LS coupling is

$$\begin{aligned}|\{nln'l'\}SM_SLM_L\rangle & \\ = F[\,|(nl)_1(n'l')_2,SM_SLM_L\rangle & \\ - |(nl)_2(n'l')_1,SM_SLM_L\rangle, &\end{aligned} \tag{48}$$

where F is a normalization factor. An interchange of the subscripts 1 and 2, which refer to the coordinates of the electrons, causes the state on the right to change sign. The curly brackets that appear in the state on the left constitute a special notation that we will use to specify an antisymmetric combination.

Equation (48) can be cast into another form by taking advantage of the special symmetry properties of the vector-coupling coefficients with respect to an interchange of the two constituent angular momenta,

$$\begin{aligned}\langle j_2m_2, j_1m_1 | JM\rangle & \\ = (-1)^{j_1+j_2-J}\langle j_1m_1, j_2m_2 | JM\rangle. &\end{aligned} \tag{49}$$

We may use this relation to reverse the order of the angular momenta in the second term that appears on the right. In doing this, we must reverse the coupling of the two spins as well as the two orbital angular momenta. This gives the two phase factors $(-1)^{S+1}$ and $(-1)^{l+l'+L}$. Equation (48) then becomes

$$\begin{aligned}|\{nln'l'\rangle,SM_SLM_L\rangle & \\ = F[\,|(nl)_1(n'l')_2,SM_SLM_L\rangle & \\ + (-1)^{l+l'+S+L} & \\ \times |(n'l')_1(nl)_2,SM_SLM_L\rangle]. &\end{aligned} \tag{50}$$

If $n=n'$ and $l=l'$, the two electrons are said to be equivalent. In this case, the right-hand side of Eq. (50) reduces to

$$F[1+(-1)^{S+L}]\,|(nl)_1(nl)_2,SM_SLM_L\rangle.$$

This will be nonvanishing only if $S+L$ is even, and hence only those functions for which $S+L$ is even correspond to physical states. The normalization factor F is then equal to $\frac{1}{2}$ and the normalized, antisymmetric state becomes

$$|\{nl^2\}SM_SLM_L\rangle = |(nl)_1(nl)_2,SM_SLM_L\rangle, \quad S+L \text{ even}. \tag{51}$$

Thus if $S+L$ is even, ordinary vector coupling leads in this case to proper antisymmetric wave functions.

If, on the other hand, the two electrons are not equivalent, the two states that appear in Eq. (50) are orthogonal, and F is $\sqrt{2}$.

4.6 The Coulomb Interaction for Two-Electron Systems in *LS* Coupling

We first consider the case of two equivalent electrons. Using the partial-wave expansion of the Coulomb interaction and Eq. (51), we obtain

$$\langle\{nl^2\}SL|1/r_{12}|\{nl^2\}SL\rangle = \sum_k f_kF^k(nl,nl), \tag{52}$$

where f_k is given by the formula

$$\begin{aligned} f_k &= \langle (nl)_1(nl)_2,SL|\mathbf{C}^k(1)\cdot\mathbf{C}^k(2) \\ &\quad \times |(nl)_1(nl)_2,SL\rangle \\ &= \langle l_1l_2,L|\mathbf{C}^k(1)\cdot\mathbf{C}^k(2)|l_1l_2,L\rangle, \end{aligned} \tag{53}$$

and where the two-electron Slater integral $F^k(nl,nl)$ was defined in Sec. 4.4. The Coulomb interaction is a scalar operator in both the spin and orbital spaces. For this reason, the Coulomb matrix elements are independent of M_S and M_L, and we have left out these quantum numbers.

Explicit formulas for evaluating the coefficients f_k have been given by Condon and Shortley (1959) and by Cowan (1981). At this point, we shall only cite the results for the np^2 configuration that we have considered previously. As we have seen, this configuration has three *LS* terms: ^1S, ^1D, and ^3P. The Coulomb matrix elements for these states are

$$\langle np^2\ {}^1S|1/r_{12}|np^2\ {}^1S\rangle = F^0+\tfrac{2}{5}F^2, \tag{54}$$

$$\langle np^2\ {}^1D|1/r_{12}|np^2\ {}^1D\rangle = F^0+\tfrac{1}{25}F^2, \tag{55}$$

$$\langle np^2\ {}^3P|1/r_{12}|np^2\ {}^3P\rangle = F^0-\tfrac{1}{5}F^2. \tag{56}$$

From these equations, we obtain the *LS* levels illustrated in Fig. 2. Each level has a multiplicity corresponding to the number of possible M_S and M_L values to which it corresponds. For example, the multiplicity of the ^1D state is 5 since $M_S=0$ while $M_L=-2,-1,\ldots,2$. A weighted average of the energy levels produces

$$\begin{aligned} E_{\text{av}} &= \tfrac{1}{15}[1E(^1S)+5E(^1D)+9E(^3P)] \\ &= F^0-\tfrac{2}{25}F^2. \end{aligned} \tag{57}$$

As before, we may use the explicit form of the wave function given in Sec. 4.5 and the symmetry properties of the vector-coupling coefficients to obtain the following general expression for the Coulomb matrix elements of a configuration of two nonequivalent electrons:

$$\begin{aligned} &\langle\{nln'l'\}SL|1/r_{12}|\{nln'l'\}SL\rangle \\ &\quad = \sum_k [f_kF^k(nl,n'l')+g_kG^k(nl,n'l')], \end{aligned} \tag{58}$$

where

$$\begin{aligned} f_k &= \langle l_1l_2',L|\mathbf{C}^k(1)\cdot\mathbf{C}^k(2)|l_1l_2',L\rangle, \\ g_k &= (-1)^{l+l'+S+L}\langle (nl)_1(n'l')_2,SL|\mathbf{C}^k(1) \\ &\quad \cdot\mathbf{C}^k(2)|(n'l')_1(nl)_2,SL\rangle. \end{aligned} \tag{59}$$

From these expressions, one can make some general, qualitative observations about the direct and exchange interactions. The coefficients f_k, which determine the character of the direct interaction, depend only upon the orbital quantum numbers l, l', and L. One can describe this situation by saying that the direct part of the Coulomb interaction couples the two orbital angular momenta l and l' together to form L. The two orbital momenta are also coupled by the exchange interaction, but this effect is usually quite small compared to the direct coupling. The exchange coefficients g_k also depend upon the total spin quantum number S, and so the exchange interaction couples the two spins.

A particularly simple example of a configuration of two nonequivalent electrons is provided by an ls configuration ($l'=0$). In this case, Eq. (58) becomes simply

$$\begin{aligned} &\langle\{nln's\}SL|1/r_{12}|\{nln's\}SL\rangle \\ &\quad = F^0(nl,n's)+(-1)^S\frac{G^l(nl,n's)}{2l+1}. \end{aligned} \tag{60}$$

This configuration has two *LS* terms: a triplet term with $S=1$ (^3l) and a singlet term with $S=0$ (^1l). As shown in Fig. 4, these two terms are split by an amount $2G^l(nl,n's)/(2l+1)$ by

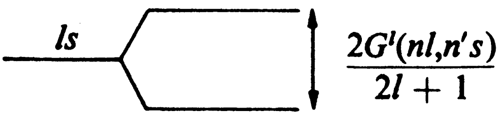

FIG. 4. Splitting of the *ls* state in *LS* coupling.

the exchange part of the Coulomb interaction. The splitting of the two spin states is a consequence of the antisymmetry of the wave function.

4.7 Coupling Schemes for Two-Electron Systems

In the previous sections, we have considered the *LS* coupling scheme for two-electron systems in some detail. We would now like to review from a general point of view the different coupling schemes that may be used to describe a configuration of two electrons. As we shall see, the coupling scheme that best describes the configuration and the general appearance of the energy levels depends upon the relative magnitude of the Coulomb and spin-orbit interactions. Our discussion here owes much to the work of Cowan and Andrew (1965).

There are four angular momenta associated with a two-electron system—$\mathbf{s}_1,\mathbf{s}_2,\mathbf{l}_1,\mathbf{l}_2$—and we begin by considering the interactions involving pairs of these angular momenta. As we have seen in Sec. 4.6, the direct part of the Coulomb interaction couples the two orbits together, and the exchange part of the Coulomb interaction couples the two spins. The magnetic interactions are responsible for coupling the spin and orbital motions together. For all but the lightest atoms, the magnetic interactions can usually be represented quite well by an effective spin-orbit operator, which for a two-electron configuration is

$$H_{\mathrm{so}}=\zeta_1\mathbf{s}_1\cdot\mathbf{l}_1+\zeta_2\mathbf{s}_2\cdot\mathbf{l}_2\,. \tag{61}$$

The one-electron spin-orbit operator $\zeta\mathbf{s}\cdot\mathbf{l}$ can be written

$$\zeta\mathbf{s}\cdot\mathbf{l}=\tfrac{1}{2}\,j(\mathbf{j}^2-\mathbf{s}^2-\mathbf{l}^2), \tag{62}$$

where $\mathbf{j}$ is the total angular momentum operator for one electron, $\mathbf{j}=\mathbf{s}+\mathbf{l}$. The effect of the spin-orbit operator upon a coupled single-electron state is

$$\langle(sl)j|\zeta\mathbf{s}\cdot\mathbf{l}|(sl)j\rangle=\tfrac{1}{2}\,j[j(j+1) -s(s+1)-l(l+1)]. \tag{63}$$

Using this relation, it is easy to show that the spin-orbit operator splits the energy levels of the electrons in the way shown in Fig. 5. This situation can be described by saying that the spin-orbit interaction couples the spin and the orbit of each individual electron.

The way in which the various angular momenta are coupled is illustrated in Fig. 6. The spin-orbit interaction couples the spin and the orbital angular momenta of each electron. The direct part of the Coulomb interaction couples the two orbits, and the exchange interaction couples the two spins.

For the low-*Z* elements the electrostatic interactions are predominant, which means that both the direct and the exchange interactions are larger than the spin-orbit interactions. In this case the coupling of the four angular momenta is usually best described by *LS* coupling,

$$|(ss')S,(ll')L\rangle. \tag{64}$$

For the heavy elements the spin-orbit interaction is comparable to or sometimes larger than the electrostatic interactions, and the coupling approaches the *j-j* limit. The states in this coupling scheme are of the form

$$|(sl)j,(s'l')j',J\rangle. \tag{65}$$

Both the *LS* and *j-j* coupling schemes are symmetric. The angular momenta of each electron are coupled together in the same way. These coupling schemes are usually best for the ground or low-lying configurations. Then the wave functions of the two elements have about the same spatial extent, and the interactions of the electrons are about the same.

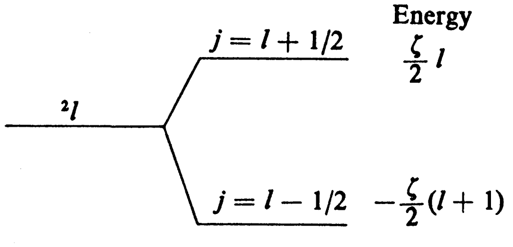

FIG. 5. Spin-orbit splitting of the single-electron energy levels.

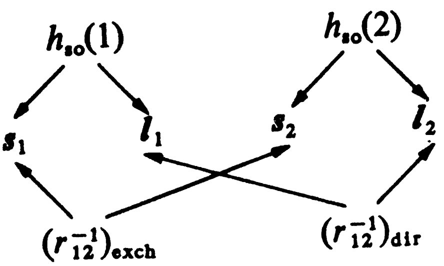

FIG. 6. Coupling of the angular momenta by the Coulomb and spin-orbit interactions.

When one of the outer electrons is more highly excited, and particularly when it has a high value of l, the configuration is highly asymmetric in the two electrons, and the symmetric couplings are usually no longer a good approximation. The highly excited electron, to which we give quantum numbers $n's'l'$, usually has a very small spin-orbit interaction. The wave functions of the two electrons are localized in different regions of space, and so the exchange interaction will also be quite small. Under these circumstances, the spin of the excited electron is weakly coupled to the other angular momenta, and the energy levels of the atom will occur in pairs with the J values of the levels of each pair differing by unity. How the angular momenta are coupled together in this case depends upon the relative magnitude of the direct interaction and the spin-orbit interaction of the inner electron. If the direct interaction is larger, then a third type of coupling is appropriate:

$$|((ll')L,s)K,s',J\rangle, \tag{66}$$

where K is the quantum number associated with an intermediate angular momentum obtained by coupling L and s together. Following Cowan and Andrews, we shall call this LK coupling, since in this case both L and K are fairly good quantum numbers.

For highly excited states, however, the direct interaction may become smaller than the spin-orbit interaction of the inner valence electron. We will then have another kind of coupling, called jK coupling:

$$|((sl)j,l')K,s'J\rangle. \tag{67}$$

In each case the angular momenta used to denote the coupling scheme are good quantum numbers to the extent that the interactions that are responsible for the coupling dominate over the other interactions of the two-electron system.

4.8 Energy-Level Structure of Many-Electron Atoms

As we have seen, the Coulomb interaction among the electrons splits a configuration up into a number of LS terms. This effect can be understood by considering the expression for the energy. The energy is given by the expectation value of H,

$$E=\langle\gamma SLM_SM_L|H|\gamma SLM_SM_L\rangle, \tag{68}$$

where

$$H=\sum_{i}^{N}\left(-\frac{1}{2}\nabla_i^2-\frac{Z}{r_i}\right)+\sum_{i<j}\frac{1}{r_{ij}} \tag{69}$$

is the Hamiltonian of the system and γ denotes the additional quantum numbers necessary to specify the many-electron state.

We can evaluate the term energies once we have formed proper LS functions. There are two general approaches that one can use to form antisymmetric LS wave functions. The first method is to express the LS wave function as a linear combination of Slater determinants. The expectation value of the energy can then be evaluated using formulas such as those given in Eqs. (10) and (12). The other general approach is to build up LS states with the proper symmetry from coupled two-electron states using the technique of fractional parentage. For the definition and use of fractional parentage the reader is referred to the books by Judd (1963) and Lindgren and Morrison (1986). The approach has the advantage that it enables one to make use of powerful tensor operator techniques for evaluating matrix elements. Whichever method one uses, the expression for the matrix elements of the Hamiltonian operator consists of a number of one-electron matrix elements involving the kinetic and nuclear-potential energy of the electrons and a number of two-electron matrix elements involving the Coulomb interaction among the electrons. As an example, we give here the expectation value of the energy for the carbon atom, which has a $1s^22s^22p^2$ configuration:

$$\begin{aligned} E &= \langle H \rangle \\ &= 2I(1s)+2I(2s)+2I(2p)+F^0(1s,1s) \\ &\quad +F^0(2s,2s)+4F^0(2s,1s)-2G^0(2s,1s) \\ &\quad +4F^0(2p,1s)-\tfrac{2}{3}G^1(2p,1s)+4F^0(2p,2s) \\ &\quad -\tfrac{2}{3}G^1(2p,2s)+F^0(2p,2p) \\ &\quad +\tfrac{1}{25}\,aF^2(2p,2p), \end{aligned} \tag{70}$$

where the single-electron integrals $I(nl)$ are defined as

$$I(nl)=\int_0^\infty P_{nl}(r)\left(-\frac{1}{2}\frac{d^2}{dr^2}+\frac{l(l+1)}{2r^2}-\frac{Z}{r}\right)P_{nl}(r)dr. \tag{71}$$

The coefficient $a=10,1,-5$ for the ^1S, ^1D, and ^3P states, respectively, and $a=-2$ for the weighted average of these states.

4.9 Hartree-Fock Model

In this section, we shall optimize the description within the general framework of the central-field model by choosing the radial part of the orbitals, $(P/r)Y_{lm_l}\chi_{m_s}$, so that the energy is minimized. This energy could either be that of a particular LS term or the average energy of a configuration. As before, the radial equations for the Hartree-Fock (HF) procedure are derived by requiring that the expectation value of the total energy be stationary for small changes in the radial part of the orbitals. The orbitals are required to be of the above form, to be orthonormal, and also to satisfy the same boundary conditions as in the one-electron case.

This leads as in Sec. 3.1 to a coupled set of differential equations known as the Hartree-Fock equations. Rather than go through this variational procedure again with central-field orbitals, we note that there is a one-to-one correspondence between the terms in the expression for the energy and the left-hand side of the resulting HF equations. The HF equation for a particular orbital can be obtained immediately by making the following replacements in the energy terms that depend on that orbital:

$$I_a \to \frac{1}{q_a}\left(-\frac{1}{2}\frac{d^2}{dr^2}+\frac{l_a(l_a+1)}{2r^2}-\frac{Z}{r}\right)P_a(r), \tag{72}$$

$$F^k(a,b) \to \frac{1+\delta(a,b)}{q_a}\frac{1}{r}\,Y^k(bb,r)P_a(r), \tag{73}$$

$$G^k(a,b) \to \frac{1+\delta(a,b)}{q_a}\frac{1}{r}\,Y^k(ab,r)P_b(r). \tag{74}$$

Here q_a is the occupation number of shell a, and the functions $Y^k(ab,r)$ are defined by

$$Y^k(ab,r)=r\int_0^\infty \frac{r_<^k}{r_>^{k+1}}P_a(r')P_b(r')dr'. \tag{75}$$

As an example, we shall obtain the HF equation for the $2p$ orbital of the carbon atom. The terms in the energy expression for carbon that depend upon the $2p$ orbital are

$$\begin{aligned} E|_{2p} &= 2I(2p)+4F^0(2p,1s)-\tfrac{2}{3}G^1(2p,1s) \\ &\quad +4F^0(2p,2s)-\tfrac{2}{3}G^1(2p,2s)+F^0(2p,2p) \\ &\quad +\tfrac{1}{25}\,aF^2(2p,2p), \end{aligned} \tag{76}$$

where as before

$$a=10,1,-5,\ \text{and}\ -2 \tag{77}$$

for the ^1S, ^1D, ^3P, and the configuration average, respectively. Making the replacements given above with $q_a=2$ and $l_a=1$, we obtain

$$\begin{aligned} &\left(-\frac{1}{2}\frac{d^2}{dr^2}+\frac{1}{r^2}-\frac{Z}{r}+\frac{2}{r}\,Y^0(1s1s,r)+\frac{2}{r}\,Y^0(2s2s,r)\right. \\ &\quad \left.+\frac{1}{r}\,Y^0(2p2p,r)+\frac{a}{25}\frac{1}{r}\,Y^2(2p2p,r)\right) \\ &\quad \times P_{2p}(r)-\frac{1}{3}\frac{1}{r}\,Y^1(2p1s,r)P_{1s}(r) \\ &\quad -\frac{1}{3}\frac{1}{r}\,Y^1(2p2s,r)P_{2s}(r) \\ &= \epsilon_{2p}P_{2p}(r). \end{aligned} \tag{78}$$

A good, systematic treatment of the Hartree-Fock method has been given by Fischer (1986).

4.10 Properties of Hartree-Fock Orbitals

The Hartree-Fock method provides a qualitative understanding of some of the general features of atoms. In the remaining part of this section, we shall use it to discuss some of the properties of atomic orbitals. In later sections of this article, we will consider correlation effects that cause departures from this single-particle description.

4.10.1 Radial Shell Dependence. The Hartree-Fock wave function for a single electron has the same angular dependence and the same nodal structure as the corresponding hydrogenic wave function. The most important difference between these two functions is due to the fact that the screening of the nucleus increases in the HF model as the electron moves away from the nucleus, while for a hydrogen atom it remains the same.

If one neglects exchange, the radial Hartree-Fock equations for a closed-shell atom can be written in the form

$$\left(-\frac{1}{2}\frac{d^2}{dr^2}+\frac{l(l+1)}{2r^2}-\frac{Z-\sigma(r)}{r}\right)P_{nl}(r)$$
$$=\epsilon_{nl}P_{nl}(r), \tag{79}$$

where the effect of all the other electrons in the atom has been incorporated into an r-dependent screening parameter, $\sigma(r)$. To the extent that the exchange terms can be approximated by a local potential, their effect can also be included in the screening. So this equation frequently provides a surprisingly good representation of the Hartree-Fock approximation.

It is the strong radial dependence of the screening that is mainly responsible for the departure from hydrogenic behavior. As an example, we consider the neutral argon atom. Near the nucleus, a $3s$ electron "sees" an effective charge of very nearly $Z=18$; however, the effective charge decreases continuously from the nucleus to the outermost reaches of the atom. At a distance of about 0.3–0.5 Bohr radii, the nucleus is almost fully screened by the two K-shell electrons and partially screened by the L-shell electrons, so that the effective charge has been reduced by about 5–6 units. Still farther out, beyond one Bohr radius, the nucleus is almost completely screened by the eight L-shell electrons as well as the K shell. As a result of this change, the orbital wave functions are far from hydrogenic.

This is illustrated in Fig. 7 in which the Hartree-Fock $3p$ orbital function for the ground state of neutral argon is shown. In the upper part of the figure, the Hartree-Fock wave function is compared with a hydrogenic $3p$ function with a value of Z chosen so that the function approximately matches the HF function in the tail region. This corresponds to a nuclear charge of 6. The bottom part of the figure compares the same Hartree-Fock function with another hydrogenic function for which the nodal points match. The outer loop of this second hydrogenic function, which corresponds to a nuclear charge of 12, completely fails to represent the Hartree-Fock function in the tail region. By comparing these two figures, one can see that as one moves inward from large r, the effective field becomes continuously stronger, drawing the wave function in towards the nucleus.

Because of the contraction of atomic orbitals as the nuclear charge increases, all atoms in the same column of the periodic table differ in size by no more than a factor of 2 or 3. The size of atoms is described by the one-electron charge-density distribution, which is obtained by integrating the total charge density over all but one of the radial coordinates:

$$\rho(r)=\int d\Omega\int dV_2\cdots$$
$$\times\int dV_N|\Psi(\mathbf{r},\mathbf{r}_2,\cdots,\mathbf{r}_N)|^2. \tag{80}$$

The charge-density distribution of three noble-gas atoms is illustrated in Fig. 8. In the figure, the horizontal scale is the same for the three atoms, but the vertical scale increases with Z because of the increase in the number of electrons. The shell structure of the atoms is clear and quite pronounced, but with the inner shells contracting closer to the nucleus with higher nuclear charge. The valence shell of krypton ($n=4$) is less than twice as far out as the valence shell ($n=2$) of neon, even though the nuclear charge increases from 10 to 36.

4.10.2 *LS* Term Dependence. As we have seen, the Hartree-Fock equations are determined by requiring that the expectation value of the total energy E be stationary with respect to small changes in the form of the radial wave functions. The HF equations should, in principle, be different for each LS term, just as the expectation value of the energy is different; however, it has become traditional since the earliest days of quantum mechanics to treat the different LS terms as merely different angular-momentum couplings of the same set of atomic orbitals. This artifice can be accommodated within the framework of the Hartree-Fock approximation by apply-

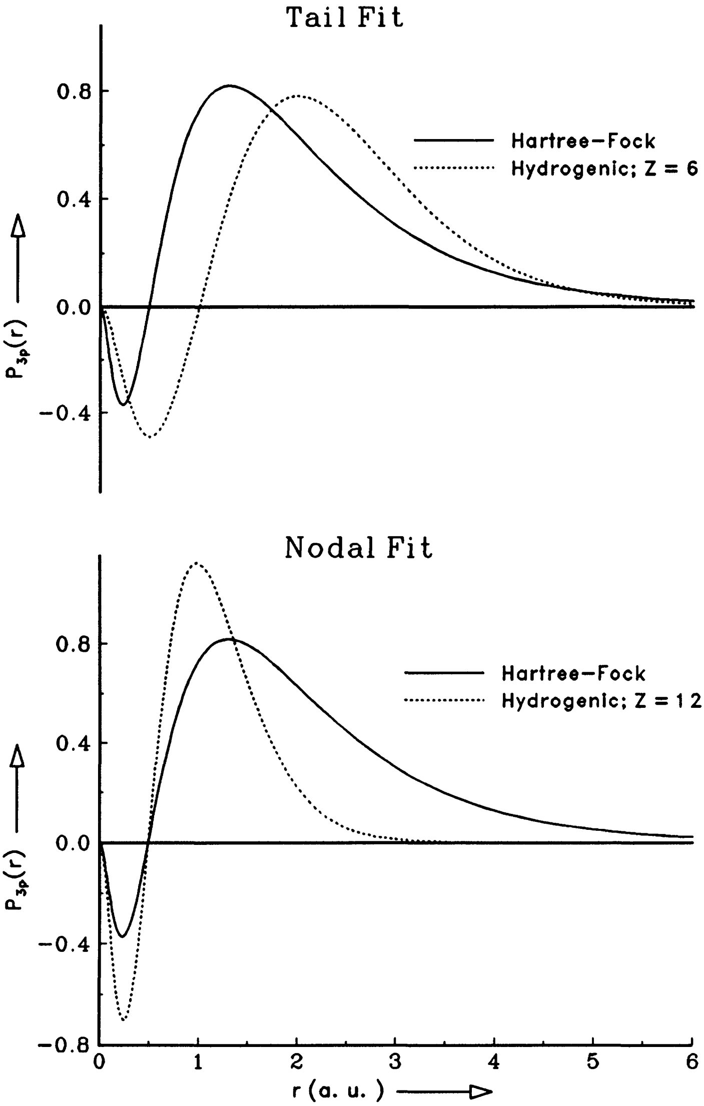

FIG. 7. Hartree-Fock and scaled hydrogenic $3p$ orbitals for the ground state of argon, $3s^2 3p^6\ {}^1S$, from the kinetic energy operator.

ing the variational principle to the weighted average of the total energies of all these states, with the degeneracies $(2S+1)(2L+1)$ as the weight factors. This leads to a set of equations for the orbitals of the center of gravity, or average energy, of the configuration and does in fact variationally define a set of orbital functions common to all states of the configuration.

The configuration-average approach frequently produces sufficiently accurate results. It is also much easier to calculate matrix elements between different states of a configuration if one has a common set of orbitals. There are cases, however, where the Hartree-Fock radial functions are quite strongly dependent on the particular LS term of the configuration. The best known example of such a term dependence was discovered by Hartree and Hartree in 1936 for the $1s^2 2s2p$ configuration of the beryllium atom, which gives rise to two terms, the triplet and singlet P states ${}^3P$ and ${}^1P$. The total energy for these states is given by

$$
\begin{aligned}
E(^{1,3}P) = {} & 2\langle 1s|h|1s\rangle + \langle 2s|h|2s\rangle + \langle 2p|h|2p\rangle + \langle 1s1s|1/r_{12}|1s1s\rangle + 2\langle 1s2s|1/r_{12}|1s2s\rangle \\
& - \langle 1s2s|1/r_{12}|2s1s\rangle + 2\langle 1s2p|1/r_{12}|1s2p\rangle - \langle 1s2p|1/r_{12}|2p1s\rangle \\
& + \langle 2s2p|1/r_{12}|2s2p\rangle \pm \tfrac{1}{2}\langle 2s2p|1/r_{12}|2p2s\rangle, \qquad (81)
\end{aligned}
$$

where h is the one-electron hydrogenic Hamiltonian. The upper sign in this expression refers to the singlet state and the lower sign to the triplet. The opposite sign of the exchange integral not only splits the term energies; it also influences the potentials of the Hartree-Fock radial equations for the $2s$ and $2p$ orbitals. The combined effect of the repulsive centrifugal and exchange potentials in the $2p$ equation of the ^1P state makes the $2p$ function for this state dramatically more diffuse than that for the triplet. The two $2p$ functions together with the $2s$ of the ^3P state are illustrated in Fig. 9. The $2s$ function is not very much different for the two states and thus serves as a convenient reference point. The mean value of r for the $2p$ orbital is 2.88 a.u. for the ^3P state and 5.02 for the ^1P state, and the maximum is twice as far out for the singlet state as the triplet.

This pronounced term dependence is closely related to the existence of a singly occupied orbital with the same principal quantum number, which gives rise to a large exchange interaction. The $3s3p$ configuration of magnesium also displays a striking singlet–triplet term dependence, as do the corresponding configurations of calcium and zinc, and the ^3P and ^1P terms of the $3p^5 3d$ configurations of singly ionized potassium. This last case is due in part to the very large angular factor for the exchange in the ^1P matrix element.

4.10.3 Shell Collapse. The case of singly ionized potassium, which we have just mentioned, provides information about another important atomic property. For light atoms, the $3d$ orbital is usually quite diffuse and hydrogenic; however, as the nuclear attraction becomes strong in comparison to the centrifugal repulsion, the d orbital is drawn into the core of the atom. In the region of the periodic table around potassium the $3d$ or-

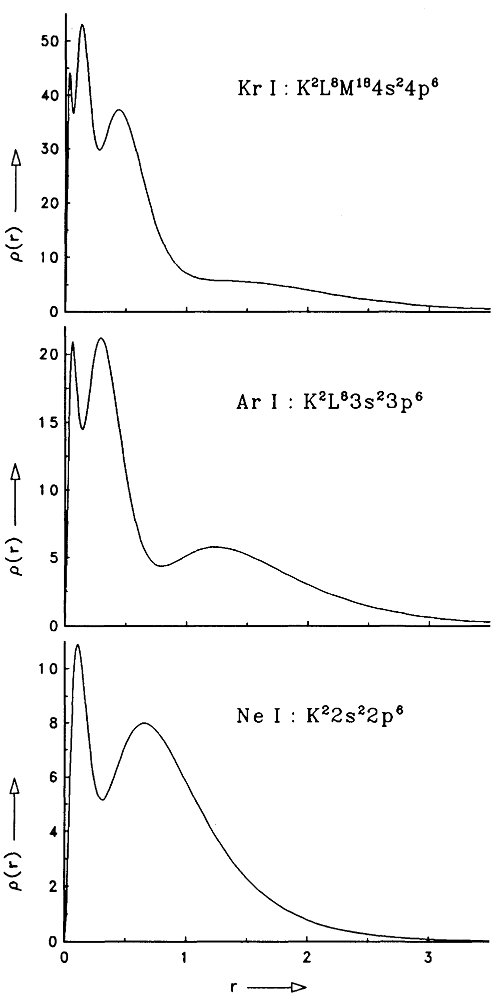

FIG. 8. Hartree-Fock radial charge-density distributions for the ground states of the noble gases Ne, Ar, and Kr. Note the change of vertical scale for the different atoms.

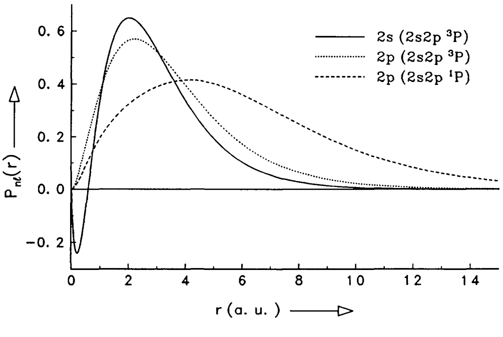

FIG. 9. Hartree-Fock orbitals for the $2s2p$ configuration of the beryllium atom.

bital "teeters" on the verge of collapse, giving rise to the sensitive term dependence just discussed. As the nuclear charge increases more the *3d* orbital collapses and becomes quite similar in spatial extent to the already filled *3s* and *3p* orbitals. In Fig. 10, we show the behavior of the mean radii of the Hartree-Fock orbitals for the elements potassium through copper. For potassium, we quote results for the two different states $3p^6 4s$ and $3p^6 3d$ and for calcium for $3p^6 3d 4s\ ^3D$. All others refer to the lowest term of the configuration $3p^6 3d^n 4s^2$, which, with the exception of chromium, represents the ground state of the atom.

In a similar manner, the *4d* shell begins to collapse around rubidium ($Z=37$), producing the second transition-metal row of the periodic table. The *5d* shell collapses shortly after cesium ($Z=55$), giving rise to the third transition-metal row.

A still more dramatic shell collapse occurs shortly beyond cesium, when the much larger centrifugal repulsion for $l=3$ is finally overcome by the attractive nuclear field, and the *4f* shell collapses. In this case, the collapse places the *4f* orbital well inside the $5s^2 5p^6$ shells. The progressive filling of this collapsed *4f* shell gives rise to the rare-earth elements, which are well known for their nearly identical chemical properties.

Some descriptive material on the properties of atomic orbitals can be found in the book by Cowan (1981) and in the review articles by Weiss (1970,1973).

5. CORRELATION IN ELECTRONIC STRUCTURE THEORY

5.1 Nature of Electron Correlation

In assigning each electron to its own single-particle state, independent-particle models implicitly treat the interaction among the electrons in an average fashion, thereby neglecting the detailed manner in which the motion of each electron is correlated with the motions of the other electrons. The error this introduces into the calculation is called the correlation error. It has become conventional to treat the Hartree-Fock model as the standard independent-particle model and to define the correlation contribution to any property as the difference between the value calculated with the exact wave function and that calculated in the Hartree-Fock approximation.

In the Hartree-Fock approximation, the wave function is written as an antisymmetrized product of single-particle functions. The product nature of the function implies that the many-electron problem is separable into a set of single-particle problems, a result that cannot be achieved for a system of interacting particles. For example, the spatial part of the Hartree-Fock function for the ground state of helium is

$$\Psi_{\mathrm{HF}}=\phi(r_1)\phi(r_2), \tag{82}$$

whereas the exact nonrelativistic Hamiltonian is given by

$$\mathscr{H}=-\frac{1}{2}\nabla_1^2-\frac{1}{2}\nabla_2^2-\frac{Z}{r_1}-\frac{Z}{r_2}+\frac{1}{r_{12}}\,. \tag{83}$$

It is the term $1/r_{12}$ that causes departures from the independent-particle description.

In order to satisfy the condition

$$(\mathscr{H}\Psi)/\Psi=E=\text{const.}, \tag{84}$$

the exact wave function must have a cusplike singularity at the nucleus:

$$\left(\frac{1}{\Psi}\frac{\partial\Psi}{\partial r_1}\right)_{r_1=0}=\left(\frac{1}{\Psi}\frac{\partial\Psi}{\partial r_2}\right)_{r_2=0}=-Z. \tag{85}$$

These conditions can be satisfied by a Hartree-Fock product function. However, the exact wave function must also satisfy the cusp condition

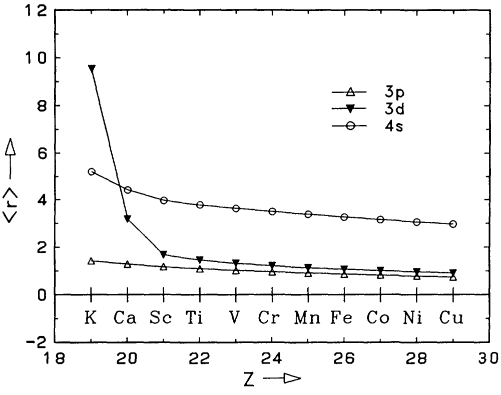

FIG. 10. Hartree-Fock orbital expectation values of *r* for the first transition elements.

$$\left(\frac{1}{\Psi}\frac{\partial\Psi}{\partial r_{12}}\right)_{r_{12}=0}=\frac{1}{2}, \tag{86}$$

which is always violated by any orbital product function, as illustrated schematically in Fig. 11. This is the root source of the correlation problem. All methods of calculating correlation corrections to the wave function can be regarded as attempts to account for this cusp condition.

The magnitude of the correlation correction to the total energy for selected first-row atoms and ions is given in Table 1. With the exception of the heliumlike systems, the energies labeled "exact" are estimates based on a combination of calculations and a careful evaluation of experimental data. The magnitude of the correlation energy is always a very small fraction of the total energy; however, it is generally comparable to the binding energy of the other electrons, which are responsible for the chemical and optical properties of atoms. Also, the changes in the wave function due to correlation may lead to more serious changes in other physical properties than it does for the energy itself.

5.2 The Hylleraas Method

The most accurate approach to the correlation problem was introduced by Hylleraas (1964). It involves explicitly introducing the interelectronic coordinate r_{12} into a variational trial function. Because of their extraordinary complexity, these calculations have been confined almost exclusively to two-electron atoms and molecules, i.e., helium and its isoelectronic ions and the hydrogen molecule. They provide benchmarks of accuracy by which all other approximations of electronic structure are judged.

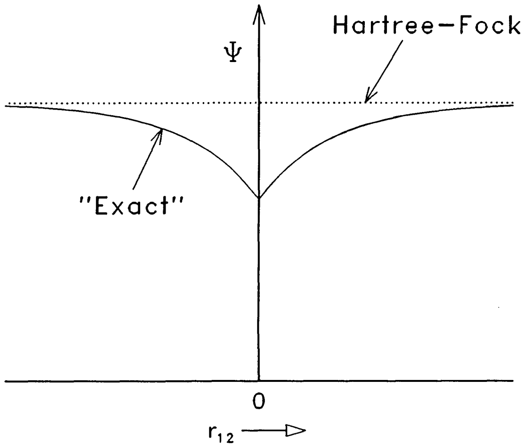

FIG. 11. Schematic behavior of Hartree-Fock and exact wave functions as $\mathbf{r}_{12}$ passes through zero, for $|r_1|=|r_2|$.

For the ground state, or any ^1S state, of a heliumlike atom, the trial function takes the form

$$\Psi=\left(\sum_{p,q,\mu} c_{pq\mu}\Phi_{pq\mu}(r_1,r_2,r_{12})\right)\times\frac{\alpha(1)\beta(2)-\beta(1)\alpha(2)}{\sqrt{2}}, \tag{87}$$

where the two-electron basis function has the general form

$$\Phi_{pq\mu}=(e^{-\zeta r_1-\zeta' r_2}r_1^p r_2^q+e^{-\zeta r_2-\zeta' r_1}r_2^p r_1^q)r_{12}^{\mu}, \tag{88}$$

ζ and ζ' being variational parameters. The total energy is then given by

$$E=\frac{\langle\Psi|\mathscr{H}|\Psi\rangle}{\langle\Psi|\Psi\rangle}=\frac{\Sigma_{i,j}c_i c_j\langle\Phi_i|\mathscr{H}|\Phi_j\rangle}{\Sigma_{i,j}c_i c_j\langle\Phi_i|\Phi_j\rangle}, \tag{89}$$

where the single indices stand for the $\{p,q,\mu\}$ triplets in Eq. (88). The variation of the energy with respect to the expansion coefficients is

$$\delta E=\frac{2}{\Sigma_{i,j}c_i\langle\Phi_i|\Phi_j\rangle c_j}\sum_i \delta c_i\left(\sum_j\langle\Phi_i|\mathscr{H}|\Phi_j\rangle c_j - E\sum_j\langle\Phi_i|\Phi_j\rangle c_j\right). \tag{90}$$

Since the variational principle requires $\delta E=0$ for any arbitrary variation of the coefficients δc_i, the quantity inside the large parentheses must vanish identically, leading to

$$\mathbf{Hc}=E\mathbf{Sc}, \tag{91}$$

where the matrix elements in this notation are defined as

$$(\mathbf{H})_{ij}=\langle\Phi_i|\mathscr{H}|\Phi_j\rangle,\quad (\mathbf{S})_{ij}=\langle\Phi_i|\Phi_j\rangle. \tag{92}$$

The calculation thus reduces to a matrix eigenvalue problem for the eigenvector of expansion coefficients. The nonlinear parameters ζ and ζ' can be chosen to ensure the correct asymptotic large-r behavior of the wave function,

Table 1. Total correlation energies (in a.u.) for selected first-row atoms and ions. [This table is taken essentially from Davis *et al.* (1991).]

Atom	Electron no.	E_{total} Exact	E_{total} Hartree-Fock	Correlation energy
He: $1s^2\ ^1S$	2	−2.903 72	−2.861 68	−0.042 04
Be^{2+}: $1s^2\ ^1S$	2	−13.655 57	−13.611 30	−0.044 26
Be: $1s^2 2s^2\ ^1S$	4	−14.667 36	−14.573 02	−0.094 34
C^{2+}: $1s^2 2s^2\ ^1S$	4	−36.534 90	−36.404 50	−0.126 40
B: $1s^2 2s^2 2p\ ^2P$	5	−24.653 93	−24.529 06	−0.124 87
C: $1s^2 2s^2 2p^2\ ^3P$	6	−37.844 99	−37.688 62	−0.156 37
N: $1s^2 2s^2 2p^3\ ^4S$	7	−54.589 25	−54.400 93	−0.188 32
O: $1s^2 2s^2 2p^4\ ^3P$	8	−75.067 2	−74.809 40	−0.257 8
F: $1s^2 2s^2 2p^5\ ^2P$	9	−99.733 8	−99.409 35	−0.324 4
Ne^{+}: $1s^2 2s^2 2p^5\ ^2P$	9	−128.144 3	−127.817 81	−0.326 5
Ne: $1s^2 2s^2 2p^6\ ^1S$	10	−128.938 8	−128.547 10	−0.391 7

$$\Psi_{r\to\infty} \to \exp(-Zr_1 - I^{1/2} r_2) + \exp(-Zr_2 - I^{1/2} r_1), \qquad (93)$$

where I is the exact ionization energy. They can also be taken to be purely variational parameters, adjusted to minimize the energy.

The Hylleraas approach, which has recently been extended to include several pairs of exponential parameters, can be applied in a straightforward fashion to excited states, to triplets, and to states of non-S symmetry. The energy spectrum of helium and heliumlike ions has been determined with a precision of 9–11 significant figures.

5.3 The Configuration-Interaction Method

Unlike the Hylleraas method, most approaches to the correlation problem make use of the general language of the independent-particle model. They are based on the multiconfiguration expansion of the wave function,

$$\Psi = c_0\Phi_0 + \sum_{a,i} c_a^i \Phi_a^i + \sum_{a,b}\sum_{i,j} c_{ab}^{ij}\Phi_{ab}^{ij} + \sum_{a,b,c}\sum_{i,j,k,} c_{abc}^{ijk}\Phi_{abc}^{ijk} + \cdots, \qquad (94)$$

where Φ_0 is normally taken to be the antisymmetric single-configuration function that most accurately describes the wave function. It is referred to as the reference state, or reference configuration, and it is usually taken to be the corresponding Hartree-Fock function. In this case, the remaining terms represent the correlation corrections. Φ_a^i denotes a symmetry-adapted antisymmetric function obtained from Φ_0 by substituting an excited orbital φ_i for orbital φ_a, occupied in Φ_0. Φ_{ab}^{ij} refers to the corresponding double-substitution configurations, and so forth. For some atomic and molecular states, the wave-function expansion converges much more rapidly if the reference function Φ_0 corresponds to a linear combination of configurations. The substitutions are then made into all of the configurations of this multiconfiguration referent.

If the Hamiltonian of the system can be represented by an approximate operator whose eigenfunctions are known, perturbation theory may be used to evaluate the coefficients in the expansion of the wave function. This approach will be discussed at some length below. The configuration-interaction (CI) method is implemented by requiring that the total energy be stationary with respect to small changes in the expansion coefficients. This leads to matrix eigenvalue equations of exactly the same form as that for the Hylleraas method. In this case, though, the matrix elements must be evaluated using the configuration-state functions described at the beginning of this section. In CI calculations, it is common to assume that the orbitals are orthonormal. The overlap matrix **S** is then a unit matrix.

A variety of strategies can be used to select the orbitals in such a way as to optimize the convergence of the expansion. The most common approach is to select a set of orthogonalized Slater-type functions or Gaussians and vary the exponential parameters to minimize the total energy. While the correction terms in the expansion of the wave function have the appearance of excited states, the correlation orbitals are generally much more compact than are the orbitals for realistic excited states. The unfettered application of the variational principle usually leads to a set of orbitals for which the correlation part of the wave function maximally overlaps the reference state.

The CI approach has been used to obtain results with an accuracy of 10 cm^{-1} or better for selected, simple atoms and molecules, utilizing expansions of 10^3–10^4 configurations. It has also been applied to the ground and excited states of a wide variety of atomic and molecular species using somewhat more truncated expansions, omitting classes of terms such as those involving correlations of the core electrons that are assumed to play a small role in valence-shell spectroscopy. Predicted excitation and ionization energies typically have an accuracy of the order of 10^3 cm^{-1}. The method has found its most extensive and intensive applications in the calculation of electronic structure of molecules, where it is not uncommon to find expansion lengths of the order of 10^5–10^6 terms. Molecular applications of CI are discussed in Sec. 8.

The principal drawback of CI arises from the rapid increase in the size of the calculation, not only as one saturates the virtual-orbital basis, but with the inclusion of higher-order substitution configurations.

5.4 Multiconfiguration Hartree-Fock Method

A natural extension of the CI method is to require that the energy be stationary with respect to simultaneous variations of *both* the CI coefficients and the orbitals. This leads to a coupled set of integro-differential equations analogous to the Hartree-Fock equations. In this case, however, the differential equation for each orbital depends upon the mixing coefficients that appear in the expansion of the wave function as well as upon the other orbitals. The conventional procedure for solving these equations is to iterate back and forth between the configuration-interaction secular equation and the integro-differential equations for the orbitals until consistency is achieved for both the orbitals and expansion coefficients.

As an example of the multiconfiguration Hartree-Fock (MCHF) procedure, we consider the ground state $1s^22s^2\ {}^1S$ of the neutral beryllium atom. It is well known that the $1s^22p^2\ {}^1S$ state mixes strongly with this state, and it is reasonable to suppose that the two-component multiconfiguration Hartree-Fock function,

$$\psi^{\text{MCHF}}=a|1s^22s^2\ {}^1S\rangle+b|1s^22p^2\ {}^1S\rangle,$$

provides a better description of the ground state than does the single-configuration wave function of the ordinary Hartree-Fock theory. Here the coefficients a and b give the weight of each configuration in the MCHF wave function. The energy is then

$$\begin{aligned}E=\,&a^2\langle 1s^22s^2\ {}^1S|H|1s^22s^2\ {}^1S\rangle\\&+2ab\langle 1s^22s^2\ {}^1S|H|1s^22p^2\ {}^1S\rangle\\&+b^2\langle 1s^22p^2\ {}^1S|H|1s^22p^2\ {}^1S\rangle.\end{aligned}\tag{95}$$

This expression assumes that

$$\int_0^\infty P_{nl}(r)P_{n'l'}(r)dr=\delta_{nn'},\quad a^2+b^2=1.\tag{96}$$

As in the single-configuration Hartree-Fock theory, we introduce a Lagrange multiplier for each constraint on the wave function. In this way, we obtain the energy functional

$$\begin{aligned}W=\,&E+\lambda_{1s,1s}\langle 1s|1s\rangle+\lambda_{1s,2s}\langle 1s|2s\rangle\\&+\lambda_{2s,2s}\langle 2s|2s\rangle+\lambda_{2p,2p}\langle 2p|2p\rangle.\end{aligned}\tag{97}$$

The requirement that this functional be stationary with respect to variations of the radial part of the wave functions leads to the MCHF equations for the $1s$, $2s$, and $2p$ orbitals,

$$\begin{aligned}LP_{1s}=\,&-\frac{2}{r}\,Y^0(1s,1s)P_{1s}+\frac{2a^2}{r}[2Y^0(2s,2s)P_{1s}\\&-Y^0(1s,2s)P_{2s}]+\frac{2b^2}{r}\bigg[2Y^0(2p,2p)P_{1s}\\&-\frac{1}{3}\,Y^1(1s,2p)P_{2p}\bigg]+\epsilon_{1s,1s}P_{1s}\\&+\epsilon_{1s,2s}P_{2s}\,,\end{aligned}\tag{98}$$

$$LP_{2s}=\frac{2}{r}[2Y^0(1s,1s)+Y^0(2s,2s)]P_{2s}$$

$$-\frac{2}{r}\,Y^0(1s,2s)P_{1s}$$

$$-\frac{2}{\sqrt{3}}\frac{b}{a}\frac{1}{r}\,Y^1(2s,2p)P_{2p}+\epsilon_{2s,2s}P_{2s}$$

$$+\epsilon_{2s,1s}P_{1s}\,, \tag{99}$$

$$LP_{2p}=\frac{2}{r}[2Y^0(1s,1s)+Y^0(2p,2p)$$

$$+\tfrac{2}{5}Y^2(2p,2p)]P_{2p}-\tfrac{2}{3}Y^1(1s,2p)P_{1s}$$

$$-\frac{2}{\sqrt{3}}\frac{a}{b}\,Y^1(2s,2p)P_{2s}+\epsilon_{2p,2p}P_{2p}\,, \tag{100}$$

where the operator L is defined as

$$L=\frac{d^2}{dr^2}+\frac{2Z}{r}-\frac{l(l+1)}{r^2}\,,$$

$Y^k(nl,n'l')$ are the functions introduced in Sec. 4.9, and the Lagrange multipliers in these equations are related to the coefficients in the energy functional.

The addition of the single-configuration $1s^22p^2$ to the wave function accounts for nearly half of the correlation energy of the beryllium atom. However, since the optimum-correlation $2p$ orbital is quite similar in radial extent to the $2s$, the added configuration has a fairly small effect upon the charge distribution of the atom.

Since the MCHF method determines the variationally optimum set of orbitals and CI coefficients simultaneously, it can provide a significantly more compact representation of correlation effects than the straightforward CI method. Relaxation of the occupied orbitals in the field of the correlation configurations is automatically taken into account. Indeed, since the orbitals seek whatever form is optimum for the multiconfiguration trial function, the distinction between occupied and excited orbitals can become somewhat blurred, which might well be exactly what is called for by the particular structure problem under consideration. For longer expansions, however, the rapid increase in the number of couplings of terms with smaller and smaller coefficients leads to convergence problems. In extensive MCHF calculations, convergence difficulties may lead one to freeze certain sets of orbitals while variationally determining the mixing coefficients and the remaining orbitals. Thus a calculation that began as a MCHF calculation may end as partially a CI calculation.

Just as with the Hartree-Fock approximation, one can expand the orbitals in a basis of analytical functions. The integro-differential equations then become matrix Hartree-Fock equations for the orbital expansion coefficients, which are, in turn, coupled with the secular equation for the CI coefficients. The expansion-method representation of the MCHF orbitals enables one to employ a radically different computational strategy. Since the total-energy expression is a function of the orbital coefficients, it is possible to develop algorithms for directly calculating numerical corrections to an initial guess of these coefficients, instead of going through the process of iteratively solving the Euler-Lagrange equations for the variational problem. In the area of atomic physics, a number of MCHF calculations have been reported recently that make use of a local basis of B splines. These calculations, which make use of the more direct iterative schemes just mentioned, also have the advantage that they are able to represent continuum and bound states together on the same footing.

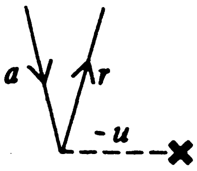
5.5 Many-Body Perturbation Theory

As we have indicated previously, perturbation theory provides another way of calculating the effect of configuration interaction upon atomic and molecular properties. In this brief review of the applications of perturbation theory, we shall first describe the lowest-order corrections to the wave function and the energy of a closed-shell atom, and then indicate some of the different features that arise for higher-order treatments.

In order to implement a perturbative approach, the electrostatic Hamiltonian is separated into an approximate Hamiltonian and a perturbation, $H=H_0+V$. The approximate Hamiltonian H_0 is a sum of one-electron operators,

$$h_0(i)=-\tfrac{1}{2}\nabla_i^2-(Z/r_i)+u(r_i), \tag{101}$$

and the perturbation is



$$= \frac{|\alpha_a^r\rangle\langle r|-u|a\rangle}{\varepsilon_a-\varepsilon_r}$$

FIG. 12. Goldstone diagram that describes a process in which a single electron is excited from a core state by a potential interaction.

$$V=\sum_{i<j}^{N}\frac{1}{r_{ij}}-\sum_{i=1}^{N}u(r_i). \qquad (102)$$

A closed-shell state may be formed by constructing determinants of the eigenfunction of h_0. These states are eigenfunctions of H_0 corresponding to an eigenvalue that is the sum of the single-electron eigenvalues.

An account of the formalism of perturbation theory and its application to atomic systems has been given by Kelly (1969) and by Lindgren and Morrison (1986). In our notation, the first-order correction to the determinantal wave function $|\alpha\rangle$ is

$$\Psi^{(1)}=\sum_{\beta\neq\alpha}\frac{|\beta\rangle\langle\beta|V|\alpha\rangle}{E_0-E_0^{\beta}}. \qquad (103)$$

The perturbation V has a one-electron part that describes the interaction of the electrons with the average potential and a two-electron part that corresponds to the Coulomb interaction among the electrons. The one-body part of the perturbation gives the contribution

$$\Psi_U^{(1)}=\sum_{\beta\neq\alpha}\frac{|\beta\rangle\langle\beta|-U|\alpha\rangle}{E_0-E_0^{\beta}}, \qquad (104)$$

where

$$-U=-\sum_{i=1}^{N}u(r_i). \qquad (105)$$

Since a one-body operator can only join determinantal states that differ by a single electron, the sum over determinants only includes single-substitution states. Using this fact and equations for the matrix elements of one-body operators between determinantal states similar to those given in Sec. 2, this contribution to the first-order wave function can be written

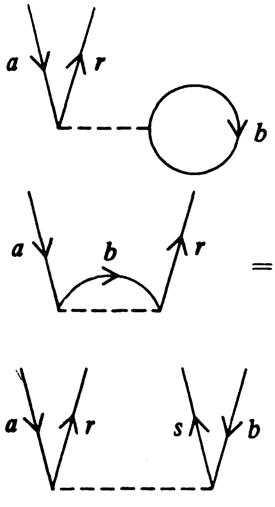
$$\Psi_U^{(1)}=\sum_{a,r}\frac{|\alpha_a^r\rangle\langle r|-u|a\rangle}{\epsilon_a-\epsilon_r}. \qquad (106)$$

The terms in this summation are clearly described by the diagram shown in Fig. 12. This type of diagram, which is a modification of the original Feynman graph, is referred to as a Goldstone diagram. The diagram describes a process in which a single electron is excited from a core state labeled a into an excited state labeled r. As is customary, the interaction is denoted by a dotted horizontal line, the core orbital is represented by a line directed downwards, and the excited state is represented by a line directed upwards.

The contribution to the first-order wave function, which is due to the Coulomb interaction among the electrons, can be written out explicitly in terms of two-particle matrix elements:

$$\Psi_C^{(1)}=\sum_{a,r}\frac{|\alpha_a^r\rangle}{\epsilon_a-\epsilon_r}\sum_b(\langle rb|1/r_{12}|ab\rangle -\langle rb|1/r_{12}|ba\rangle) +\frac{1}{2}\sum_{a,b,r,s}\frac{|\alpha_{ab}^{rs}\rangle\langle rs|1/r_{12}|ab\rangle}{\epsilon_a+\epsilon_b-\epsilon_r-\epsilon_s}. \qquad (107)$$

The first two terms describe the excitation of a core state labeled a to an excited state r by means of a direct and an exchange interaction with a core orbital b. The last term describes a two-electron excitation. These three processes are described by the Goldstone diagrams in Fig. 13.



$$= \frac{|\alpha_a^r\rangle\langle rb|r_{12}^{-1}|ab\rangle}{\varepsilon_a-\varepsilon_r}$$

$$= -\frac{|\alpha_a^r\rangle\langle br|r_{12}^{-1}|ab\rangle}{\varepsilon_a-\varepsilon_r}$$

$$= \frac{1}{2}\frac{|\alpha_{ab}^{rs}\rangle\langle rs|r_{12}^{-1}|ab\rangle}{\varepsilon_a+\varepsilon_b-\varepsilon_r-\varepsilon_s}$$

FIG. 13. Goldstone diagrams that describe the excitation of a single electron from a core state by means of a Coulomb interaction.

The higher-order terms in the perturbative expansion may also be represented graphically. Some of the diagrams that correspond to second-order contributions to the wave function are shown in Fig. 14. One may notice that the lowest part of each of these diagrams is the same as one of the diagrams that appear in the first-order wave function. An additional interaction occurs in each of the diagrams, however, as one follows the diagram from bottom to top. For instance, in the first diagram in Fig. 14, there is an additional interaction between a core and an excited orbital. All of the diagrams that appear in the expansion of the wave function are said to be linked, which means that they do not have a closed, disconnected part. The linked nature of the diagram expansion can be used to show that the energy of an extended system has the proper linear dependence upon the number of particles.

5.6 Correlation in Atomic Spectroscopy

Although the Hartree-Fock approximation generally provides a good qualitative description of the atom, there are a number of areas where it is essential to include the effects of correlation. Atomic spectroscopy is one area where correlation, at least at the level of a minimal configuration interaction, is frequently important to account correctly for the experimental results. Transition strengths in particular can be quite sensitive to the corrections arising from an adequate treatment of correlation.

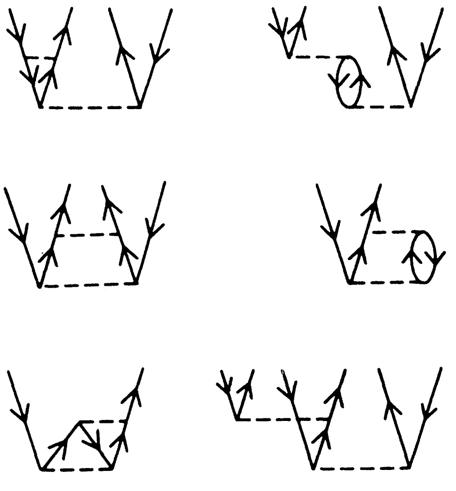


FIG. 14. Some typical second-order Goldstone diagrams.

The fundamental quantity for describing electronic transitions is the transition multiplet strength, or line strength, which for an electric dipole transition is given by

$$\mathbf{S}_{ij}=\sum_{\mu,\nu}|\langle\Phi_{i,\mu}|\mathbf{r}|\Phi_{j,\nu}\rangle|^2. \tag{108}$$

Here, Φ_i and Φ_j are the full multielectron, initial- and final-state wave functions of the transition, with μ and ν representing the degeneracies in each state. The sum over degeneracies of this scalar product, for an independent-particle model, can be carried out analytically to give the multiplet strength in the general form

$$S_{ij}=\mathscr{C}_{ij}\,\sigma_{ij}^2, \tag{109}$$

where

$$\sigma=\frac{1}{\sqrt{4l_>^2-1}}\int_0^\infty dr P_{n_i l}(r)\,r P_{n_j l'}(r), \tag{110}$$

and $\mathscr{C}_{ij}$ is a factor depending only on the orbital angular-momentum coupling in the two states. The P_{nl} functions that appear in this last formula are the radial functions of the "jumping electron." For example, in the $2s^2$–$2s2p$ transition of the beryllium atom, the relevant functions are P_{2s} and P_{2p}. It has been assumed here that all orbitals in both states are orthogonal.

Transition strengths are frequently discussed in terms of the oscillator strength, or f value, a dimensionless quantity that is given by

$$f_{ij}=\tfrac{2}{3}(\Delta E_{ij}/g_i)S_{ij}, \tag{111}$$

where ΔE is the transition energy and g_i the statistical weight of the initial state, which in LS coupling is given by $(2L+1)(2S+1)$. There are alternative, and formally equivalent, formulations of the transition strength, utilizing different transition operators, the dipole velocity and acceleration forms of the multiplet strength. All of these forms must give identical results for the exact wave functions, but need not, and usually do not, when using approximate wave functions.

The correlation corrections to the wave function can have a profound effect on the calculation of f values, as well as on the relative positions of levels in the energy level spectrum. In Fig. 15, a comparison of the Hartree-Fock and experimental binding energies for a few states of the beryllium atom are shown. All level positions are given in electron volts and are relative to the ionization limit, which is lithiumlike Be^+ $1s^22s$. One can see that there is a rather substantial shift of the $2s^2$ ground state of about 1.25 eV. Unlike most other atoms and ions, this correlation shift is accounted for largely by only a single configuration interaction, namely $2s^2+2p^2$. As discussed in the section on multiconfiguration Hartree-Fock (MCHF) methods (Sec. 5.4), the optimum $2p$ function is computed self-consistently for this state and is somewhat different from the Hartree-Fock $2p$ orbitals of the states of either $2s2p$ or $2p^2$, although not drastically so. Another feature to notice in Fig. 15 is the relatively large shift of the $2p^2$ ^1D state to a position below the ^3P of the same configuration. This energy shift may be accounted for in the MCHF theory by adding the configuration $2s3d$ to the $2p^2$ configuration.

In an MCHF calculation, the $3d$ orbital is determined self-consistently within this multiconfiguration context and it, in fact, bears very little resemblance to any independent-particle model orbital corresponding to the $2s3d$ state. This MCHF $3d$ orbital can be written as an expansion in the independent-particle model nd functions of the Rydberg series, $3d_{\mathrm{MCHF}}=\Sigma_n c_n nd$, so that the exact wave function can be written

$$\Psi(^1D)=a_0 1s^2 2p^2+\sum_n b_n 1s^2 2snd+\cdots. \qquad (112)$$

It is understood here that the sum extends over the continuum ϵd functions of the independent-particle model. This correlation effect can therefore be described as an interaction of the perturbing $2p^2$ configuration with the entire Rydberg nd series. In this case, the nd series members are displaced upwards from what the Hartree-Fock theory would predict.

Turning now to oscillator strengths, we note that the correlating effect of the $2p^2$ configuration upon the ground state will affect the f value for the transition $2s^2$ ^1S–$2s2p$ ^1P. The dominant contributions to the transition moment, taking it here to be the z component, are

$$\begin{aligned}\langle\Psi(2s^2)|z|\Psi(2s2p)\rangle &=\langle a_0 2s^2+a_1 2p^2+\cdots|z|b_0 2s2p+\cdots\rangle\\ &=a_0b_0(2s|2s)(2s|z|2p)+a_1b_0(2p|2p)\\ &\quad\times(2p|z|2s)+\cdots. \qquad (113)\end{aligned}$$

The contribution from the dominant correlating configuration in the ground state, $2p^2$, can add to, or subtract from, the HF contribution. In this case, correlation reduces the resonance-line oscillator strength by about 25%. A similar mechanism comes into play in the case of the transition to the series perturber, $2p^2$ ^1D, from $2s2p$ ^1P, for which the mixing of the $2s3d$ configuration with the $2p^2$ ^1D state reduces the oscillator strength essentially to zero. This cancellation effect occurs quite generally for transitions involving configurations that are strong series perturbers and that lie below the series that they perturb. There is a converse enhancement of the oscillator strengths throughout the perturbed series. For more complete treatments of transition probabilities, the reader is referred to the articles by Nicholls and Stewart (1962), Weiss (1973), and Fischer (1988).

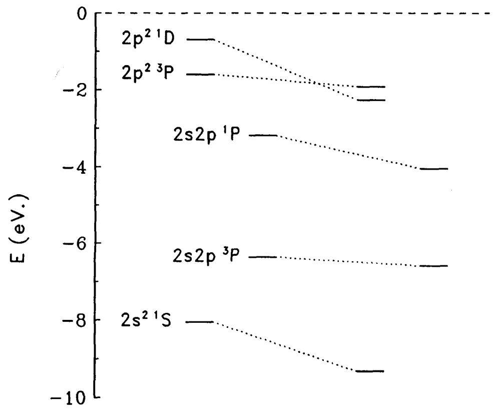

FIG. 15. Comparison of Hartree-Fock and experimental binding energies for some low-lying states of the beryllium atom. The zero of energy is the lithiumlike ion limit. Note the correlation inversion of the states of $2p^2$.

6. RELATIVISTIC EFFECTS IN ATOMIC STRUCTURE

We begin our relativistic treatment of electronic structure with a discussion of the Dirac equation. This equation can be obtained by employing the following linearized expression for the energy:

$$E = c\boldsymbol{\alpha}\cdot\mathbf{p} + \beta mc^2. \tag{114}$$

The requirement that this expression for the energy be consistent with the relativistic equation for the energy of a particle, $E^2 = c^2p^2 + m^2c^4$, leads to the condition that the components of the α and β operators have unit magnitude,

$$\alpha_1^2 = \alpha_2^2 = \alpha_3^2 = 1, \quad \beta^2 = 1, \tag{115}$$

and obey the anticommutation relations

$$\alpha_i\alpha_j + \alpha_j\alpha_i = 0, \quad \alpha_i\beta + \beta\alpha_i = 0. \tag{116}$$

Here m denotes the rest mass of the particle and c the speed of light, which in atomic units is the inverse of the fine-structure constant, 137.036. In most computational applications, the electron mass is set equal to unity just as in the nonrelativistic theory.

The time-dependent form of Dirac's equation is obtained by making the usual replacements,

$$E \to i\hbar\frac{\partial}{\partial t} + eA_0, \quad \mathbf{p} \to -i\hbar\nabla. \tag{117}$$

The customary stationary-state *Ansatz*,

$$\psi(r,t) = e^{-i(E_R/\hbar)t}\psi(r), \tag{118}$$

then yields the time-independent Dirac equation for a single particle in the external potential $U(r)$,

$$[c\boldsymbol{\alpha}\cdot\mathbf{p} + U(r) + \beta mc^2]\psi = E_R\psi. \tag{119}$$

It should be noted that the relativistic energy eigenvalue E_R includes the rest energy,

$$E_R = mc^2 + E, \tag{120}$$

where the binding energy E has the same meaning as that in the nonrelativistic theory.

The above conditions upon the α and β operators are satisfied by the matrices

$$\alpha = \begin{pmatrix} 0 & \sigma \\ \sigma & 0 \end{pmatrix}, \quad \beta = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}, \tag{121}$$

where the σ's are the usual 2×2 Pauli spin matrices. It is convenient to make use of this block structure and to express the four-component Dirac wave functions as two-component functions of the form

$$\psi = \begin{pmatrix} \phi^L \\ \phi^S \end{pmatrix}. \tag{122}$$

The Dirac equation reduces then to a pair of coupled first-order equations for the large and small components:

$$c\boldsymbol{\sigma}\cdot\mathbf{p}\phi^s + U\phi^L = E\phi^L, \tag{123}$$

$$c\boldsymbol{\sigma}\cdot\mathbf{p}\phi^L + (U - 2mc^2)\phi^S = E\phi^S. \tag{124}$$

For an atomic central-field problem, each of the wave-function components can be separated into a radial function and an angular factor just as in the nonrelativistic case. Because the momentum operator appears linearly in the above equations, the large and small components must have opposite parities. Following Rose (1961), we write the two components as

$$\phi^L_{nljm} = g_{nlj}(r)\chi_{\kappa,ki,j,m}\,, \tag{125}$$

$$\phi^S_{nljm} = -if_{nlj}(r)\chi_{-\kappa,j,m}\,, \tag{126}$$

where the angular factor is a coupled product of orbital and spin angular-momentum functions,

$$\chi_{\kappa,j,m} = \sum_{\mu=-1/2}^{1/2} \langle lm-\mu, \tfrac{1}{2}\mu \,|\, jm\rangle Y_{l\,m-\mu}\eta_\mu\,. \tag{127}$$

Here, the spherical harmonic $Y_{l\,m-\mu}$ and the spin eigenfunction η_μ are coupled together to form a state having the total angular-momentum quantum numbers j and m. The "relativistic quantum number" κ is defined as

$$\kappa = l, \quad j = l - \tfrac{1}{2}, \tag{128a}$$

$$\kappa = -l - 1, \quad j = l + \tfrac{1}{2}. \tag{128b}$$

The coupled equations for the radial functions can then be written

$$c\left(-\frac{d}{dr} + \frac{\kappa - 1}{r}\right)f(r) + V(r)g(r) = Eg(r), \tag{129}$$

$$c\left(\frac{d}{dr} + \frac{\kappa + 1}{r}\right)g(r) + [V(r) - 2mc^2]f(r) = Ef(r). \tag{130}$$

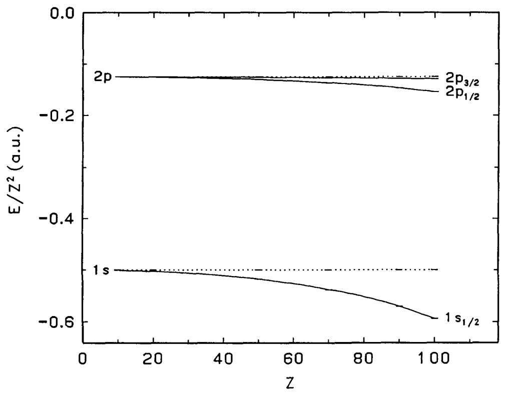

FIG. 16. Comparison of relativistic and nonrelativistic scaled binding energies for hydrogenlike ions.

For the hydrogenic atoms, these equations are exactly soluble, just as in the nonrelativistic theory.

The energy eigenvalues for the $n=1$ and 2 states of hydrogenic ions as functions of the nuclear charge Z are shown in Fig. 16. In this figure, the 2*s* state is not shown, since it is degenerate with the $2p_{1/2}$ state. The energy is scaled by Z^2, which is the exact Z dependence of the nonrelativistic theory. As indicated in the figure, relativistic effects are weaker for states with higher principal quantum numbers where the electron is farther from the nucleus and moves more slowly. It is also clear from the figure that relativistic corrections become larger with increasing nuclear charge. Relativity removes the $2p_{1/2}$-$2p_{3/2}$ degeneracy but not the $2s_{1/2}$-$2p_{1/2}$ degeneracy, which is removed by the Lamb shift. It should be clearly understood that the radial wave functions themselves are now j dependent as well as l dependent.

As in the nonrelativistic case, the radial functions are traditionally multiplied by r. P and Q functions are defined, $P_{nlj}(r)=rg_{nlj}(r)$, $Q_{nlj}(r)=rf_{nlj}(r)$. The nonrelativistic and relativistic wave functions of the $j=\frac{1}{2}$ 1*s* and 2*p* states for $Z=50$ are compared in Fig. 17. For this charge state, the large-component corrections are quite small, and for lower-Z atoms, relativistic effects, while not necessarily negligible, are generally quite small. The first and most dramatic effect of relativity with increasing Z is the development of a small component, which is entirely absent in nonrelativistic theory.

The energy eigenvalues we have discussed thus far are for the positive-energy states. The Dirac equation has a second class of solutions corresponding to a set of negative-energy states. These states, for which the large and small wave-function components reverse their roles, originally presented a puzzle as to their interpretation. Dirac resolved this by asserting that, in a vacuum, *all* these states were fully occupied, and therefore, because of the Pauli exclusion principle, completely undetectable. If, however, one of these electrons were to be excited, the remaining hole would behave as an electron but with a positive charge. The negative-energy solutions have thus become associated with the electron's antiparticle, the positron.

For an electron moving under the influence of a small effective nuclear charge, the effect of relativity may be treated as a small correction. The process of calculating a relativistic correction is initiated by formally solving the second Dirac equation for the small component,

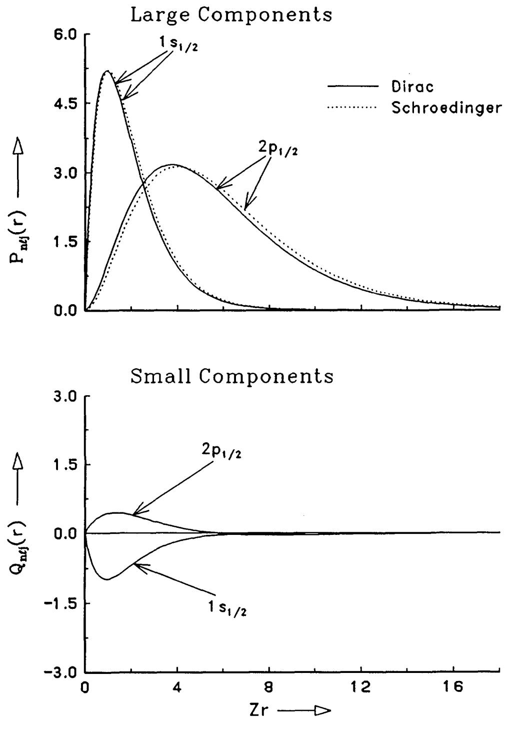

FIG. 17. Relativistic and nonrelativistic hydrogen wave functions for 1*s* and 2*p* states at $Z=50$. Both large and small components are drawn to the same scale.

$$\phi^S = \frac{c\sigma\cdot\mathbf{p}\phi^L}{2mc^2\{1+[E-V(r)]/2mc^2\}}\,. \tag{131}$$

The essential assumption of the Pauli approximation is to assume that $E-V(r)$ is much smaller than the rest energy, which allows one to expand the denominator of this equation. This leads to

$$\phi^S = \frac{1}{2mc}\,\sigma\cdot\mathbf{p}\phi^L - \frac{E-V(r)}{4m^2c^3}\,\sigma\cdot\mathbf{p}\phi^L + \cdots. \tag{132}$$

Inserting this for ϕ^S in the first Dirac equation gives

$$\begin{aligned}&\frac{1}{2m}(\sigma\cdot\mathbf{p})(\sigma\cdot\mathbf{p})\phi^L - \frac{1}{4m^2c^2}\,\sigma\cdot\mathbf{p}[E-V(r)]\sigma\cdot\mathbf{p}\phi^L\\ &\quad+\cdots+V(r)\phi^L\\ &\quad= E\phi^L.\end{aligned} \tag{133}$$

The second operator in this equation, called the Pauli operator, represents the lowest-order correction due to relativity. The leading relativistic correction to the energy is obtained by evaluating the expectation value of the Pauli operator with nonrelativistic wave functions. This leads to the energy correction

$$\begin{aligned}\delta E = &-\frac{1}{8m^3c^2}\langle p^2\phi|p^2\phi\rangle - \frac{4\pi}{8m^2c^2}\langle\phi|\delta(\mathbf{r})|\phi\rangle\\ &-\frac{1}{2m^2c^2}\left\langle\phi\left|\frac{1}{r}\frac{dV}{dr}\,\mathbf{l}\cdot\mathbf{s}\right|\phi\right\rangle.\end{aligned} \tag{134}$$

Here the first term, the mass–velocity term, can be identified as the lowest-order relativistic correction to the classical kinetic energy. The second term, the Darwin term, is purely quantum mechanical and produces an energy shift for *s* states only. The last term, the spin-orbit interaction, is nonvanishing for states with $l>0$ and produces a splitting of the *j* levels arising from such states. All of these expressions are to be evaluated using nonrelativistic wave functions. The Pauli approximation is a reasonable approach for atoms of moderate size.

The basic theoretical framework for treating multielectron atomic or molecular systems is generally the same as for the nonrelativistic theory. Orbitals are replaced, though, by Dirac-type orbitals, with large and small components, and angular-momentum couplings are based on the *j* values of the orbitals. *l* and *s* are no longer appropriate orbital quantum numbers. As of this writing, all computational schemes for the relativistic treatment of multiparticle electronic-structure problems are based on the somewhat *ad hoc* generalization of the corresponding Schrödinger equation,

$$\left(\sum_{\mu} h_{\mathrm{D}}(\mu) + \sum_{\mu>\nu}\frac{1}{r_{\mu\nu}}\right)\Psi = E\Psi, \tag{135}$$

where $h_{\mathrm{D}}(\mu)$ is the single-particle, time-independent Dirac Hamiltonian. The Dirac Hartree-Fock equations are derived in exactly the same way as for the nonrelativistic case. Since pure *j-j* coupling occurs far less often than *LS* coupling, however, the multiconfiguration HF scheme is much more important in the relativistic treatment than the nonrelativistic treatment.

While fundamental objections can be raised about the overall approach, a wealth of experience has been obtained at the Dirac-Fock and multiconfiguration Dirac-Fock stages of approximation. Some relativistic many-body calculations have been done on selected atoms, but very little work has been reported using extensive configuration interaction. The benchmark r_{12} type of study of heliumlike ions still remains to be done.

As with single-electron systems, the dominant effect of relativity is to shrink the electron density closer to the nucleus than in nonrelativistic theory. Because of changes in the screening of the inner electrons and because of the imposition of orthogonality on the orbital set, the contraction propagates to the outer reaches of the atom. This is illustrated in Fig. 18, which shows the Hartree-

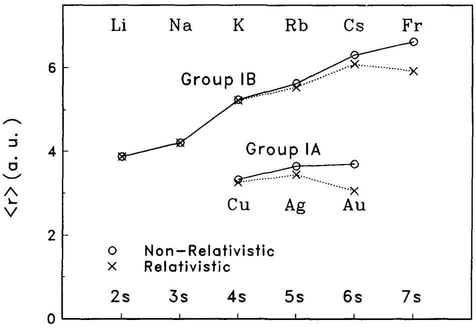

FIG. 18. Mean values of *r* for the valence orbital of the alkali-metal elements (group I of the periodic table). Comparison of nonrelativistic Hartree-Fock and Dirac-Hartree-Fock calculations.

Table 2. Ratio of relativistic to nonrelativistic HF mean values of r for the beginning and ending rare-earth elements.

Orbital	Praesodymium $4s^2 4p^6 4d^{10} 4f^3 5s^2 5p^6 6s^2$	Lutetium $4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d 6s^2$
$4s$	0.954	0.927
$4p_{1/2}$	0.953	0.924
$4p_{3/2}$	0.992	0.983
$4d_{3/2}$	0.994	0.984
$4d_{5/2}$	1.008	1.005
$4f_{5/2}$	1.067	1.029
$4f_{7/2}$	1.080	1.050
$5s$	0.952	0.918
$5p_{1/2}$	0.950	0.912
$5p_{3/2}$	0.997	0.987
$5d_{3/2}$	...	1.084
$5d_{5/2}$	...	1.118
$6s$	0.920	0.916

Fock expectation values of r for the outermost s electron in the ground state of the alkali-metal atoms. As a result of this relativistic contraction, francium and gold are actually smaller than the corresponding lighter atoms, cesium and silver. In Table 2, the ratios of the Dirac HF and HF expectation values of r are given for the first and last rare-earth elements (Desclaux, 1972). Since the higher-angular-momentum d and f orbitals are pushed farther from the nucleus by the centrifugal repulsion, the contracted s and p functions are able to screen them more completely than in the nonrelativistic case. The end result is that the $4f$ and $5d$ orbitals expand relative to the predictions of the nonrelativistic Hartree-Fock theory.

7. FUNDAMENTALS OF MOLECULAR ELECTRONIC STRUCTURE

The increased complexity in the description of molecular electronic structure due to the presence of two or more atoms in a single entity is very significant. While many of the techniques derived for atoms in the previous sections are similar to those applied to molecules, there are a number of issues that are unique to molecules. These considerations include bonding, dissociation, nuclear motion, and the multicentered nature of the Coulombic interactions. These issues, in addition to the inevitable compromises between accuracy and computational effort, may lead to significant differences in the ways in which the various techniques are applied. The development of theoretical models of molecular electronic structure has largely taken place within the field of quantum chemistry, and so much of the vocabulary is that of chemistry rather than physics.

Molecular structure involves both nuclear and electronic coordinates. In Sec. 7.1, a widely used approximation is introduced that allows one to treat separately the motion of the nuclei and the motion of the electrons. Because the focus of this article is on "electronic" structure, very little will be said about the nuclear motion problem. However, it should be noted that the vibrational and rotational nuclear degrees of freedom complicate significantly the spectroscopy of a molecule. Transitions between electronic energy levels in a molecule are usually accompanied by transitions between vibrational and rotational levels. Electronic transitions are generally observed at ultraviolet (900–4000 Å) and optical (4000–6000 Å) wavelengths. Transitions involving only the vibrational and rotational energy levels of a molecule generally take place at much lower energies, observable from the infrared into the microwave region of the electromagnetic spectrum. In addition, large changes in the nuclear framework, such as bond stretching, leading ultimately to dissociation, have profound effects on molecular electronic structure.

There are a variety of different reasons for carrying out molecular electronic-structure calculations on a particular system. One aim might be simply to obtain a qualitative description of the bonding. A more common goal is the characterization of the key features on a potential-energy surface relevant to a chemical reaction, such as the equilibrium geometries of reactants and products, any local minima, and the positions of potential-energy barriers (transition states). Another goal, which is quite different, is to obtain a balanced, high-quality description of one or more states of a system over a wide range of nuclear geometries. In the latter case, more emphasis tends to be placed on generating a description of a consistent quality than on obtaining the highest possible accuracy at a single geometry. Such considerations generally govern which methods have become the most successful for particular applications.

7.1 The Born-Oppenheimer Approximation

Molecular calculations are usually based on a nonrelativistic Hamiltonian that involves the electronic coordinates **r** and the nuclear coordinates **R** but that contains no spin-dependent terms. The total molecular wave function $\Psi_{\text{tot}}(\mathbf{r},\mathbf{R})$ depends explicitly on **r** and **R**. This molecular Hamiltonian consists of operators relating to the kinetic energies of the nuclei and of the electrons, and of operators relating to the Coulombic interactions between all of these charged particles. In SI units,

$$H_{\text{tot}}=\sum_{A}-(\hbar^2/2M_A)\nabla_A^2-\sum_{i}(\hbar^2/2m_e)\nabla_i^2+\sum_{A<B}\frac{Z_AZ_B\,e^2}{4\pi\epsilon_0|\mathbf{R}_A-\mathbf{R}_B|}-\sum_{A,i}\frac{Z_Ae}{4\pi\epsilon_0|\mathbf{R}_A-\mathbf{r}_i|}+\sum_{i<j}\frac{e^2}{4\pi\epsilon_0|\mathbf{r}_i-\mathbf{r}_j|}, \tag{136}$$

in which A and B label nuclei, i and j label electrons, Z_A and Z_B are atomic numbers, and M_A and m_e are masses of nuclei and electrons, respectively. In order to simplify the present discussion, it is convenient to introduce symbols for the individual kinetic-energy (T) and potential-energy (V) terms in the Hamiltonian for the electrons (e) and the nuclei (N):

$$H_{\text{tot}}=T_N+T_e+V_{NN}+V_{Ne}+V_{ee}\,. \tag{137}$$

The majority of theoretical studies of molecular systems implicitly assume the Born-Oppenheimer approximation, which separates the electronic-structure problem from that of the motion of the nuclei. The electronic wave function and the corresponding energy still depend on the positions, but not on the momenta, of the nuclei. The physical justification for the Born-Oppenheimer approximation is that the nuclei are thousands of times more massive than the electrons. From the point of view of the electronic structure of the molecule, the nuclei can be regarded as instantaneously stationary, creating a fixed potential of positive charges in which the electrons move.

In the Born-Oppenheimer approximation, Ψ_{tot} is factorized into separate electronic (Ψ_{el}) and nuclear (χ_{nuc}) parts:

$$\Psi_{\text{tot}}(\mathbf{r},\mathbf{R})=\Psi_{\text{el}}(\mathbf{r}\,|\,\mathbf{R})\chi_{\text{nuc}}(\mathbf{R}) \tag{138}$$

in which $\Psi_{\text{el}}(\mathbf{r}\,|\,\mathbf{R})$ depends explicitly on **r** but only parametrically on **R**. Substitution of this product wave function into the Schrödinger equation, after neglecting certain cross terms, leads to two equations:

$$(T_e+V_{Ne}+V_{ee})\Psi_{\text{el}}=E_{\text{el}}\Psi_{\text{el}} \tag{139}$$

and

$$(T_N+V_{NN}+E_{\text{el}})\chi_{\text{nuc}}=E_{\text{tot}}\chi_{\text{nuc}}\,. \tag{140}$$

The terms that have been neglected in making this separation of nuclear and electronic coordinates have the following form:

$$-\sum_{A}\frac{\hbar^2}{2M_A}[2(\nabla_A\Psi_{\text{el}})(\nabla_A\chi_{\text{nuc}})+\chi_{\text{nuc}}\nabla_A^2\Psi_{\text{el}}] \tag{141}$$

and are generally of the order of 10^{-5} to 10^{-7} times the electronic energy.

This factorization of Ψ_{tot} into a *single* product of an electronic wave function and a nuclear-motion wave function is a very good approximation unless two or more electronic states lie very close in energy. The breakdown of the so-called adiabatic approximation is of particular importance when one considers "curve-crossing" problems (see Sec. 9.3).

A molecular electronic-structure calculation in the Born-Oppenheimer approximation involves finding approximate solutions of the time-independent Schrödinger equation for *fixed* values of the nuclear coordinates, with the "clamped-nucleus" Hamiltonian:

$$H=-\sum_{i}\frac{1}{2}\nabla_i^2-\sum_{A,i}\frac{Z_A}{r_{Ai}}+\sum_{i<j}\frac{1}{r_{ij}}\,. \tag{142}$$

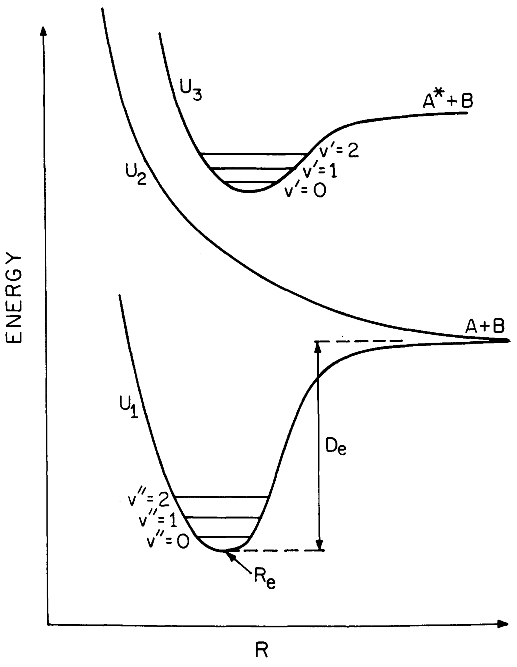

FIG. 19. Potential-energy curves of a generic molecule *AB*. U_1, a bound state, and U_2, a repulsive state, both dissociate to ground-state atoms $A+B$. Also shown is a bound-excited-state potential U_3, dissociating to the excited asymptote A^*+B. The lowest vibrational energy levels of the bound states are shown.

Here, the Hamiltonian is written in atomic units and the symbols r_{Ai} and r_{ij} are used to denote the quantities $|\mathbf{R}_A-\mathbf{r}_i|/a_0$ and $|\mathbf{r}_i-\mathbf{r}_j|$, respectively, where a_0 is the Bohr radius. The value of the energy that is obtained from such a calculation is the electronic energy E_{el}. The total electronic energy of the system is the sum of E_{el} and the fixed value of the Coulomb repulsion between the nuclei (E_{NN}). In general, the Schrödinger equation must then be solved for a number of different nuclear geometries.

A potential-energy surface $U(\mathbf{R})$ for a polyatomic system (a potential-energy curve for a diatomic molecule) consists of the total electronic energy of the system ($E_{\text{el}}+E_{NN}$) as a function of all the nuclear coordinates $\mathbf{R}$. The concept of the potential-energy surface is extremely useful in molecular physics, as it governs the theoretical interpretation of chemical reactions and molecular spectroscopy and of all atomic- and molecular-collision processes. Three idealized potential-energy curves for a diatomic molecule, *AB*, are shown in Fig. 19. The lowest potential (labeled U_1 in the figure) exhibits a minimum at a lower energy than the separated atoms and thus corresponds to a bound molecular electronic state. The minimum energy $U_1(R_e)$ occurs at the equilibrium nuclear separation R_e. The difference between $U_1(R_e)$ and the energy at the separated-atom limit is known as the binding energy, or dissociation energy D_e. The first three nuclear vibrational energy levels are shown schematically. The second potential shown in Fig. 19 (labeled U_2) represents an unbound molecular state, or "repulsive" state, for which there is no potential well and thus no binding. The top curve (U_3) represents a bound excited molecular state with the corresponding vibrational levels.

For polyatomic systems, it becomes exceedingly difficult to visualize the complete multidimensional potential-energy surfaces, and it is usual to display the surfaces in three dimensions by fixing all but two geometric variables. An example of an idealized surface for a triatomic system *ABC* is shown in Fig. 20 as contours of $U(R_{AB},R_{BC})$. Of course, provided potential-energy surfaces are available, it is possible to treat the nuclear motion problem, but this is beyond the scope of the present account, and the remainder of this article concentrates instead on the electronic-structure problem.

The clamped-nucleus Hamiltonian contains no spin-dependent terms, and so it is entirely reasonable to insist that the electronic wave functions Ψ_{el} should correspond to a

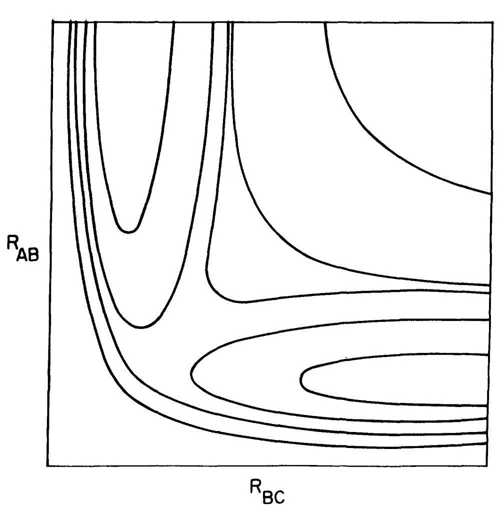

FIG. 20. Contours of $U(R_{AB},R_{BC})$ for a generic triatomic system *ABC*.

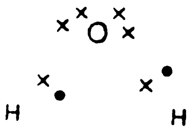
well-defined value for S, the quantum number for the total spin. This means that Ψ_{el} must be an eigenfunction of the spin operator S^2:

$$S^2\Psi_{el}=S(S+1)\Psi_{el}. \qquad (143)$$

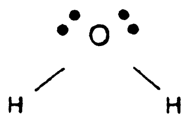
7.2 Qualitative Ideas

One of the first successful attempts to account in a qualitative way for molecular electronic structure can be traced back to 1916, several years before the advent of the Schrödinger equation, and it is usually associated with the name of Gilbert Lewis. The basic idea behind Lewis structures is that the various atoms in a molecule share some or all of their valence electrons so as to form electron pairs. Achieving the same number of electrons as the next noble-gas element is deemed particularly favorable; for atoms such as, say, carbon or chlorine this involves completing an "octet" of electrons.

The Lewis structure of the water molecule may be represented as



where the six valence electrons of the O atom have been denoted by crosses and the single valence electrons of each H atom by circles. By "sharing" two of its electrons with the H atoms, the oxygen atom achieves an octet. The H atoms achieve the corresponding magic number of two electrons (as in He). Each of the shared pairs of electrons may be termed a covalent bond, whereas the pairs of valence electrons on oxygen not involved in bonding are termed lone pairs. A more conventional representation of the Lewis structure for water takes the form



in which the notation O–H signifies a two-center, two-electron covalent bond and each pair of dots represents a lone pair.

A simple, but fairly reliable, means of predicting geometries from Lewis structures is provided by the valence-shell electron-pair repulsion or VSEPR model. The rationale is that the various classes of repulsions between pairs of electrons are ordered

$$\text{lone pair–lone pair} > \text{lone pair–bond} > \text{bond–bond}. \qquad (144)$$

In the case of H_2O, for example, the four pairs of valence electrons on oxygen would be expected to adopt an approximately tetrahedral arrangement. In the VSEPR model, the repulsions between the two lone pairs dominate the repulsions between the two covalent bonds, and so the bond angle is reduced from the tetrahedral angle $[\cos^{-1}(-\frac{1}{3})\approx 109.5°]$ to approximately 104.5°.

Many of the qualitative notions implicit in Lewis structures and in the VSEPR model were given a firm quantum-mechanical basis with the introduction of classical valence-bond theory, which is outlined in the following section.

7.3 Classical Valence-Bond Theory

The basic idea behind valence-bond (VB) theory is very appealing, and it implements in a clearcut way much of the experience of chemistry, in that the electronic wave function for a molecule is constructed directly from the wave functions of the constituent atoms or fragments. It is clear that VB concepts such as hybridization (see later), two-center two-electron bonds, and lone pairs have a strong influence on the interpretation of electronic structure and bonding. Nonetheless, VB theory has largely been eclipsed by molecular-orbital methods, which will be described later.

In constructing a molecular wave function from those of its fragments, a fundamental requirement is that it must be antisymmetric: the simultaneous interchange of the space and spin coordinates of any two electrons must induce only a change in the sign of the wave function (Pauli principle). In particular, the wave function must be antisymmetric with respect to the interchange of electrons stemming from different fragments. This leads to the exchange contribution to the energy, which is a key to understanding the formation and strength of covalent bonds. The magnitude of this exchange energy and thus the strength of covalent bonding are determined to a large extent by the degree of overlap between the wave functions of the fragments. This nonorthogonality is the hallmark of VB approaches and is also the source of most of the computational difficulties. However, for a given level of accuracy, the use of nonorthogonal orbitals can lead to much more compact wave functions than are available from methods based on orthogonal orbitals.

As a simple example of a classical VB wave function, consider the singlet ground state of the H_2 molecule, with the two nuclear centers denoted A,B and the two electrons labeled 1,2. The spin part of the wave function, which is antisymmetric, takes the form

$$\Theta=2^{-1/2}[\alpha(1)\beta(2)-\alpha(2)\beta(1)]. \tag{145}$$

In the simplest VB description, there are three "structures" to consider: the covalent structure H–H and the two ionic structures H^+H^- and H^-H^+. The spatial wave function Φ_{cov} for the covalent structure can be written

$$\Phi_{\text{cov}}=a(1)b(2)+a(2)b(1), \tag{146}$$

where a and b are atomic 1s functions on centers A and B, respectively. In a similar fashion, the spatial wave function Φ_{ion} for the two ionic structures, which must enter the total wave function with equal weights so as to preserve the molecular symmetry, can be written

$$\Phi_{\text{ion}}=a(1)a(2)+b(1)b(2). \tag{147}$$

The VB wave function Ψ_{VB} for this system then takes the form

$$\Psi_{\text{VB}}=[\Phi_{\text{cov}}+\mu\Phi_{\text{ion}}]\Theta, \tag{148}$$

where μ is a variationally optimized parameter that varies with the internuclear distance.

It is possible to rewrite the VB wave function just described in a much more compact form known as the Coulson-Fischer wave function:

$$\Psi_{\text{CF}}=\Phi_{\text{CF}}\Theta. \tag{149}$$

The H_2 molecule is described here by the spatial configuration Φ_{CF}, which has exactly the same form as Φ_{cov} above, except that the functions a and b are no longer restricted to be localized on a single center. Instead, these functions are given by

$$a=(1s_A+\lambda 1s_B),\quad b=(1s_B+\lambda 1s_A), \tag{150}$$

where $\lambda(R)$ is a (small) variationally optimized parameter, which tends to zero for large nuclear separations. The spatial function Φ_{CF} incorporates the optimal balance between the covalent and ionic structures in a *single* spatial configuration. The optimization of nonorthogonal orbitals using multicenter basis sets, as in modern VB methods (see Sec. 8.5), is crucial for the development of accurate, compact, and easily interpreted VB descriptions of molecular electronic structure.

The experimentally determined tetrahedral arrangement of the hydrogen atoms in methane (CH_4) was something of a puzzle in the early days of quantum mechanics, in that it is difficult to see why the atomic configuration of carbon ($1s^2 2s^2 2p^2$) should give rise to four equivalent C–H bonds. The solution suggested by Linus Pauling is based on taking certain linear combinations of the 2s and 2p orbitals known as hybrid orbitals. So-called sp^3 hybridization involves constructing four equivalent, orthogonal linear combinations of

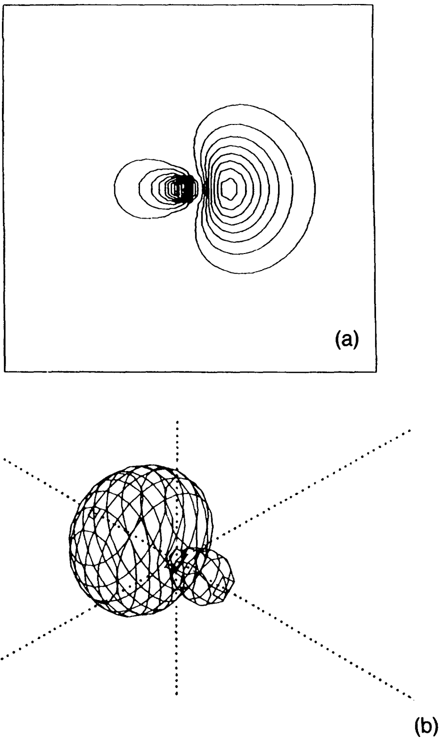


FIG. 21. An sp^3 hybrid orbital for carbon: (a) a contour plot, (b) a perspective view.

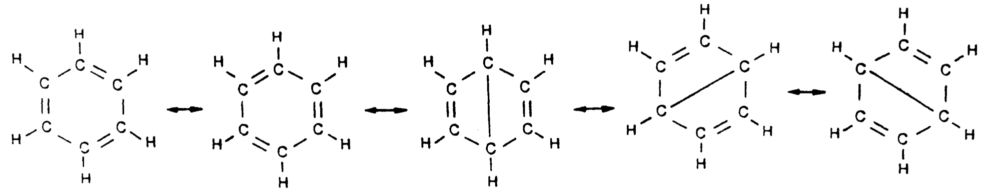
$2s$, $2p_x$, $2p_y$, and $2p_z$ functions that point towards the corners of a tetrahedron. A contour plot of an sp^3 hybrid orbital for carbon is shown in Fig. 21(a), and a perspective view in Fig. 21(b). Hybridization is a very widely used concept, particularly in organic chemistry. Hybrid orbitals of this general type arise automatically in modern VB approaches simply by minimizing the total energy, without any form of constraints on the wave function.

Some molecules cannot be realistically represented by a single Lewis structure. The mixing of different structures in valence-bond theory is called resonance, and it is usually denoted by means of a double-headed arrow. An important example in this respect is the benzene molecule C_6H_6, which features a regular hexagonal arrangement of carbon atoms. In classical VB theory, the bonding in this molecule might be represented as



(151)

This notation signifies that the total wave function is represented as a linear combination of the various structures: it does *not* mean that the molecule is spending some of its time in one form and some of its time in another.

7.4 Molecular-Orbital Theory—The Hartree-Fock Self-Consistent Field Approach

In many respects, molecular-orbital theory is much more similar than is valence-bond theory to the model used for describing atomic structure, although there are also a number of important differences. The basic premise is that each electron is described by a function called a molecular orbital φ_i, which may have nonzero amplitude over the entire nuclear framework. A function of the spatial coordinates of one electron, $\varphi_i(\mathbf{r})$, can be, and usually is, associated with at most two electrons of opposing spins and spin functions α and β. It is usual in SCF calculations to use the same spatial functions for the electrons of α and β spins. Such a calculation is referred to as a restricted Hartree-Fock or RHF calculation.

For molecules, the simplest electronic-structure problem is provided by the hydrogen molecular ion H_2^+, with one electron bound to two protons fixed in space at a separation R. To a first approximation, the wave function of this one-electron system consists of one molecular orbital (MO) composed of the ground-state atomic orbitals ($1s$) of each constituent atom, denoted a and b:

$$\varphi_i = 1s_a + 1s_b \,. \tag{152}$$

This model is derived from the recognition that the fundamental building blocks of molecules are atoms (cf. VB theory). The concept, easily extended to larger many-electron systems, is denoted the LCAO-MO (linear combination of atomic orbitals–molecular orbital) method and takes the form

$$\varphi_i = \sum_p c_{ip} \chi_p \,, \tag{153}$$

in which the χ_p are atomic orbitals centered on each of the nuclei.

The molecular orbital for H_2^+ as expressed above is a "bonding" orbital that describes the accumulation of electron density in the region between the two nuclei. This leads to a favorable contribution to the potential energy of the molecule and the formation of a bond. An important contribution to the total energy arises from the fact that the functions $1s_a$ and $1s_b$ contract significantly upon molecule formation. An "antibonding" combination of the hydrogen atomic orbitals, $1s_a - 1s_b$, depletes the electron density in the internuclear region. It can be shown for a range of nuclear separations R that the energy corresponding to the bonding orbital of H_2^+ is lower than the energy of a hydrogen atom and a hydrogen ion at infinite separation. Conversely, the energy corresponding to the antibonding orbital at finite R is greater than that at infinite separation. The ground state of H_2^+, in which the electron occupies the lowest-energy orbital, exhibits a bound potential-energy curve, similar to U_1 in Fig. 19, whereas the first excited state of H_2^+ is repulsive with a potential curve similar to U_2.

To a large extent, the Hartree-Fock procedure for determining the optimum set of linear expansion coefficients c_{ip} for each MO takes the same form as outlined for atoms in Sec. 3. The RHF wave function for a closed-shell molecule is based on a single configuration of doubly occupied orthonormal molecular orbitals, $\varphi_1^2\varphi_2^2\cdots\varphi_n^2$, and is conveniently written as a Slater determinant. Application of the variation principle to the expectation value of the energy E_{el} results in a series of one-electron equations (as derived in Sec. 3), which can be written

$$F\varphi_i=\epsilon_i\,\varphi_i\,. \tag{154}$$

Each electron experiences the average field of all the other electrons as well as the potential defined by the clamped nuclei. Because the Fock matrix depends implicitly on the form of all the orbitals, i.e., on all c_{ip}, an iterative scheme must be employed to find a solution to this generalized eigenvalue problem. Starting from a set of atomic orbitals χ_p (or, more generally, basis functions as mentioned in Sec. 3) and an initial guess for the c_{ip}'s, the Fock matrix is constructed and the relevant matrix equation is solved to find a new set of c_{ip}'s. The process is repeated until the change in energy from one cycle to the next is less than a preselected threshold and/or the elements of **c** are essentially constant. Various sophisticated schemes are available to accelerate the convergence of this process in the minimum number of iterations. In actual practice, the scheme for optimizing the occupied orbitals may rely on repeated mixing of these orbitals with unoccupied or "virtual" orbitals.

The ground-state energy obtained in an SCF calculation cannot be lower than the ground-state energy of the exact solution of the clamped-nucleus electronic-structure problem. Although the basis functions χ_p were originally conceived of as atomic orbitals, in actual calculations the basis set is more likely to consist of a significant number of relatively simple analytic functions with no direct relationship to atomic orbitals (as mentioned in Sec. 3). The Hartree-Fock energy obtained with use of a mathematically complete set of basis functions is termed the Hartree-Fock limit energy. In practice, of course, the basis sets used in molecular calculations are not complete, and so the calculated energy is higher (less negative) than the Hartree-Fock limit energy.

The MOs that are obtained by solving the Hartree-Fock equations are termed the canonical orbitals and can be classified according to their symmetry properties. For example, the occupied (bonding) orbital of H_2^+ is, to a first approximation, an in-phase combination of 1*s* functions on the two centers. This orbital is cylindrically symmetric around the internuclear axis (σ symmetry) and it is unchanged on inversion through the center of mass (*gerade*, or g symmetry). Consequently, this orbital is denoted $1\sigma_g$, where the 1 indicates that this orbital is the first one of σ_g symmetry. The lowest unoccupied (antibonding) orbital of H_2^+ is, to a first approximation, an out-of-phase combination of 1*s* functions on the two centers. This orbital is denoted $1\sigma_u$, where the subscript u, meaning *ungerade*, indicates that this orbital changes sign on inversion through

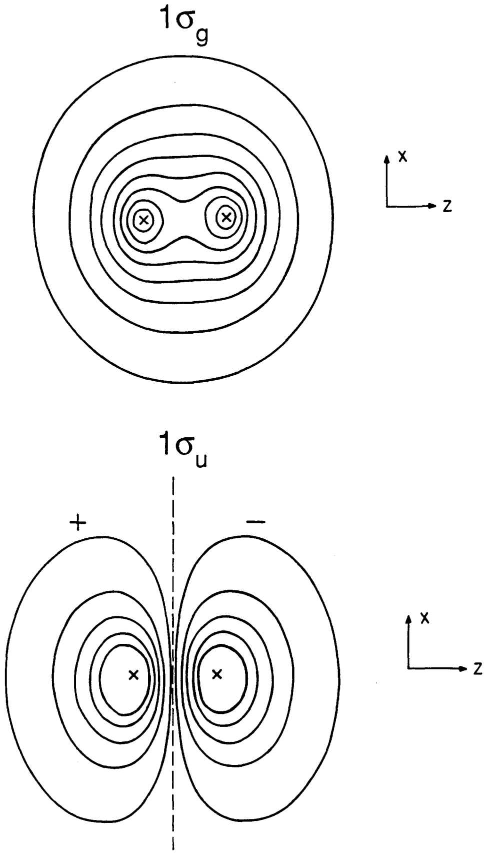


FIG. 22. Contour plots of $1\sigma_g$ bonding and $1\sigma_u$ antibonding orbitals in H_2^+.

the center of mass. These two orbitals are illustrated in Fig. 22.

For more complicated polyatomic systems it can be very useful to transform the orbitals to a more localized set, giving a clearer indication of the nature of the bonding. This relies on an important feature of the SCF wave function, namely that it is invariant against arbitrary unitary transformations of the doubly occupied orbitals. A number of schemes, of varying objectivity and computational expense, is available for generating localized MOs. In the case of methane, for example, the application of such a localization procedure results in four equivalent C–H bonding orbitals, each composed of an sp^3-like hybrid on carbon and a $1s$ function on hydrogen. A useful supplement to the use of computer graphics in analyzing canonical or localized MOs is to estimate the integrated electron density or "electron population" around different nuclear centers. There is, of course, no unique criterion for partitioning the electron density into contributions from different sites, and so several different schemes are in widespread use.

The simplest molecule beyond H_2^+ is molecular hydrogen with two electrons of opposing spins. In the ground state, each electron can be described spatially by a $1\sigma_g$ orbital of a very similar form to the bonding orbital in H_2^+. The wave function for such a system can be written

$$\Psi(1,2)=1\sigma_g(1)1\sigma_g(2)\Theta, \qquad (155)$$

where the spin function

$$\Theta=2^{-1/2}[\alpha(1)\beta(2)-\beta(1)\alpha(2)] \qquad (156)$$

is antisymmetric with respect to interchange of the two electrons 1 and 2. With a large flexible basis set of functions centered on each nucleus, the above wave function can give a Hartree-Fock energy (including the nuclear repulsion energy) of -1.134 a.u. at the equilibrium separation $R_e=1.4a_0$. The error made using the RHF approximation, or correlation energy (as defined in Sec. 5.1), is known to be 0.0409 a.u. for H_2 at R_e. The RHF energy gives over 96% of the exact total energy. However, a much more relevant quantity for molecules is the binding energy D_e, as defined in Fig. 19. D_e is computed as the difference of two energies, $E(R_e)$ and $E(\text{large } R)$, which may have very different amounts of correlation error. Thus, the dissociation energy, which is always much smaller than total energies, is very sensitive to correlation error.

In addition, there is a serious problem unique to *molecular* restricted Hartree-Fock theory that develops as the nuclei are pulled apart. In the case of H_2, multiplying out

$$\Psi(1,2)=[1s_a(1)+1s_b(1)] \times[1s_a(2)+1s_b(2)]\Theta, \qquad (157)$$

it is clear that the wave function consists of an equal mixture of terms such as $1s_a(1)1s_b(2)$, which correctly describe two neutral H atoms, and terms such as $1s_a(1)1s_a(2)$, which describe ionic asymptotes. The fact that ionic terms account for 50% of the wave function for all nuclear separations means that the RHF energy at large R becomes grossly inaccurate.

A number of molecular properties are affected by the fact that in the Hartree-Fock approximation electron–electron interactions are not accounted for exactly, but in an average sense. In general, RHF bond distances are shorter than spectroscopically derived values. For H_2, for example, the RHF minimum occurs at $R=1.38a_0$ instead of $1.40a_0$. Usually, errors in RHF bond lengths calculated with high-quality basis sets are on the order of $(0.02–0.04)a_0$. For polyatomic molecules, RHF bond angles are typically within 1°–2° of spectroscopically determined angles. With these caveats, SCF calculations have been very successful in predicting molecular geometries.

The Hartree-Fock approximation tends to exaggerate the polarity of bonds (cf. the weight given to ionic structure in the case of H_2). Thus the dipole moment, which characterizes the distribution of charge in the molecule and which is calculated as the expectation value of a one-electron operator, as indicated in Sec. 9.3, tends to be overestimated at the Hartree-Fock level of theory, often by as much as 0.5 to 1.0 D.

Much of the discussion so far has been restricted to closed-shell systems with doubly occupied MOs. RHF calculations for open-shell systems are less straightforward, although certain simplifications do arise for the special case in which all the open-shell orbitals are exactly half-filled and the corresponding electron spins are coupled to the maximum possible value. The label ROHF is often used to denote open-shell restricted Hartree-

Fock calculations. In practice, ROHF calculations usually require the input of coupling coefficients that define the energy expression to be minimized. Note that restricted Hartree-Fock wave functions for closed- and open-shell systems are eigenfunctions of the spin operator S^2.

One alternative to the use of RHF and ROHF wave functions is to allow different orbitals for different spins. Such a calculation is denoted unrestricted Hartree-Fock or UHF. The α and β spin orbitals in such a wave function are separately orthonormal, but the spatial parts of the two sets of orbitals are not orthogonal to one another. In spite of the increased number of orbitals to be optimized, it is generally much more straightforward to generate UHF wave functions than ROHF wave functions. UHF calculations yield lower energies than RHF wave functions and can often describe reasonably well the breaking of a single two-electron bond (see also Sec. 8.1). The major objection to UHF wave functions is that they are not eigenfunctions of the spin operator S^2, i.e.,

$$S^2\Psi_{\mathrm{UHF}} \neq S(S+1)\Psi_{\mathrm{UHF}} .$$

Such a situation is known as spin contamination and can lead to spurious, unphysical behavior, especially when states of different spin multiplicity are close in energy to one another. As discussed in Sec. 8.3, spin contamination can lead to very serious problems if UHF wave functions are used as the starting point for more sophisticated calculations. UHF wave functions are available from many of the standard quantum chemistry computational packages and are consequently very widely used. There has very recently been significant progress in developing open-shell SCF methods in which the wave function is effectively constrained to have the correct eigenvalue of S^2.

There are several useful theorems that apply to closed-shell RHF wave functions. According to Koopmans's theorem, previously discussed in Sec. 3.1, the orbital energies ϵ_i, obtained as solutions of the Fock equations, may be thought of as ionization potentials of the molecule. The approximations inherent in Koopmans's theorem include the neglect of the orbital relaxation that follows ionization and of the differences in correlation energy between the parent molecule and its ion (see Sec. 9.2). Nevertheless, orbital energies provide useful initial guidance for the interpretation of photoelectron spectra. Differences in the relativistic contributions to the energy can cause significant errors if Koopmans's theorem is used to interpret experiments such as x-ray photoelectron spectroscopy in which core electrons are ionized. It is important to point out that the orbital energies cannot be used on their own to provide meaningful estimates of the electronic excitation energies in a molecular system.

Brillouin's theorem states that there are no nonzero matrix elements of the Hamiltonian between the SCF wave function and singly excited wave functions that differ from the first one only by the promotion of one electron from an occupied spin orbital to a virtual spin orbital. This has consequences for the construction of more sophisticated wave functions (see Sec. 8), although singly excited configurations may be crucial for the accurate calculation of molecular properties and they do contribute, albeit indirectly, to the correlation energy.

7.5 Molecular Symmetry

The nuclear framework of the molecule establishes a spatial symmetry, termed the point-group symmetry, which must be reflected in the clamped-nucleus Hamiltonian and in the electronic wave functions of the system. Molecular states are classified according to the spin multiplicity, $2S+1$, and by the symmetry properties of the spatial part of the wave function. Symmetry considerations are very useful in molecular-structure calculations. Indeed, many qualitative properties of an electronic state, such as degeneracies and selection rules for making transitions, may be deduced from symmetry arguments alone. Furthermore, it is often possible to use the molecular point-group symmetry to reduce significantly the size of electronic-structure calculations.

As a simple example of the use of symmetry to classify molecular states, we consider the water molecule. The axis convention for this molecule is shown in Fig. 23. The nuclear framework (and thus also the Hamiltonian) is unchanged upon rotation through an angle of 180° about the z axis. This axis is denoted C_2, where the subscript $n=2$ indicates that the rotation angle is $2\pi/n$ radians. The nuclear

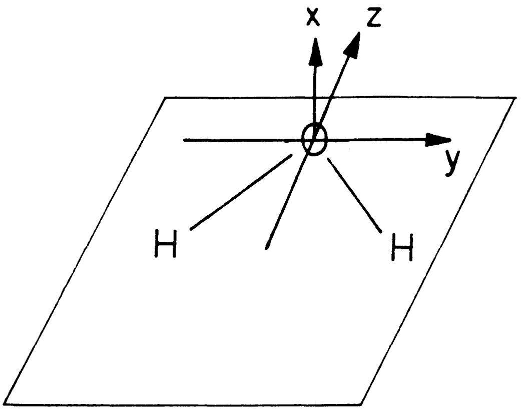

FIG. 23. Axis convention for the H_2O molecule (C_{2v} symmetry). The molecule plane is *yz*.

framework is also unchanged by reflection in the *yz* molecular plane (denoted σ_v'), reflection in the *xz* plane (denoted σ_v), or the identity operation. These four symmetry operations combine to form a group, known as the point group C_{2v}. Wave functions for a molecule possessing C_{2v} symmetry can be classified according to their symmetry properties under the various operations that form the group. Just four symmetry types or "irreducible representations" can occur, labeled A_1, A_2, B_1, and B_2. The ground state of H_2O has the term symbol $^1A_1$, where A_1 denotes the spatial symmetry and the superscript 1 indicates that the spin multiplicity is $2S+1=1$ (i.e., $S=0$). The canonical orbitals of H_2O from an RHF calculation are similarly labeled a_1, a_2, b_1, and b_2, so that the Hartree-Fock electronic configuration of the ground state of water near its equilibrium geometry is $1a_1^2 2a_1^2 3a_1^2 1b_1^2 1b_2^2$.

There are only four common labels for MOs in nonlinear molecules:

1. *a* or *b*: nondegenerate. The precise difference between *a* and *b* symmetries is linked to the behavior under rotation about the C_n axis with highest *n*. Such orbitals can accommodate a maximum of two electrons.
2. *e*: a pair of degenerate MOs. Such orbitals can accommodate a maximum of four electrons.
3. *t*: a set of three degenerate MOs. Such orbitals can accommodate a maximum of six electrons.

Each of these symbols *a,b,e,t* can be modified with various additional labels such as g and u, which we encountered in the case of H_2 (see Sec. 7.4). Other possible labels include 1, 2, and various primes, as in a''. Most chemical physicists do not concern themselves with the precise meaning of all of these symbols, but regard them instead as names that distinguish one orbital from another.

In the special case of heteronuclear diatomic molecules, or indeed any linear molecule that is not centrosymmetric (such as OCS), the point group is $C_{\infty v}$. The rotation axis, which passes through all the nuclei, is denoted C_∞, where the subscript $n=\infty$ signifies the special property of cylindrical symmetry that the nuclear framework, and thus the clamped-nucleus Hamiltonian, is invariant against *any* arbitrary rotation around the internuclear axis. The symmetry designations of the orbitals $\sigma,\pi,\delta,\phi,\ldots$, which correspond to quantized projections of the electronic orbital angular momentum along the internuclear axis of 0,1,2,3,..., are analogous to the labels used for atoms (*s,p,d,f,...*). Molecular electronic states in $C_{\infty v}$ symmetry are similarly labeled $\Sigma,\Pi,\Delta,\Phi,\ldots$ according to the value (0,1,2,3,...) of Λ, the projection of the total electronic orbital angular momentum along the symmetry axis. The full designation of term symbols for $C_{\infty v}$ molecules is $^{2S+1}\Lambda_\Omega$, in which the numerical value of Λ is replaced by the corresponding symbol ($\Sigma,\Pi,\Delta,\Phi,\ldots$), and $\Omega=|\Lambda+\Sigma|$ is the total angular momentum about the internuclear axis, where Σ (here) is the corresponding projection of the total spin *S*. For $\Lambda>0$, the molecular states are doubly degenerate, whereas for $\Lambda=0$ the states are labeled Σ^+ or Σ^- according to whether or not the electronic wave function changes sign upon reflection in any plane containing the C_∞ axis.

Of course, many states of a molecule can correspond to the same spin multiplicity and spatial symmetry, and so it is necessary to find some means of uniquely labeling each state. The ground state is designated with a capital *X* before the spin multiplicity; the ground state of the OH radical, for example, is $X\,^2\Pi_{3/2}$. Excited states with the same spin multiplicity ($2S+1$) as the ground state are labeled with capital letters (*A,B,C,...*) whereas lowercase letters (*a,b,c,...*) are used to designate states of different spin multiplicity.

Homonuclear diatomic molecules, or indeed any linear molecule that is centrosymmetric (such as CO_2), belong to the point

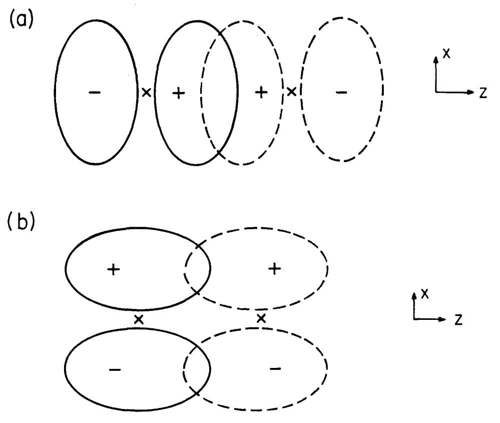

FIG. 24. Schematic representation of orbitals in a diatomic molecule: (a) bonding σ combination of $2p_z$ functions; (b) bonding π combination of $2p_x$ functions.

group $D_{\infty h}$. The labeling of orbitals and of molecular states is analogous to the designations just described for $C_{\infty v}$. The main difference, as already encountered in Sec. 7.4, is the addition of subscripts g or u to signify whether the orbital or wave function is even or odd under inversion through the center of mass. Thus the ground state of H_2, with RHF configuration $1\sigma_g^2$, is denoted $X\,^1\Sigma_g^+$.

7.6 Bonding in Diatomic Molecules

As described in Sec. 7.4, the in-phase combination of two hydrogen $1s$ orbitals in H_2 leads to a bonding orbital ($1\sigma_g$), whereas the out-of-phase combination leads to an antibonding orbital ($1\sigma_u$). Similarly, linear combinations of two hydrogen $2s$ orbitals generate the $2\sigma_g$ and $2\sigma_u$ MOs. If we bring together two $2p_z$ orbitals, where z is the internuclear axis, then the in- and out-of-phase combinations generate the $3\sigma_g$ and $3\sigma_u$ orbitals [see Fig. 24(a)]. If the two atomic centers are different, so that the molecule has $C_{\infty v}$ symmetry, then the g and u labels no longer apply and so the bonding and antibonding combinations of $2p_z$ orbitals are denoted 5σ and 6σ, respectively, with the first four σ orbitals corresponding to bonding and antibonding combinations of the $1s$ and $2s$ functions. The analogous combinations of $2p_x$ orbitals (or, equivalently, $2p_y$ orbitals) have very different symmetry properties [see Fig. 24(b)]. The two bonding combinations $2p_x+2p_x$ and $2p_y+2p_y$ constitute a degenerate pair which is labeled 1π in $C_{\infty v}$ symmetry, or $1\pi_u$ in $D_{\infty h}$ symmetry. The corresponding antibonding combinations, $2p_x-2p_x$ and $2p_y-2p_y$, constitute a degenerate pair that is labeled 2π in $C_{\infty v}$ symmetry, or $1\pi_g$ in $D_{\infty h}$ symmetry.

A schematic molecular-orbital energy-level diagram of O_2 is shown in Fig. 25, in which the arrows signify which orbitals are occupied by electrons of α and β spins. It can be seen that the electronic configuration of the ground state of this molecule is $1\sigma_g^2 1\sigma_u^2 2\sigma_g^2 2\sigma_u^2 3\sigma_g^2 1\pi_u^4 1\pi_g^2$. According to Hund's rule, electrons in partially filled degenerate orbitals, such as $1\pi_g$, preferentially couple to the maximum possible spin ($S=1$, in this case). The prediction of unpaired electrons in O_2 and thus the rationalization of the paramagnetism of this molecule was one of the early successes of MO theory.

In extending this type of qualitative argument so as to generate schematic molecular energy-level diagrams, there are five very useful principles:

1. There must be no symmetry reason why the atomic functions cannot overlap. In a diatomic molecule, a $2s$ function on one center cannot mix with $2p_x$ on another: the regions of positive and negative contributions cancel to give a net overlap of zero. For diatomic molecules, "allowed" contributions include $s\pm s$, $s\pm p_z$, $p_z\pm p_z$, $p_x\pm p_x$, and $p_y\pm p_y$.
2. Bonding MOs arise from combinations of atomic orbitals that have similar energies and that have a large value for the overlap integral.
3. For every bonding MO there is a corre-

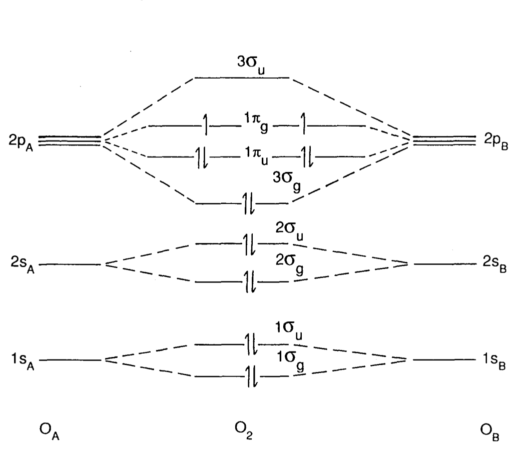

FIG. 25. A schematic molecular-orbital energy-level diagram for O_2 ($D_{\infty h}$). The arrows denote the electron configuration.

sponding antibonding MO.

4. Atomic orbitals that do not mix with functions on other centers are neither bonding nor antibonding. Such orbitals are said to be nonbonding.
5. It is usually necessary only to consider the valence electrons.

As a simple heteronuclear example, consider OH with nine electrons. This molecule dissociates to $O(1s^22s^22p^4)$ and $H(1s)$. The oxygen $1s$ and $2s$ orbitals do not enter into the bonding and are designated 1σ and 2σ, respectively. Of the four $2p$ electrons on oxygen, the one in the $2p_z$ orbital overlaps with the $1s$ function on hydrogen so as to form a σ bond (the 3σ MO). The remaining three electrons in the $2p_x$ and $2p_y$ orbitals occupy the 1π orbitals, so that the electron configuration of the ground state of OH is written $1\sigma^22\sigma^23\sigma^21\pi^3$. Bonding orbitals in heteronuclear molecules often have significantly more electron density in the vicinity of one nucleus than around the other. One such example occurs in the $1\sigma^22\sigma^2$ electronic configuration of the ground state of LiH ($X\,^1\Sigma^+$). In this case, the doubly occupied 1σ MO is effectively $1s^2$ on lithium. The 2σ bonding orbital, which formally arises from the overlap of Li$(2s)$ and H$(1s)$, has sufficient amplitude on the hydrogen center that the molecule can be said to have substantial Li^+H^- character.

Finally, we consider the ground state of HBr molecule with six valence electrons: H$(1s)$ and Br$(\cdots 4p^5)$. Significant $4s$-$4p$ mixing (or hybridization) is not likely for an element so far to the right of the periodic table. The combination H$(1s)$ + Br$(4p_z)$ leads to a σ-bonding MO. The corresponding out-of-phase combination leads to an antibonding MO of σ symmetry. It is common, particularly in organic chemistry, to denote the antibonding character by means of an asterisk, as in σ^*. For symmetry reasons, there can be no net overlap between the $1s$ orbital on hydrogen and the $4p_x$ or $4p_y$ orbitals on bromine. This means that the (degenerate) $4p_x$ and $4p_y$ orbitals give rise to a nonbonding MO of π symmetry.

A schematic energy-level diagram for HBr, based on these arguments, is presented in Fig. 26, and suggests an electronic configuration of $\sigma^2\pi^4$. We can predict a bond order of unity, i.e., a single H–Br σ bond, and four nonbonding valence electrons. Removal of an electron from the highest occupied MO (π nonbonding) should not significantly alter the bond length or the dissociation energy. Similarly, promoting one of the π electrons of the neutral molecule into the antibonding σ^* orbital should generate an excited electronic state with a weaker and longer bond. All of these various predictions have been confirmed by means of appropriate spectroscopic measurements.

7.7 Basis Sets for Molecular Calculations

A dominant factor in determining the accuracy of molecular electronic-structure calculations is the quality of the basis set $\{\chi_p\}$ in terms of which the orbitals are expanded:

$$\varphi_i = \sum_p c_{ip}\chi_p \,. \qquad (158)$$

In the most extensive contemporary calculations of correlation energy (see Sec. 8) the largest source of uncertainty is the basis-set truncation error. The calculated values of molecular properties tend to be particularly sensitive to the quality of the basis set.

In principle, molecular wave functions could be expanded in terms of a one-center expansion, as in the case for atoms. Such expansions have a number of potentially useful features, such as the ease of integral evaluation and the avoidance of linear dependence. However, one-center basis sets are only very rarely used in molecular studies, because the rate of convergence with the size of basis set is unacceptably slow. The vast majority of molecular calculations use multicenter basis sets, with basis functions centered on each of the nuclei.

Computation of the energy requires integrals of the one- and two-electron parts of the clamped-nucleus Hamiltonian introduced in Sec. 7.1. The computationally most expensive integrals are the two-electron integrals, arising from the electron–electron repulsion terms in the Hamiltonian:

$$(\chi_a\chi_c|\chi_b\chi_d) = \int \chi_a(1)^*\chi_b(2)^*(1/r_{12}) \times\chi_c(1)\chi_d(2)dr_1^3dr_2^3. \qquad (159)$$

The choice of functional form for the basis functions is a compromise between the ease of calculating accurate values of such integrals and the number of functions required to represent adequately the orbitals on which the total wave function is based.

The most commonly encountered functional forms are known as Slater-type orbitals (STOs) and Gaussian-type orbitals (GTOs). The STOs, or exponential-type functions, take the form

$$\chi = N_{n\zeta}\, r^{n-1} \exp(-\zeta r) Y_{lm}(\theta,\phi), \qquad (160)$$

in which r,θ,ϕ are polar coordinates, n,l,m are the usual atomic quantum numbers, and $N_{n\zeta}$ is a normalization constant. The value of ζ is usually referred to as the exponent. Basis functions of this type generally provide rapidly convergent representations of atomic and molecular orbitals. Note that the radial parts of these functions are nodeless, unlike hydrogen-atom orbitals.

"Minimal" STO basis sets consist of a single basis function for each occupied orbital of the constituent atoms. For a molecule containing a carbon atom, for example, this implies a 1*s* STO, a 2*s* STO, and three equivalent 2*p* STOs, each corresponding to a different value of *m*. "Double-ζ" basis sets allow two STOs with different exponents for each occupied atomic orbital, while "triple-ζ" basis sets allow three values of ζ.

In principle, all of these exponents could be taken from atomic calculations or they could be modified to take account of the molecular environment. The latter is especially important for functions centered on hydrogen nuclei, for which it is necessary to use exponents greater than the atomic value of unity. In the case of negative ions, for example, it is essential to include suitable diffuse (low-ζ) functions. In some calculations, the STO exponents have been generated by geometric series.

These various basis sets are almost always augmented with so-called "polarization functions," which correspond to the next value of *l*, i.e., *p* functions on hydrogen atoms or *d* functions on carbon atoms, for example. A double-ζ basis set augmented with polarization functions is often denoted DZP or DZ+P. Such polarization functions are essential for obtaining good descriptions of molecular systems and may have a significant effect on calculated values of molecular properties while contributing relatively little to the energies of the separated atoms.

Particular care is required in the design of large, flexible basis sets suitable for calculations that go beyond the SCF approximation. Fairly extensive tables have been published of STO basis sets suitable for molecular calculations.

STOs are still extensively used in calculations on small linear molecules, particularly diatomic molecules. However, multicenter two-electron integrals involving STOs are computationally very expensive for nonlinear systems, and it may be difficult to obtain the integrals to the required accuracy, particularly for functions with $l > 1$. This is the main reason for the dominance of GTOs as basis functions in contemporary molecular calculations.

A Cartesian GTO can be written in the form

$$\chi = N_{abc\alpha} x^a y^b z^c \exp(-\alpha r^2), \qquad (161)$$

where x,y,z are the usual Cartesian coordinates, a,b,c are integers that determine the type of GTO, α is the exponent, and $N_{abc\alpha}$ is a normalization constant. An *s* function corresponds to $a=b=c=0$—notice that there is no dependence on *n*, the principal quantum number. In the case of *d* functions $(a+b+c=2)$ there are six unique components instead of the usual five. This is equivalent to adding an extra *s* function to the basis set. Similar considerations apply to *f* functions.

As well as Cartesian GTOs, it is also common to use spherical GTOs in the form

$$\chi = N_{l\alpha} r^l \exp(-\alpha r^2) Y_{lm}(\theta,\phi). \qquad (162)$$

For *s* and *p* functions, the Cartesian and spherical GTOs are essentially equivalent, but there are only five components for a *d* function in the case of a spherical GTO.

Gaussian functions provide very poor representations of atomic and molecular orbitals in the regions of space close to the nucleus on which they are centered, since GTOs, unlike STOs, do not possess a cusp. In order to achieve a given accuracy, it is usually necessary to use significantly more GTOs than STOs, particularly for core orbitals. A factor of 3 in the number of functions required is not uncommon. Furthermore, the occurrence of $-r^2$ rather than $-r$ in the exponent means that the long-range form of a GTO is also inappropriate. This necessitates particular care in calculations of properties such as polarizabilities and in studies of intermolecular forces.

In view of the problems just outlined, it might seem surprising that GTOs are used at all. However, these disadvantages are more than offset by two further considerations: the ease with which the integrals can be computed accurately and the form of the derivative of a Gaussian function (see Sec. 9.1). The overwhelming majority of molecular electronic-structure calculations employ GTOs. It is straightforward to show that the product of two Gaussian-type orbitals on centers *A* and *B* takes the form of a Gaussian-type orbital centered on a point *P* that is located on the line between *A* and *B*. Consequently, the calculation of two-electron integrals becomes very straightforward.

The Gaussian-type functions described so far are termed "primitive" functions, because each basis function consists of a single GTO with a single exponent. A practical means of reducing the size of the basis set without significantly reducing the accuracy of molecular electronic-structure calculations is to form new basis functions, called contracted GTOs, which are fixed linear combinations of primitive GTOs:

$$g=\sum_j k_j\chi_j\,, \tag{163}$$

where the k_j are called contraction coefficients. The high-exponent primitive GTOs, which contribute mostly to the inner-shell or core orbitals, can often be contracted with little loss of accuracy. The more diffuse primitive GTOs are not usually contracted in this way.

The need for diffuse functions for negative ions and for polarization functions arises in the same way for GTOs as for STOs. Contracted Gaussian basis sets are often given acronyms such as DZP or TZVP, which give an indication of the type or the size of STO basis set that would be of similar accuracy. A TZVP basis set for the carbon atom is listed in Table 3; the letters TZVP or TZV+P denote "triple-ζ valence" (the core is less well represented) plus polarization (the single set of *d* functions). Some of the basis sets in common use with some of the standard computational packages were originally based on least-squares fits of Gaussian functions to STO basis sets and bear names such as 4-31G, which reflect this parentage. A 4-31G basis set for the carbon atom is also listed in Table 3.

The computation of the one- and two-electron integrals accounts for a significant proportion of the total computational requirements of a geometry optimization using an SCF wave function. One alternative to the *ab initio* calculation of all the integrals is to use semiempirical approximations. Such methods treat the integrals, and related quantities, as parameters to be obtained by least-squares fits to experimental data, or to the results of small *ab initio* calculations, for a large sample of molecules. A number of semiempirical techniques are in widespread use, particularly for large organic molecules, for which *ab initio* calculations might be rather expensive. Semiempirical calculations are particularly useful as a means of estimating equilibrium geometries and heats of formation and for obtaining an approximate idea of the qualitative features of the molecular orbitals. The forms of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) are particularly useful for interpreting organic reactivity, using "frontier orbital theory." However, semiempirical techniques are not in general suitable for high-quality calculations of entire potential-energy surfaces.

8. METHODS FOR TAKING ACCOUNT OF ELECTRON CORRELATION IN MOLECULES

While there has been a great deal gained in terms of qualitative descriptions of molecular electronic structure via independent-particle methods, an up-to-date account of current

work in the field would be somewhat deficient without some mention of methods that extend this picture. As discussed in Sec. 2, independent-particle models, such as Hartree-Fock theory, include only the average electron–electron interactions, whereas the motion of the electrons is in fact strongly correlated. In molecular electronic-structure work, the impetus to move beyond the Hartree-Fock model comes not just from the desire to reduce the correlation error, defined as the difference in energy between the exact solution of the clamped-nucleus Schrödinger equation and the Hartree-Fock solution. Equally important is allowing for flexibility in the electronic wave function to describe a changing charge distribution as the nuclear framework distorts and bonds are made or broken. Particularly for systems for which excited electronic states, molecular properties (see Sec. 9), and significant portions of the potential-energy surface(s) are required, it is necessary to consider calculations which account for some degree of charge rearrangement, recoupling of electron spins, and electron correlation. Many methods have been developed for taking into account the most important electron-correlation effects. The purpose of this section is to give a flavor of the more standard and the most widely used approaches for obtaining more accurate electronic energies, wave functions, and properties for molecular systems.

8.1 Multiconfiguration Self-Consistent-Field Method

A fundamental deficiency of the MO-theory SCF approach to molecular electronic structure is that it does not provide descriptions of uniform quality as the internuclear distances are varied. In particular, the single-configuration wave function does not describe correctly the process of molecular dissociation. As was shown in Sec. 7.4, the configuration $1\sigma_g^2$ describes H_2 reasonably well near its equilibrium geometry but corresponds at large nuclear separations to a mixture of the correct ground-state asymptote, $H(^2S)+H(^2S)$, and the ionic asymptotes $H^+ + H^-(^1S)$ and $H^-(^1S) + H^+$. In order to eliminate the ionic asymptotes, a linear combination of two configurations is required, namely $1\sigma_g^2 - 1\sigma_u^2$. In this section, we describe the extension of the Hartree-Fock theory single-determinantal wave function to a superposition of Slater determinants. This treatment is analogous to the description of the multiconfiguration Hartree-Fock (MCHF) method for atoms in Sec. 5.4 but, for historical reasons, the method is usually known in the molecular literature as multiconfiguration self-consistent-field (MCSCF) theory.

The main objective of a multiconfiguration self-consistent-field calculation is usually to obtain qualitatively correct molecular wave functions that properly describe all the dissociation processes of interest and that take account of any near-degeneracy effects. Such a wave function Ψ_{MC} can be written in the form

$$\Psi_{\mathrm{MC}} = \sum_I C_I \Phi_I, \qquad (164)$$

in which the configurations Φ_I are constructed from a common set of orthonormal orbitals, which are fully optimized together with the configuration interaction or CI coefficients C_I.

The first step in selecting the configurations to be included in an MCSCF wave function is to decide which, if any, orbitals are to remain doubly occupied in all configurations. These "core" orbitals, and the electrons which occupy them, are termed "inactive." The remaining orbitals are partitioned into the "active" or "internal" orbitals, which are allowed to have different occupancies in different configurations, and the "external" or "virtual" orbitals, which are unoccupied in all configurations. During the calculation, internal and external orbitals are mixed with one another, by means of orthogonal rotations, until the optimum internal orbitals are obtained. It is also possible, by means of additional orbital rotations, to allow the doubly occupied core orbitals to relax, in a self-consistent fashion, in the optimized field defined by the active electrons.

A common choice for the internal orbitals is the set of valence orbitals. In the case of LiH, for example, the 1σ orbital corresponds to $\mathrm{Li}(1s^2)$, and it is treated as a core orbital. The valence orbitals in this case arise from $1s$ on hydrogen and from $2s$ and $2p$ on lithium. These give rise to the valence 2σ, 3σ, and 1π orbitals, of which only the 2σ orbital is occupied in the SCF description of the ${}^1\Sigma^+$ ground state. It is more usual to include *all* configurations of the correct spin multiplicity and spatial symmetry that can be generated by distributing the two active electrons among the internal orbitals, rather than to attempt to select just those configurations that are essential for correct dissociation. MCSCF wave functions in which the list of configurations consists of all allowed distributions of the active electrons in the internal orbitals are known as complete active-space self-consistent-field or CASSCF wave functions. The CASSCF wave function for our LiH example would therefore include configurations $1\sigma^2 2\sigma^2$, $1\sigma^2 3\sigma^2$, $1\sigma^2 2\sigma 3\sigma$, and $1\sigma^2 1\pi^2$. Such CASSCF calculations are typically more straightforward and computationally less expensive than smaller MCSCF calculations based on the same active space. This occurs, in part, because the CASSCF wave function is invariant to arbitrary unitary transformations of the internal orbitals.

The energy corresponding to an MCSCF wave function can be written in the form

$$E = \sum_{t,u} \gamma_{tu} h_{tu} + \sum_{t,u,v,w} \Gamma_{tuvw} (tu|vw), \qquad (165)$$

where γ and Γ are known as one- and two-electron density matrices, respectively. h_{tu} are one-electron integrals in the MO basis, and $(tu|vw)$ are the corresponding two-electron integrals defined by Eq. (159). The density matrices are composed of orbital coefficients c_{ip}, configuration-interaction coefficients C_I, and various coupling constants. Much effort has been expended to develop highly efficient algorithms that allow the construction of the density matrices without the need to precompute and store extensive lists of intermediate quantities, and to minimize both the number of iterations and the number of times that the integrals must be transformed to the MO basis.

The MCSCF method was initially developed as a natural extension of the Hartree-Fock method and was used to describe dissociation processes correctly and to take some account of electron correlation. A comparison of the LiH $X\,{}^1\Sigma^+$ RHF energy (at R_e) of $-7.987\,313$ hartrees with the corresponding energy of $-8.021\,321$ hartrees from a small, 15-configuration MCSCF calculation demonstrates an improvement of almost 1 eV. Whereas dissociation energies for LiH obtained using single-configuration wave functions were totally unreliable, often being in error by several electron volts, this small MCSCF calculation leads to a value of 2.41 eV, to be compared with an experimental value of 2.52 eV (Stwalley and Zemke, 1992). Nowadays, an MCSCF calculation is usually used as the first step in a more sophisticated configuration-interaction (CI) calculation (cf. Secs. 5.3 and 8.2): the MCSCF step is used to obtain a multiconfiguration zeroth-order wave function based on an appropriate set of valence orbitals. Molecular MCSCF or, more often, CASSCF calculations with 10^2–10^4 configurations are now essentially routine, and calculations with much longer lists of configurations are not uncommon. Many of the standard quantum chemistry computational packages now include the facility to carry out such calculations.

8.2 Configuration Interaction

A configuration-interaction (CI) wave function Ψ_{CI} consists of a linear combination of configurations Φ_I constructed from a common *fixed* set of orthonormal orbitals:

$$\Psi_{\mathrm{CI}}=\sum_I C_I\Phi_I\,. \tag{166}$$

Superficially, at least, this type of wave function looks very similar to an MCSCF expansion, but the main purposes of the two types of calculation and the classes of configurations that are usually included are somewhat different.

The correlation energy taken into account by an MCSCF wave function, so as to produce qualitatively correct features, is often referred to as "nondynamical" correlation. In general, an MCSCF calculation recovers much less than one half of the total correlation energy. The purpose of a CI calculation is to recover a large proportion of the remaining correlation, termed "dynamical" correlation, and to obtain quantitatively accurate results. It should be stressed that there is no sharp dividing line between nondynamical and dynamical correlation, although the (approximate) distinction between them remains useful.

The simplest strategy for a closed-shell molecule is to start from the single-configuration SCF wave function Φ_0, and to partition the occupied orbitals into core and internal sets, in much the same way as in the MCSCF case. The usual form of CI calculation for such a system then includes all configurations of the correct spin multiplicity and spatial symmetry that can be generated by single and double replacements of the internal orbitals in Φ_0 by the external orbitals, i.e., those that are not occupied in Φ_0. Such a calculation is typically called a "singles and doubles" CI, or SDCI, and is further labeled "single reference," because all of the excitations stem from a single configuration. The term multireference CI, or MRCI, usually denotes a configuration-interaction expression that includes all single and double excitations from more than one reference configuration, such as the configurations obtained in an MCSCF calculation. It can be particularly important for Φ_0 to be a multireference function if several points on a potential-energy surface are to be studied. In general, the number of external orbitals is very much larger than the number of internal orbitals, and so the largest class of configurations consists of those that have two electrons in external orbitals. The total number of molecular orbitals and consequently the size of a CI calculation are determined by the total number of atomic basis functions.

Whereas the MCSCF energy expression is fourth order in the orbitals, the CI problem is a linear eigenvalue problem, in that only the CI coefficients C_I are determined. The eigenvalue problem to be solved takes the form

$$(\mathbf{H}-E\mathbf{1})\mathbf{C}=\mathbf{0}, \tag{167}$$

in which $\mathbf{C}$ is a vector of the CI coefficients and $\mathbf{H}$ is the matrix of the Hamiltonian operator, with elements $\langle\Phi_I|H|\Phi_J\rangle$. The different roots of this secular problem correspond to the different electronic states. The computational effort typically scales approximately linearly with the number of roots extracted from the CI calculation. The expression for the CI energy in terms of density matrices and one- and two-electron integrals takes exactly the same form as in the MCSCF case. A typical CI calculation involves 10^4–10^6 configurations, although larger calculations are now possible, and so explicit construction and diagonalization of $\mathbf{H}$ are not a practical proposition. Instead, an iterative strategy is usually adopted.

It is usual to exploit the fact that different molecular symmetries do not couple through the Hamiltonian operator H to construct different wave functions and to solve different secular problems for each symmetry. Provided the wave function has been properly constructed from an appropriate set of orbitals, it is relatively straightforward to obtain the lowest root of each symmetry with the same accuracy as the ground state. If excited states of a given symmetry are required, successively higher roots can be extracted from the secular equation. It is important, however, to make sure that orbitals have been included that are appropriate to the *occupied* orbitals of the excited state(s) and that all necessary reference configurations are present in Φ_0. It is often difficult to describe with equal accuracy states of very different character; this can be a particular problem for molecular Rydberg states, and particular care is required in order to treat Rydberg and valence states on an equal footing. These remarks can be illustrated by looking again at the LiH molecule (Stwalley and Zemke, 1992), which in its first excited state ($A\ ^1\Sigma^+$) has the RHF configuration $1\sigma^2 2\sigma 3\sigma$. If wave functions are required for both of the $X\ ^1\Sigma^+$ and $A\ ^1\Sigma^+$ states, then it is important to make sure that the 3σ orbital takes the form of an occupied orbital of the $A\ ^1\Sigma^+$ state rather than the form of a correlating orbital for the ground state. If the $B\ ^1\Pi$ state of LiH ($1\sigma^2 2\sigma 1\pi$) were also required, then it would be much more appropriate to construct Φ_0 from orbitals obtained via an MCSCF calculation on the $B\ ^1\Pi$ state instead of the analogous calculation on the ground state. In this way, the valence 1π orbital would be much better determined. The dissociation energy of the $X\ ^1\Sigma^+$ state of LiH from a large CI calculation is 2.48 eV, which is within 0.04 eV of the experimental value and which shows an improvement of 0.07 eV over the 15-configuration MCSCF value.

A full CI, or FCI, calculation is one in which all possible replacements of internal orbitals by external orbitals are included in the wave function. It corresponds to the exact solution, within a given one-particle basis set, of the usual electronic structure problem. Usually such calculations are prohibitively expensive when using sufficiently large one-particle basis sets to obtain quantitative accuracy. Single and double excitations are, however, by far the most important for most purposes. Truncated CI expansions that start from a qualitatively incorrect reference space are not likely to give high-quality results, even with very large numbers of configurations. With this proviso, affordable FCI calculations generally give much poorer results than truncated CI expansions with larger basis sets.

A disadvantage of singles and doubles CI expansions is that they are not size consistent. As a simple example, consider two well-separated helium atoms. Clearly, the energy of this system should be exactly twice that of a single helium atom, and if this is the case, then the calculation is said to be size consistent. More formally, the wave function for this system should be equal to the product of the two helium-atom wave functions. In the case of an ordinary SDCI calculation, the list of configurations includes those that are double replacements of occupied orbitals on one center by virtual orbitals on the other, and so the total wave function is not the product of the wave functions of the two fragments. In a full CI calculation, these unwanted contributions to the energy and wave function are cancelled exactly by higher-order excitations. Various simple schemes have been suggested that allow estimates to be made of the size-consistency errors in truncated CI expansions, without the need to include further classes of excitations.

The interpretation of large CI wave functions is not very straightforward, unless it turns out that the wave function is overwhelmingly dominated by a small number of configurations. A practical alternative to examining long lists of CI coefficients is to generate natural orbitals. The natural orbitals for a given approximate CI calculation are obtained by diagonalizing the one-electron density matrix, γ_{tu}. The diagonal elements of the density matrix in this new basis are termed occupation numbers and typically take fractional values. The interpretation of the CI wave function then relies on examining the form of the natural orbitals and the values of the occupation numbers, which give a clear idea of the importance of a given orbital in the CI expansion, such as its effectiveness as a correlating function.

Configuration mixing is a very slowly convergent process for reproducing those terms in the exact wave function that are linear in the interelectronic coordinates r_{12}. One alternative to a conventional CI approach is the explicit inclusion into an approximate wave function of terms linear in r_{12}. The chief drawback of such a strategy is that it introduces additional classes of "difficult" integrals. However, significant process is currently being made by means of suitable approximations to these integrals.

8.3 Many-Body Perturbation Theory

The basic aim of perturbation theory is to account for the changes induced in a model system by a small disturbance or perturbation. It provides a scheme for obtaining successively more accurate refinements of a model problem. A good account of perturbation theory for molecular problems has been given by Szabo and Ostlund (1982).

When perturbation theory is used to treat electron correlation in molecular systems, it is often termed many-body perturbation theory or MBPT. In its simplest form, which is applicable to single-determinant closed-shell RHF wave functions, this approach is more commonly known as Møller-Plesset (MP) theory. The SCF energy is equal to the sum of the zeroth-order and the first-order energies. In the notation of Sec. 5.5, we have

$$\begin{aligned} E^{(0)}+E^{(1)} &= \langle\alpha|H_0|\alpha\rangle+\langle\alpha|V|\alpha\rangle \\ &= \langle\alpha|H|\alpha\rangle, \end{aligned} \tag{168}$$

where $|\alpha\rangle$ is the RHF wave function. The lowest-order perturbation correction to the energy is thus the second-order (MP2) correction, which can be written in the form

$$E^{(2)}=-\frac{1}{4}\sum_{i,j}\sum_{a,b}\frac{[(ia|jb)-(ib|ja)]^2}{(\epsilon_a+\epsilon_b)-(\epsilon_i+\epsilon_j)}. \tag{169}$$

MP2 calculations are relatively inexpensive and typically recover about 80% of the correlation energy for a molecular system near its equilibrium geometry. Whereas SCF (RHF) calculations typically underestimate the lengths of single bonds by ~0.02 Å and give harmonic frequencies to ~10%, the analogous MP2 calculations underestimate single bonds by ~0.003 Å and give harmonic frequencies to ~2%. MP2 is less reliable for multiple bonds.

Evaluation of the third-order and fourth-order Møller-Plesset energies necessarily involves significantly more computational effort. Many standard packages permit the calculation of MP2, MP3, and MP4 energies, although some of the MP4 terms are sufficiently expensive that the user may be given the option to compute only selected terms.

By analogy to single-reference SDCI, it is self-evident that the results from a Møller-Plesset calculation are unlikely to be very reliable if the final wave function is not dominated by the unperturbed wave function. Methods such as MP4 are not generally applicable to the calculation of entire potential surfaces, and they do not describe correctly the dissociation of closed-shell molecules. As mentioned above, MBPT calculations are not variational. On the other hand, MBPT has the significant advantage of size consistency (see Sec. 8.2), unlike most CI-based methods.

The Møller-Plesset approach can also be used with open-shell UHF wave functions, in which case the *n*th-order terms are denoted UMP*n*. Even small amounts of spin contamination can lead to very serious convergence problems. A partial solution to this problem is to project out pure spin states at each order of perturbation theory, but many of the standard packages do not offer this feature. It is not common for terms beyond fourth order to be included in MBPT calculations on molecular systems, and so hard evidence on the convergence properties of the perturbation series is scarce. Progress for Møller-Plesset theory based on open-shell RHF wave functions or for multireference MBPT has been fairly slow for molecular calculations.

8.4 Coupled-Cluster Methods

A family of methods that is currently gaining in popularity and that has undergone extensive recent development consists of the coupled-cluster approaches. Part of the motivation, as in the case of MBPT, is that coupled-cluster wave functions are usually size consistent. However, coupled-cluster calculations do not generally offer a variational upper bound to the energy. There has been a large number of variations on the basic theme of coupled-cluster theory, and the present account is necessarily restricted to a brief outline of the simplest version.

For a closed-shell RHF configuration Φ, the coupled-cluster wave function Ψ_{CC} is defined by

$$\Psi_{\mathrm{CC}}=\exp(T)\Phi, \tag{170}$$

in which T is an excitation operator, which generates single, double, triple, etc., replacements of occupied orbitals in Φ by virtual orbitals. The exponential is defined in the usual way, i.e., by a power series expansion:

$$\exp(T)=1+T+\tfrac{1}{2}T^2+\cdots. \tag{171}$$

In coupled-cluster singles and doubles (CCSD) calculations, T is restricted to the sum of single- (T_1) and double- (T_2) excitation operators, so that terms up to quadruple excitations are included in the wave function, via $\tfrac{1}{2}T_2^2$. The corresponding energy is given by

$$E=\langle\Phi|H|(1+T_2+\tfrac{1}{2}T_1^2)\Phi\rangle, \tag{172}$$

with analogous equations to determine the CCSD wave function.

Coupled-cluster calculations such as CCSD, which start from a single determinant Φ, are not suitable for calculations of entire potential surfaces—cf. SDCI or MP*n* methods (where *n* indicates the order of perturbation theory)—but they do yield excellent equilibrium properties for systems that are reasonably well described by a single-configuration closed-shell RHF wave function. It is also possible to carry out coupled-cluster calculations starting from UHF wave functions, but this raises again the problem of spin contamination. Calculations based on open-shell RHF wave functions have been reported in the literature.

There are obvious links between the coupled-cluster and MBPT methods, but progress in developing multireference methods for the coupled-cluster approach appears to be much more promising.

8.5 Modern Valence-Bond Theory

Actual *ab initio* implementations of classical valence-bond theory are somewhat disappointing. The same is true of calculations in which molecular-orbital theory SCF wave functions are projected onto classical VB structures. In order just to match the SCF energy in a given basis set, it turns out that it is usually necessary to include large numbers of structures, particularly those of ionic character, with separation of charges. All in all, the original simple intuitive model is clouded by the requirement for multistructure wave functions.

Recent years have seen a significant resurgence of interest in methods for the optimization of nonorthogonal orbitals to be used in compact and accurate VB descriptions of potential-energy surfaces of ground and excited states. Two of the key problems of classical VB theory have been largely overcome, namely, the proliferation of ionic contributions, even in intuitively covalent systems, and the difficulty of performing calculations with nonorthogonal orbitals. Sophisticated techniques from group theory lead to efficient algorithms, but the preferred method now appears to be the expansion of the wave function in terms of Slater determinants and the evaluation of matrix elements using cofactors.

The *exact* solution Ψ_{ex} of the usual electronic structure problem for an N-electron system can be written in the form

$$\Psi_{\mathrm{ex}} = \sum_k c_{Sk} (N!)^{-1/2} \mathscr{A}(\Phi \Theta^N_{SM;k}), \tag{173}$$

in which Φ is an exact N-electron spatial function (with no particular permutational symmetry) and $\mathscr{A}$ is the antisymmetrizing operator, which ensures that the simultaneous interchange of the space and spin coordinates of two electrons induces a change in the sign of the wave function (Pauli principle). Each of the allowed ways of coupling together the individual electrons spins so as to achieve a total spin of S (and projection M) is labeled by the index k, and the $\Theta^N_{SM;k}$ form a complete set of N-electron spin functions. The c_{Sk} reflect the relative importance of the different modes of spin coupling and may be termed spin-coupling coefficients.

The spin-coupled wave function corresponds to approximating the spatial function Φ by a single configuration constructed from distinct, singly occupied nonorthogonal orbitals. The spin-coupled wavefunction Φ_{SC} can be written in the form

$$\Psi_{\mathrm{SC}} = \sum_k c_{Sk} (N!)^{-1/2} \mathscr{A}(\varphi_1 \varphi_2 \cdots \varphi_N \Theta^N_{SM;k}).$$

The orbitals are expanded in a one-particle atom-centered basis set, as in MO theory, and are fully optimized simultaneously with the spin-coupling coefficients. The spin-coupled wave function is an eigenfunction of S^2 and S_z, and so questions of spin contamination never arise. The spin-coupled description accounts for most of the available nondynamical correlation and remains qualitatively correct over the entire potential-energy surface, including the various dissociation pathways. The spin-coupling coefficients are particularly sensitive indicators of the changes occurring in the total wave function as bonds are made and broken.

In many cases, the descriptions that emerge show marked similarities to those postulated by classical VB theory, except for small distortions of the orbitals. These deformations, which correspond to the use of basis functions from more than one center, are crucial to the description and have the important consequence that just one spatial configuration overwhelmingly dominates the total wave function, without the need to include configurations with double occupancy of orbitals (ionic structures), as in classical VB theory. The spin-coupled description is invariably "simpler" and much more compact than the classical VB wave function, and in some cases leads to somewhat different interpretations of the electronic structure of polyatomic systems.

A widely used alternative to the spin-coupled wave function, known as the generalized valence-bond (GVB) wave function, is usually computed with various orthogonality constraints between pairs of singlet-coupled electrons so as to reduce the computational effort.

The spin-coupled orbitals in Ψ_{SC} can be partitioned into "core" and "active" sets, in much the same way as in MCSCF calculations, and for polyatomic systems it is usual to identify the active space with the valence electrons. The closest equivalent MO-theory wave function is a CASSCF wave function with all configurations generated by distributing N electrons in N orbitals. Because it is based on a single spatial configuration, the interpretation of the spin-coupled wave function in terms of the relevant physics and chemistry remains very straightforward.

This single-configuration description can be refined by means of a nonorthogonal CI calculation, known as a spin-coupled VB or SCVB calculation, but this inclusion of dynamical correlation does not appear to affect the essential physical picture provided by the spin-coupled wave function. The virtual orbitals, into which the electrons in occupied orbitals are excited, are constructed in such a way that they provide accurate descriptions of excited states. Consequently, the SCVB wave functions for the excited states are dominated by a very small number of spatial configurations and are easy to interpret. It is usual to include single and double excitations from the occupied orbitals of the spin-coupled description of the ground state into the first few virtual orbitals and possibly also equivalent excitations from the dominant configurations for the low-lying excited states. A typical SCVB calculation providing accurate and compact descriptions of, perhaps, 20 states of each symmetry of a polyatomic species consists of 10^2–10^3 spatial configurations. SCVB calculations are variational and are well suited to the description of entire potential surfaces, but they are not usually size consistent. However, the essentially localized character of the occupied and virtual orbitals makes it straightforward in many cases to restrict the classes of excitations so as to minimize the size-consistency error.

As a simple example of the utility of SCVB calculations we consider the simple singlet methylene insertion reaction (Cooper *et al.*, 1991)

$$CH_2(^1A_1)+H_2 \rightarrow CH_4, \tag{174}$$

which involves the complex process of forming two new C–H bonds while breaking the strong bond in molecular hydrogen. Note that CH_2 belongs to the same point group, C_{2v}, as does H_2O (see Sec. 7.5). According to simple arguments based on the orbital symmetries in the RHF wave functions for the reactants, the direct approach of H_2 to $CH_2(^1A_1)$ should be very unfavorable. This is because the nonbonding pair of electrons on carbon occupies an sp^2-like hybrid orbital, pointing along the z axis away from the H atoms; the interaction of this orbital with the doubly occupied $1\sigma_g$ orbital of H_2 is energetically unfavorable. Nonetheless, this insertion reaction is known experimentally to proceed rapidly with little or no activation barrier. The six spin-coupled orbitals for the six valence electrons of $CH_2(^1A_1)$ are depicted in Fig. 27, and it is easy to discern that orbitals φ_1–φ_4 describe two equivalent C–H bonds. The two remaining orbitals, φ_5 and φ_6, take the form of nonbonding sp^x-like hybrids ($x \approx 3$) on carbon, pointing like rabbit ears in the plane perpendicular to the molecular plane. In view of this orbital description, it is easy to envisage that the initial approach of H_2 to $CH_2(^1A_1)$ could be with its bond axis pointing along the direction of one of the nonbonding hybrids. As the molecules came together, the H atom furthest from the CH_2 would then swing around towards the second nonbonding hybrid. Detailed SCVB calculations confirm that this reaction can occur along this path with *zero* barrier.

8.6 Density-Functional Theory

The term "density-functional theory" is currently used to denote a whole family of methods in which the electronic energy is computed from functional forms involving the electron density $\rho(\mathbf{r})$. Indeed, according to the Hohenberg-Kohn theorem, the ground-state energy of a nondegenerate many-electron system is a unique functional of the electron

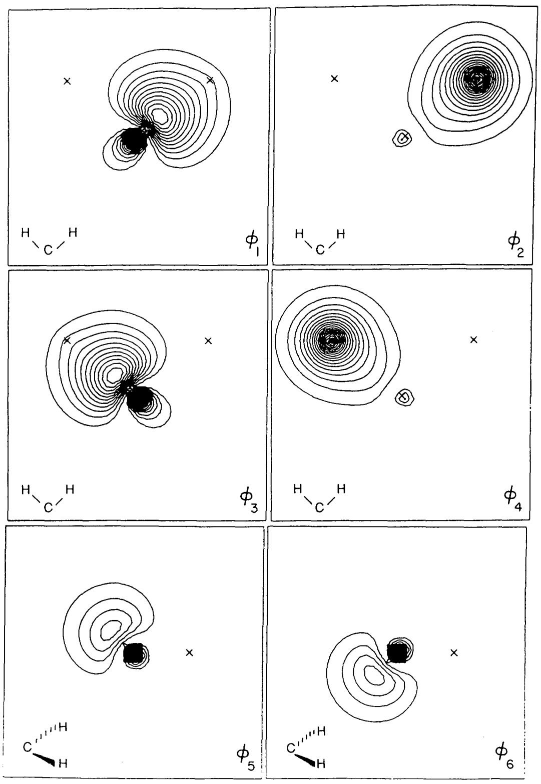

FIG. 27. Spin-coupled orbitals in CH_2 ($^1A_1$) shown as contours of $|\varphi_\mu|^2$. Spin-coupled orbitals φ_1–φ_4 are shown in the σ_v' (molecular) plane, but orbitals φ_5 and φ_6 are shown in the σ_v plane.

density. This theorem is a strong driving force behind density-functional theory but does not in itself provide a tractable computational procedure.

The most widely used practical schemes are based on the Kohn-Sham equations. A basic idea of this approach is that the exact many-electron wave function is mapped onto that of a model system of *noninteracting* electrons that has the same total electron density. In essence, the exact kinetic energy is replaced by the kinetic energy of the same number of noninteracting electrons in the lowest possible state. The electron density of this model system is constrained to be the same as that of the true system by means of an external electric field.

The total energy in the Kohn-Sham approach is written as the sum of the noninteracting kinetic energy, the electron–nuclear attraction, the "classical" electron–electron Coulomb repulsion, and a term E_{xc} that contains everything else. $E_{xc}[\rho(\mathbf{r})]$ includes the exchange and correlation energies (of the interacting system) as well as the difference in kinetic energy between the noninteracting and interacting systems. Explicitly, the Kohn-Sham equation for orbital ψ_i takes the form

$$\left(-(\tfrac{1}{2})\nabla^2+v(\mathbf{r})+\int\frac{\rho(\mathbf{r}')d^3r'}{|\mathbf{r}-\mathbf{r}'|}+v_{xc}(\rho(\mathbf{r}))\right)\psi_i =\epsilon_i\psi_i\,, \tag{175}$$

in which the first three terms correspond to the kinetic energy, the electron–nuclear attraction, and the electron–electron Coulomb repulsion, and the fourth is defined by

$$v_{xc}(\rho(\mathbf{r}))=\frac{\delta E_{xc}[\rho(\mathbf{r})]}{\delta\rho(\mathbf{r})}\,. \tag{176}$$

Various approximate exchange–correlation potentials v_{xc} have been proposed.

Provided a suitable v_{xc} has been chosen, iterative solution of the self-consistent-field Kohn-Sham equations to determine the orbitals, electron density, and total energy is relatively straightforward using either basis-set expansions or numerical methods. Approaches based on density-functional theory can provide accurate total electronic energies for molecules around the equilibrium geometry. Taken together with accurate atomic energies, these methods provide accurate dissociation energies. Density-functional theory is of particular value for molecules containing transition-metal atoms, for which it often provides results superior to those from CASSCF-CI approaches. The most efficient and accurate density-functional methods include nonlocal corrections to the exchange and correlation energies.

9. MOLECULAR PROPERTIES

9.1 Geometries and Gradients

The most obvious molecular properties to be determined are the location and character of minima on a potential-energy surface and of other stationary points, such as transition states. Significant advances have been made in recent years in the development of gradient techniques, so that the location of stationary points is now a routine task for many types of wave functions. In the present context, the term "gradient" is used to denote analytic derivatives of the total energy with respect to geometric parameters, such as bond lengths and angles.

A nuclear displacement can modify the energy of a CI wave function, for example, in three distinct ways: changes to the basis functions, because the centers on which these are located have been moved; changes to the MOs; and changes to the CI coefficients. The changes to the basis functions lead to terms in the gradient that involve two-electron integrals of the derivatives of the basis functions. The first and higher derivatives of a Gaussian-type orbital take the form of linear combinations of further GTOs, and so the integrals of basis-function derivatives are very straightforward. The same is not true of Slater-type orbitals, and this reinforces the preeminent role of GTOs in molecular calculations.

First derivatives are now available for most commonly encountered types of wave functions. Second derivatives are available in some cases, such as SCF, MP2, and CASSCF. These are useful not only for geometry optimization and the location of transition states, but also for the calculation of harmonic frequencies. Indeed, in the case of SCF wave functions, third and fourth derivatives can be calculated, making possible the calculation of anharmonic constants.

It is common, particularly for diatomic molecules, to use the calculated potential-energy curves (or surfaces) to solve the nuclear motion problem. This provides details of the vibrational and rotational energy levels of the molecular system. The wave functions $\chi_{\mathrm{nuc}}(\mathbf{R})$ and the corresponding energies can be used to generate a variety of spectroscopic constants. Comparisons of these with the equivalent experimentally derived quantities give useful information regarding the accuracy of the potential curves or surfaces. In many cases it is possible to provide reliable numerical values for constants that are very difficult to measure experimentally.

9.2 Energy Differences

Many of the quantities of interest that characterize a molecular electronic state or a manifold of states are derived from energy differences. For example, the dissociation energy D_e of a diatomic molecule is defined as the difference between the minimum energy at the equilibrium internuclear distance R_e and the energy of the component atoms at infinite separation. The excitation energy T_e of an excited molecular state is the difference between the excited-state energy and the ground-state energy, each evaluated at the respective equilibrium geometry. Other important quantities include the heights of barriers on a potential surface, as well as ionization potentials and electron affinities.

Because physical quantities are often related to energy differences, there tends to be greater emphasis in molecular calculations on obtaining potential curves or surfaces that closely parallel the exact solution, rather than attempting to generate the best possible energy at a particular geometry. However, even if the error made in an energy calculation varies as little as 0.01% as a function of nuclear coordinates or from one electronic state to another, then the errors in the corresponding energy differences can be substantial. In practice it is fairly difficult to minimize this error, but the most extensive calculations do provide estimates of important quantities that rival experimental measurements. Such calculations are of particular importance when the necessary experiments are very difficult. Electronic-structure studies are also crucial for trying to understand the magnitude of a quantity, and the way in which it varies with geometry or from state to state or from system to system.

In general, the correlation energy increases with the number of electrons in a system, but any given approximate method is likely to recover approximately the same *proportion* of the correlation energy for different systems. Difficulties arise then in the calculation of ionization potentials and electron affinities obtained as energy differences between N-electron and $(N-1)$-electron or $(N+1)$-electron systems. In addition, the correlation energy of a pair of electrons in the same spatial orbital is usually considerably greater than that of electrons in different spatial orbitals. This observation is of particular relevance to the calculation of dissociation energies, since there are usually more electron pairs in the electronic configuration of a molecule at its equilibrium geometry than there are in the constituent fragments at infinite separation. Consequently, a greater correlation error is likely in an approximate calculation at R_e

than at $R=\infty$, and so the calculated value of D_e will be too small.

Errors associated with excitation energies also usually reflect different degrees of electron pairing in different states. For example, the calculated value of T_e for the first excited state of LiH ($1\sigma^2 2\sigma 3\sigma$) is likely to be small simply because the calculated energy of the ground state ($1\sigma^2 2\sigma^2$) is subject to a larger correlation error. Assuming that the calculated dissociation energies of the two states are fairly accurate, then reliable estimates of excitation energies, ionization potentials, or electron affinities can be obtained by simple energy differences involving these dissociation energies and the experimentally determined asymptotic separations.

An additional problem, known as basis-set superposition error or BSSE, arises in studies of very weakly interacting systems and of intermolecular forces. The fundamental issue is that the individual basis sets used to describe the fragments A and B are necessarily incomplete, and so the quality of the merged basis set of the AB system, or supermolecule, will be geometry dependent. Even if there were no interaction between the two fragments, the wave function of the A fragment could in principle make some use of basis functions centered on the B fragment, thus artificially lowering the total energy of the supermolecule. Clearly, the amount of BSSE is likely to be larger for smaller separations between the two fragments. The BSSE can be minimized through the use of very extensive basis sets, but this has the potential drawback of introducing problems of linear dependence for smaller separations at which basis functions on different centers may have very large overlaps.

For very weakly bound systems, the BSSE can swamp the true interaction energy. For more strongly bound systems, BSSE is still present but it is a relatively minor source of error. An approximate correction for BSSE is provided by practical schemes collectively known as function-counterpoise or ghost-orbital methods. The basic idea is to use the same basis set for the supermolecule and for the fragments. In essence, calculations are performed (for a given geometry) for the separate A and B fragments using the *full* basis set, and these energies are subtracted from that of the AB supermolecule, i.e.,

interaction energy

$$=E_{AB}(\mathbf{R})-E_A(\mathbf{R})-E_B(\mathbf{R}), \tag{177}$$

where all the calculations use the same supermolecule basis set.

9.3 Matrix Elements and Response Functions

Molecular electronic-structure methods that produce not only an energy but also a wave function are of particular value when molecular properties are required. A number of molecular properties can be expressed as expectation values of one-electron operators: e.g., electric multipole moments, spin hyperfine constants, and field gradients at the nuclei.

The molecular property most extensively calculated is the electric dipole moment function $\mu(\mathbf{R})$, which can be expressed as

$$\mu(\mathbf{R})=\left\langle\Psi_{\mathrm{el}}(\mathbf{r}|\mathbf{R})\right|\left(-\sum_i e\mathbf{r}_i+\sum_A Z_A e\mathbf{R}_A\right) \times\left|\Psi_{\mathrm{el}}(\mathbf{r}|\mathbf{R})\right\rangle. \tag{178}$$

Because the electronic wave functions depend parametrically on the nuclear coordinates $\mathbf{R}$, the expectation value of the electric dipole operator is a function of $\mathbf{R}$. The electric dipole moment governs the absorption and emission of photons for vibration–rotation transitions within an electronic state. When $\mu(\mathbf{R})$ is identically zero, as in the case of centrosymmetric molecules such as O_2 or N_2, radiation can be emitted or absorbed only if matrix elements of higher-order moments (such as quadrupole moments) are nonzero.

In order to calculate an electric dipole moment that can be compared to an experimentally determined value for, say, a diatomic molecule, $\mu(R)$ must be obtained over a range of R values and then averaged over the nuclear wave functions:

$$\mu_{vJ}=\int \chi_{vJ}^*(R)\mu(R)\chi_{vJ}(R)dR. \tag{179}$$

Dipole moments calculated using the Hartree-Fock SCF approximation are usually in error by $(0.04\text{–}0.02)ea_0$ for closed-shell systems $[(0.2\text{–}0.4)ea_0$ for open-shell systems$]$. Using CI methods, the errors can be reduced by more than an order of magnitude. Although single-excitation terms in a CI wave function do little to improve the energy, these terms are very important for accurate calculations of the dipole-moment function.

The matrix element governing transitions from one electronic state (i) to another (f) by absorption or emission of radiation is the electric-dipole transition moment:

$$D_{if}(\mathbf{R})=\left\langle \Psi_i(\mathbf{r}|\mathbf{R})\left|\left(-\sum_i e\mathbf{r}_i\right)\right|\Psi_f(\mathbf{r}|\mathbf{R})\right\rangle . \tag{180}$$

There are no contributions from terms involving a summation over the nuclei simply because Ψ_i and Ψ_f are orthogonal. Of course, the wave functions of states i and f must be available at the same set of nuclear coordinates. In CI calculations, the computations are greatly simplified if the two wave functions are constructed from a common set of molecular orbitals. The electric-dipole transition-moment operator is a one-electron operator, and so states that differ in orbital occupation by one electron generally have the largest matrix elements.

If wave functions of the nuclear motion are available, as in the case of diatomic molecules, then $D_{if}(\mathbf{R})$ can be used to obtain the line strengths or band oscillator strengths. Electronic-structure calculations are also very important for determining lifetimes of excited states and branching ratios.

Not all molecular properties of interest are obtained as expectation values of operators. The polarizability, for instance, can be thought of either as being related to the second derivative of the energy with respect to an applied external electric field or as the change induced in the dipole moment by such a field. Properties such as the polarizability are often termed response functions because they characterize the response of a molecular system to an external perturbation. Particular care is required in the choice of sufficiently flexible basis sets for calculations of electric and magnetic response functions. The development of gradient techniques (see Sec. 9.1) has been particularly important for the efficient calculation of such quantities.

Much progress is currently being made in the development of molecular electron-correlation methods that take proper account of relativistic effects. For systems containing heavy atoms, such as second-row transition metals, such effects are crucial to achieve spectroscopic accuracy. One important consequence of relativistic effects, which appears even in molecules containing only light atoms, is the occurrence of spin-dependent terms such as spin-orbit coupling. Rather than carry out fully relativistic calculations, it is usual to include spin-orbit coupling effects as a perturbation to nonrelativistic states. The dominant contribution to fine-structure intervals in molecules arises from the Breit-Pauli Hamiltonian

$$\begin{aligned} H_{\mathrm{SO}}=&(\alpha^2/2)\sum_{i,A}(Z_A/r_{Ai}^3)(\mathbf{r}_{Ai}\times\mathbf{p}_i)\cdot\mathbf{s}_i\\ &-(\alpha^2/2)\sum_{i,j}(1/r_{ij}^3)(\mathbf{r}_{ij}\times\mathbf{p}_i)\cdot(\mathbf{s}_i+2\mathbf{s}_j), \end{aligned} \tag{181}$$

in which α is the fine-structure constant, and $\mathbf{p}$ and $\mathbf{s}$ are linear momentum and spin angular momentum operators. This Hamiltonian corresponds to an approximation valid to order α^4mc^2 (i.e., α^2 in atomic units), but it is straightforward in molecular calculations also to include the term of order $(\alpha/\pi)\alpha^4mc^2$ that arises from anomalous magnetic moment effects. Using this Hamiltonian it is possible to calculate accurate molecular spin-orbit coupling constants and to study spectroscopic perturbations such as singlet–triplet mixing, Λ doubling, and spin-splitting constants. The lowest-order contributions that are neglected in the Breit-Pauli approximation are of order α^6mc^2. These additional terms cannot easily be included as a perturbation to nonrelativistic states, but they are already fairly significant for atoms beyond halfway across the second row of the periodic table. This is clearly an area in which fully relativistic calculations are potentially very important.

Finally, we consider briefly a breakdown of the Born-Oppenheimer approximation in which terms involving changes of the electronic wave function with nuclear coordinates cannot be neglected. At particular nuclear geometries, two potential curves or surfaces of the same symmetry may interact strongly and may exhibit an "avoided crossing" (see Fig. 28) in which they appear to exchange character with one another. As indicated in Sec. 7.1, the factorization of Ψ_{tot} into a *single* product of an electronic wave

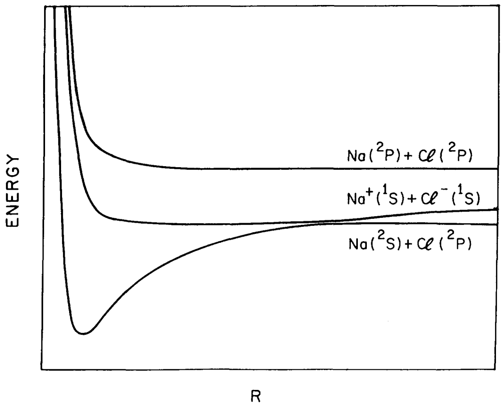

FIG. 28. Adiabatic potential-energy curves for the three lowest $^1\Sigma^+$ states of NaCl, illustrating an avoided crossing.

function and a nuclear motion wave function is dependent on potential-energy surfaces being well separated. This is clearly not the case in curve-crossing problems. In the case of diatomic systems, for example, this has the consequence that matrix elements such as $\langle\Psi_i(\mathbf{r}|R)|\partial/\partial R|\Psi_f(\mathbf{r}|R)\rangle$, arising from the nuclear kinetic energy operator, may be nonnegligible. The strong coupling of molecular states through $\partial/\partial R$ and related terms manifests itself experimentally through significant spectroscopic perturbations, leading to energy shifts, line broadening, and diffuseness of spectral lines. Such matrix elements also govern scattering processes such as charge transfer, in which an electron is transferred from one atomic center to another, e.g.,

$$O^{2+}+H\rightarrow O^{+}+H^{+}. \tag{182}$$

Matrix elements of $\partial/\partial R$ are usually calculated by numerical differentiation, although gradient techniques are to be preferred.

ACKNOWLEDGMENT

List of Abbreviations

BSSE: Basis-set superposition error.
CASSCF: Complete active-space self-consistent field.
CCSD: Coupled-cluster singles and doubles.
CI: Configuration interaction.
DZP: Double-ζ plus polarization.
FCI: Full configuration interaction.
GTO: Gaussian-type orbital.
GVB: Generalized valence bond.
HOMO: Highest occupied molecular orbital.
LCAO: Linear combination of atomic orbitals.
LUMO: Lowest unoccupied molecular orbital.
MBPT: Many-body perturbation theory.
MCSCF: Multiconfiguration self-consistent field.
MO: Molecular orbital.
MP*n*: Møller-Plesset to order *n* (starting from RHF).
MRCI: Multireference configuration interaction.
RHF: Restricted Hartree-Fock.
ROHF: Open-shell restricted Hartree-Fock.
SCF: Self-consistent field.
SCVB: Spin-coupled valence bond.
SDCI: Singles and doubles configuration interaction.
STO: Slater-type orbital.
TZVP: Triple-ζ valence plus polarization.
UHF: Unrestricted Hartree-Fock.
UMPn: Møller-Plesset to order *n* (starting from UHF).
VB: Valence bond.
VSEPR: Valence-shell electron pair repulsion.

INTRODUCTION

There are at least two (rather different) reasons why the electronic structure near the surface of a solid should differ from that of the underlying bulk. The first of these is entirely fundamental: a surface represents a special kind of defect in the ideal three-dimensional periodicity which characterizes a crystalline solid, and, in common with the situation for other defects, localized electronic states can occur (see ELECTRON STATES, LOCALIZED). This would be true even if the solid were ideally terminated (i.e., if all the atomic locations in the solid were unchanged by the presence of the surface), although, in general, the presence of the surface leads to a geometrical relaxation or reconstruction of the outermost atomic layers which can also modify the surface electronic structure. Of course, these geometrical and electronic structure changes are inexorably interlinked in that the stable geometrical structure is dictated by the minimization of the electronic energy. A second source of surface electronic structure is associated with compositional differences between the surface and the underlying bulk. In the case of nonelemental solids (compounds or alloys), these compositional changes may be associated with reestablishing thermodynamic equilibrium between the surface and the bulk, but another important area of interest concerns compositional differences associated with adsorbed species from the surrounding gas phase. These adsorbate-induced changes are of considerable interest because they are intimately related to the chemical reactivity of the surface, a feature which is highly relevant not only to heterogeneous catalysis and surface corrosion and passivation, but also to the nature of semiconductor interface formation and the resulting electronic properties of a fabricated device.

In discussing our present state of understanding of surface electronic structure it is necessary to have also some appreciation of the experimental methods of investigating this structure, and to understand what is actually measured. An exhaustive treatment of this topic is beyond the scope of this article and, in particular, we do not address in detail the problems associated with the fact that, as in all spectroscopies, the electronic structure cannot be investigated directly in the ground state; real measurements actually probe both the ground and some excited states in a technique-specific fashion. This article does, however, incorporate a presentation of some of the more important investigative techniques with an emphasis on their underlying physical

principles. These techniques are introduced as necessary to appreciate the examples of the results of experiments which support various aspects of our current understanding of surface electronic structure.

By far the most important and generally applicable experimental methods are those based on photoemission and inverse photoemission, and these techniques are described in Sec. 1. This is followed in Sec. 2 by a presentation of various aspects of the electronic structure of clean surfaces, beginning with the basic theory of surface states, particularly on metal surfaces. One of the most interesting aspects of another experimental technique, scanning tunneling microscopy, is described in the particular context of semiconductor "dangling bond" surface states. Section 2 concludes with a brief discussion of two other aspects of the electronic structure of clean surfaces, namely, their tendency in many cases to undergo reconstruction and their magnetic properties. In Sec. 3 we then discuss the electronic structure associated with adsorbed species at surfaces with particular regard to the information to be gained from electronic spectroscopy of molecular adsorbates, the nature of two-dimensional band structures formed mainly by atomic adsorbates, and the information to be gained from core-level photoemission studies.

1. PHOTOEMISSION AND INVERSE PHOTOEMISSION

The basic idea of photoemission is dictated by the demands of energy conservation as stated by Einstein in 1905, who explained the photoelectric effect by considering that the process involved a single photon giving up all its energy $h\nu$ to a bound electron in a solid. Thus, if the electron has an associated binding energy E_B, then the electron can escape with a kinetic energy given by

$$E_{\text{kin}} = h\nu - E_B. \qquad (1)$$

Evidently, if the kinetic energy of the emitted electron is measured and the photon energy is known, we have a means of determining the electronic binding energy. This process is illustrated schematically in the PES (photoelectron spectroscopy) panel of Fig. 1. Peaks in the photoelectron energy spectrum correspond directly to occupied bound states, although the actual experimental spectrum also has a rising background due to the effects of inelastic scattering. Notice that if we refer the binding and kinetic energies of Eq. (1) to the Fermi level of the solid, as is usual, there is a threshold kinetic energy needed (equal to the work function ϕ —the difference between the Fermi and vacuum levels) before photoemission can be observed in the vacuum. Typically, photoemission studies of surfaces in the laboratory use fixed photon energies in the vacuum ultraviolet (usually 21.2- or 40.8-eV lines from a He discharge) or in the soft x-ray energy range (1253.6 or 1486.6 eV from Mg or Al $K\alpha$ sources), leading to the techniques of ultraviolet and x-ray photoelectron spectroscopy (UPS and XPS). Clearly the lower energies used in UPS only give access to valence electronic states, while XPS is more extensively used for the study of core-level photoemission. Increasing use is now made of synchrotron radiation, however, which allows the use of continually variable energies throughout this range, a feature that offers important advantages for electronic structure investigations, as will be shown below, but softens the distinction between UPS and XPS defined by the two types of laboratory source.

Photoemission provides a means of probing the occupied electronic states of a solid; strictly, it also provides some information on

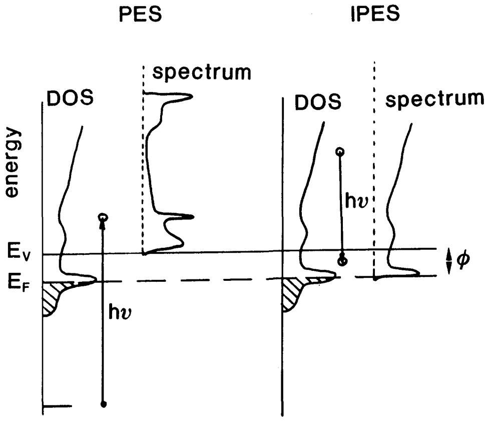

FIG. 1. Schematic diagram showing the basic principle of operation of photoelectron spectroscopy (PES) and inverse photoemission spectroscopy (IPES). Superimposed on the energy-level diagram, on which are defined the Fermi and vacuum levels, E_F and E_V, are shown the electron density of states (DOS) and the resulting PES and IPES spectra.

unoccupied states because the electron is emitted into such an unoccupied state and the transition probability must be influenced by both the initial and final states. Often, however, one is able to assume that the emitted electron has a sufficiently high kinetic energy that it can be well described by a simple free-electron state; even if this is not the case, the most interesting unoccupied states, which lie just above the Fermi level, cannot be accessed by photoemission because they lie below the vacuum level and an electron photoexcited into them is unable to escape from the solid. Complementary information on these states, however, is available from the technique of inverse photoemission, also shown schematically in the IPES (inverse photoemission spectroscopy) panel of Fig. 1.

In inverse photoemission an electron is directed at the solid and has a certain probability of losing energy by the emission of a photon, falling into a lower-energy unoccupied energy level. In this case the final electron state can lie between the Fermi and vacuum levels as well as in the continuum of higher-energy states. Although inverse photoemission is a less familiar technique than photoemission, its history actually dates from a similar period, as it is simply another name for the bremsstrahlung emission from an electron-bombarded solid which is well known in laboratory x-ray sources. The application of this method in the ultraviolet energy range is relatively new, however. In principle this technique can be exploited in either of two forms. In one, a fixed-energy incident electron beam is used and the energy spectrum of emitted photons is measured. More commonly, however, a fixed photon-energy detector is used and the incident initial-state electron energy (and thus the final-state energy *hν* below) is scanned. In this isochromat mode (also known as bremsstrahlung isochromat spectroscopy) a particularly simple version of the experiment uses a detector illustrated in Fig. 2 which comprises an iodine-filled Geiger–Müller tube fitted with a CaF_2 window; the combination of the low-energy-pass filter character of the window and the high-pass threshold ionization behavior of the iodine combine to produce a band-pass (isochromat) detector with a central energy of 9.7 eV.

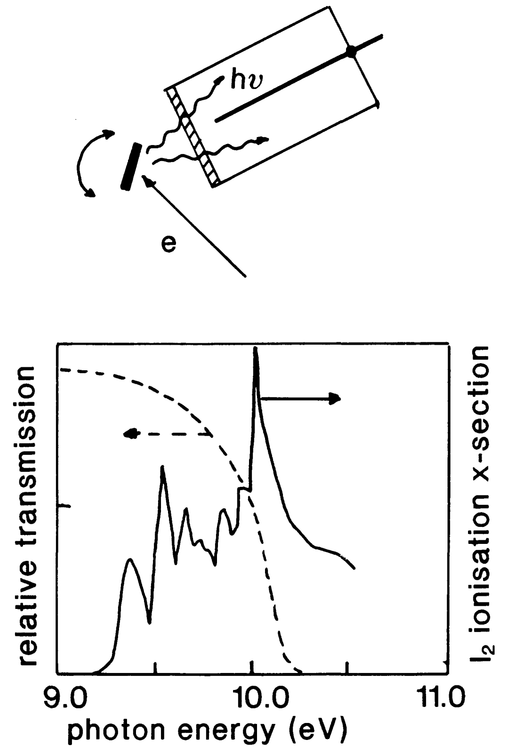

FIG. 2. Schematic diagram of the iodine-filled Geiger-Müller tube fitted with a CaF_2 window for use as a 9.7-eV isochromat detector in inverse photoemission (upper diagram), and of the low-pass window transmission and high-pass ionization cross-section threshold behavior (lower diagram) which form the basis of its operation.

Although the basis of both the photoemission and inverse photoemission experiments is energy conservation, their full power in the investigation of the electronic structure of crystalline solids and surfaces arises from the additional requirements of momentum conservation. Because a photon carries very little momentum, all optical transitions in solids are dominated by direct or vertical transitions in which the reduced electron momentum (i.e., the electron momentum within the first Brillouin zone in the reduced zone scheme) is conserved. In the case of photoemission, however, the final-state electron is detected outside the solid in the vacuum, and if both its energy and direction are measured, the final momentum is known. Energy and momentum conservation therefore mean that the initial-state energy and momentum are also known, so that it is possible to map an experimental energy-momentum (E-$\mathbf{k}$) band structure for the solid. This is the basis of angle-resolved (ultraviolet) photoelectron spectroscopy (ARUPS). In the same way, the incident electron energy and direction (and hence momentum) can be defined in inverse photoemission, allowing the unoccupied bands to be mapped by **k**-resolved inverse photoemission spectroscopy (KRIPES).

This potential is illustrated in Fig. 3, which shows the band structure of Cu along the Γ-*X* direction upon which are superimposed possible *s-p*–band direct photoemission and inverse photoemission transitions, together with the experimental spectra corresponding to these conditions, collected in normal emission or incidence at a Cu(100) surface. The arrowed peaks in the experimental spectra correspond to the *s-p*–band transitions shown on the band structure; with the photoelectron kinetic energy axis of these graphs (the abscissa) converted to a binding energy scale as shown, these arrows track the dispersion of the lower *s-p*–band through the Fermi level. This figure not only demonstrates the basic power of the techniques to map occupied and unoccupied energy bands in the solid, but also illustrates that variable photon energies are needed to achieve this along any particular direction of three-dimensional **k** space (such as the Γ-*X* symmetry direction). Strictly, however, our discussion is not exactly correct because we have assumed that the reduced electron momentum of the bulk solid is conserved. In reality, photoemission and inverse photoemission both involve the passage of relatively low-energy (tens of eV) electrons through a solid, and the mean free path for this process before inelastic scattering occurs is very short (0.5–2 nm). This means that the techniques only sample the outermost few atomic layers of the solid and therefore do not truly sample the translational symmetry (the periodicity) of the solid perpendicular to the surface. As the conservation of the reduced momentum is a direct consequence of the periodicity, this means that only the component of the electron momentum parallel to the surface, $\mathbf{k}_{\parallel}$, is strictly conserved in ARUPS and KRIPES. However, it is clear from the success of the example shown in Fig. 3 that the electron samples sufficient depth for a strong remnant of full **k** conservation to be maintained; in particular, the experimental spectra are all recorded at $\mathbf{k}_{\parallel}=0$ and the **k** varied in the Γ-*X* direction is the component *perpendicular* to the surface.

In investigations of true surface electronic structure, however, this formal absence of conservation of the perpendicular component of the momentum is not a problem. Electronic states which are localized at the surface can have no dispersion in the momentum component perpendicular to the surface, and so only the parallel component and its conservation are important. In this case the ability to vary

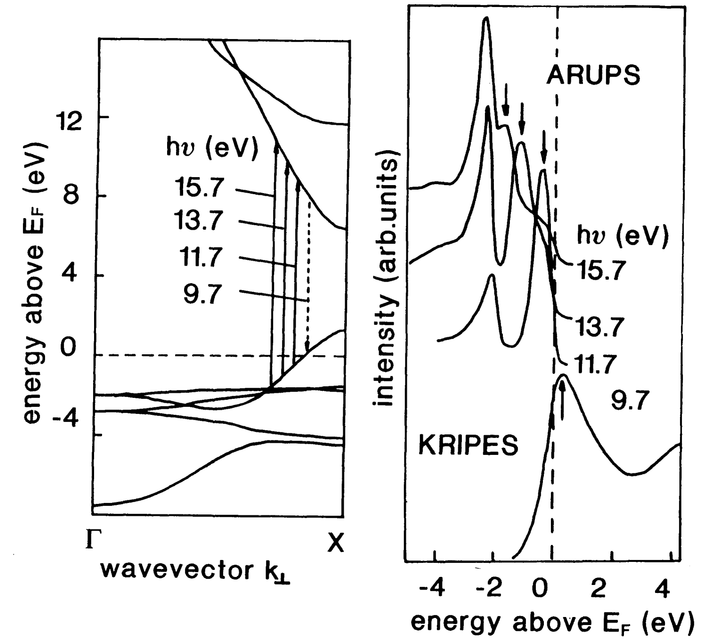

FIG. 3. Possible *s-p*–band direct transitions in photoemission and inverse photoemission for normal electron emission or incidence on Cu(100) overlaid on the appropriate part of the band structure (left), compared with the experimental spectra taken under these conditions (right). The arrowed peaks in the experimental spectra correspond to the *s-p*–band transitions indicated on the band structure. Note that the abscissa of the experimental photoemission spectra is strictly the photoelectron kinetic energy, but this is converted to the binding energy of the initial state being probed by subtracting the photon energy. The KRIPES spectrum axis is similarly converted to the final-state binding energy. After Woodruff *et al.* (1983).

the photon energy is also no longer so important because different $\mathbf{k}_{\parallel}$ can be accessed with a single photon energy simply by varying the electron emission or incidence direction. On the other hand, the absence of dispersion in the perpendicular component of the momentum for surface-localized states is a convenient way of distinguishing them from bulk states and can only be explored with variable photon energies. A more detailed description of angle-resolved photoemission and **k**-resolved inverse photoemission may be found in Kevan (1992) and Smith and Woodruff (1986), respectively.

2. SURFACE STATES AT CLEAN SURFACES

2.1 Shockley, Image-Potential, and Tamm States

At a clean surface we can identify two essentially different types of intrinsic surface state. One of these types (which includes both the so-called Shockley and image-potential states) can occur even for nearly-free-electron solids and is a direct consequence of including the effects of the crystal truncation in an otherwise perfectly periodic system in three dimensions. A rather different type of surface state is associated with more localized electronic states of the constituent atoms and arises because of the different local electronic environment of the surface atoms; these are generally known as Tamm states, and the most obvious example is the so-called dangling-bond states which occur at semiconductor surfaces. A general feature of any electronic state which is localized at the surface is that it must be unable to couple to a bulk state with the same energy and parallel component of momentum, and must therefore lie in a projected bulk band gap. (Notice that this need not be a complete bulk gap; we require only that no allowed states with the same parallel component of the wave vector exist). Its associated wave function therefore decays in an evanescent fashion into the solid (and must also decay exponentially with distance outside the surface at large distances if the energy lies below the vacuum level). In addition, however, some electronic states lying within an allowed band of the underlying solid have an enhanced electron density in the surface region relative to the bulk state to which they couple; these states are known as surface resonances.

Surface states which arise only from the termination of the solid at the surface and which are not related to semi-localized bulk states are known as Shockley states. Their possible existence and character can be derived from a simple nearly-free-electron model of the band structure of a solid by recognizing that mathematically valid solutions to Schrödinger's equation for an electron in a periodic potential do exist in the band gaps, but they have complex values of electron momentum **k** (Fig. 4). For a bulk solid these are not physically meaningful because the imaginary part of **k** leads to the wave function having a real exponential component which must become infinite in some region of space. If a surface is present, on the other hand, these solutions can correspond to states which decay into the solid but do not apply to the half-space corresponding to the vacuum. In the vacuum they must decay exponentially, and the two solutions must match in wave-function amplitude and gradient at the solid/vacuum interface. Since the phase of the evanescent wave solu-

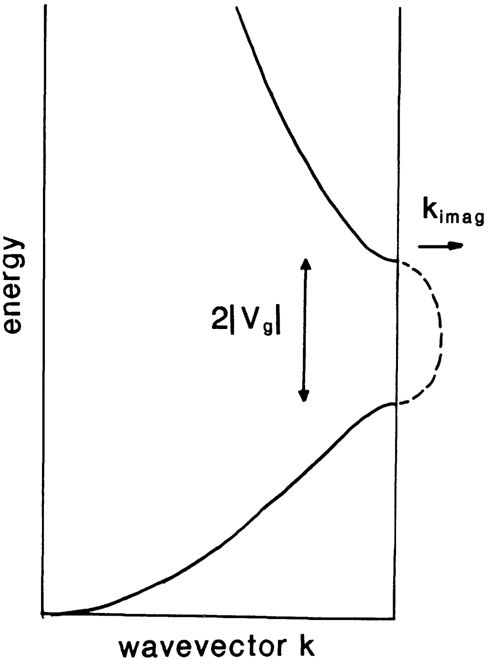

FIG. 4. Schematic diagram of a nearly-free-electron band structure showing the complex *k* solutions in the band gap.

tion at this interface changes in a systematic fashion as the energy is varied within the band gap, this matching (notably in gradient) is only possible at one particular energy in the gap, defining the Shockley-state energy. Indeed, this solution only exists for the appropriate polarity of the ion core pseudopotential amplitude, V_g (which has a magnitude of half the energy range of the band gap), and so surface states of this kind do not occur in all projected bulk band gaps.

An alternative but a particularly simple formalism which provides a description of both the Shockley and image states is as follows. Consider an electron just outside the crystal surface, at an energy below the vacuum energy and within an energy gap of the crystal. Under these conditions, the electron finds itself in a potential bounded by two rather different barriers. In particular, it is unable to penetrate the crystal because it lies in the band gap, yet it is also unable to escape into the vacuum because it is trapped by the so-called image-potential force. For a metal, the interaction of the electron with the screening charge of the substrate can be described by a Coulombic interaction with an "image" charge (of opposite sign to the electron, thus producing an attraction), which appears in the metal surface at a distance below the surface equal to the distance of the electron from the surface. For electron energies below the vacuum level, bound states can therefore be found within this potential well, defined by the repulsive solid potential and the attractive image potential.

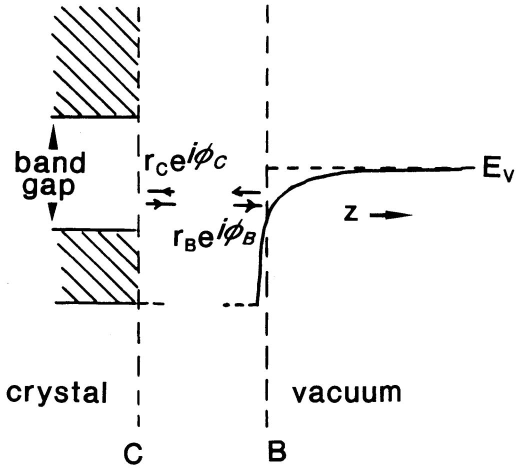

FIG. 5. Schematic diagram showing the one-dimensional potential well for an electron outside the surface of a conducting solid at a band-gap energy. The reflection amplitudes at the two barriers are shown as described in the text.

Figure 5 shows this electron potential schematically, while Fig. 6 shows the charge-density distribution associated with some of the solutions. The picture is quite similar to a one-dimensional analogue of the Coulombic potential of atomic hydrogen, and the solution involves a similar infinite series of possible solutions which converge on the vacuum level, exactly like the Rydberg states of the hydrogen atom. One way of obtaining the solutions is to consider an electron which bounces back and forth off the two walls within this potential and identifying the conditions under which the round trip involves a total phase shift which is an integral multiple (n) of 2π. This condition will generate the standing-wave solutions characteristic of a bound state. Thus, if the electron reflectances at the crystal and image potential barriers are denoted by $r_C \exp(i\phi_C)$ and $r_B \exp(i\phi_B)$, then the condition for the bound states is

$$\phi=\phi_C+2k_\perp(z_B-z_C)+\phi_B=2\pi n, \tag{2}$$

where $k_\perp$ is the component of the electron wave vector perpendicular to the solid surface, and z_C-z_B is the distance between the two barriers (typically taken to be half the atomic-layer spacing in the solid). The phase shift at the crystal barrier is determined by the energy within the gap (and hence by the size of the gap, $2V_g$) but varies by π across the gap,

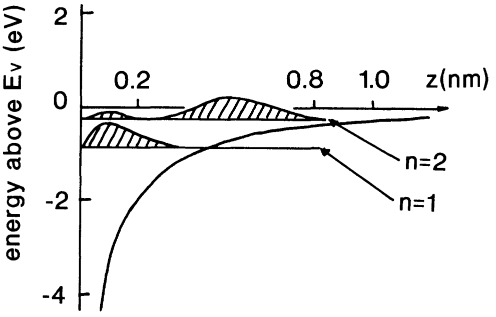

FIG. 6. Plot of the image-potential barrier and of the charge density associated with the $n=1$ and 2 bound states (Whittaker functions). The solutions are shown for the case of a quantum-defect parameter [Eq. (5)] $a=0$, which corresponds to an infinitely repulsive crystal boundary.

while the phase shift at the image barrier depends on the energy relative to the vacuum level.

Solving this problem (see, for example, Smith and Woodruff, 1986) leads to two rather different types of bound states. For $n=0$, a solution is obtained which is dominated by the crystal barrier phase shift, and corresponds to the Shockley surface state with its charge density peaked just inside the crystal surface. The higher n-value solutions, most strongly influenced by the image potential barrier, occur at energies given by

$$E=E_V-e_n+\hbar^2k_\parallel^2/2m, \tag{3}$$

$$e_n=(0.85\ \text{eV})/(n+a)^2, \quad n=1, 2, \ldots \tag{4}$$

with E_V the energy of the vacuum level. Evidently Eq. (4) defines a Rydberg-type set of states which disperse in a free-electron fashion in $k_\parallel$, but the exact energy at which these states occur is influenced by the so-called quantum-defect parameter,

$$a=\tfrac{1}{2}(1-\phi_C/\pi). \tag{5}$$

The $n=1$ and 2 solutions for $a=0$ (corresponding to an infinitely repulsive potential) are illustrated in Fig. 6.

The actual energies can be obtained from a graphical solution such as that shown in Fig. 7 for the case of Cu(111); the diagram shows the $n=0$ and 1 solutions. The $n=0$ Shockley state is predicted to lie 0.5 eV below the Fermi level (and so should be occupied at $k_\parallel=0$), while the $n=1$ lowest-energy image-potential state is 0.9 eV below the vacuum level. Both of these predictions are in rather good agreement with experimental results as shown in the KRIPES and ARUPS results of Figs. 8 and 9, summarized in the experimental band structure of Fig. 10. Notice that the occupied Shockley state is seen in the normal-emission high-resolution ARUPS data, but this state disperses up in energy as the emission angle (and thus $k_\parallel$) increases, and it crosses the Fermi level to appear in the unoccupied-state KRIPES spectra at higher incidence angles. The $n=1$ image-potential state is clearly visible in the KRIPES spectra, although the experimental resolution is too poor to resolve the higher Rydberg

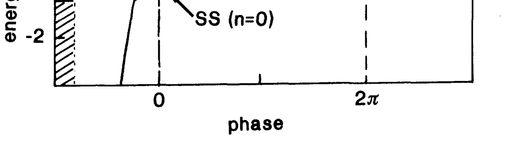

FIG. 7. Graphical solution of the multiple-reflection model of surface states for Cu(111) showing the $n=0$ (SS, Shockley state) and $n=1$ (IS, first image-potential state) solutions. The figure shows the crystal and image-potential barrier individual contributions as well as the total phase. After Hulbert *et al.* (1985).

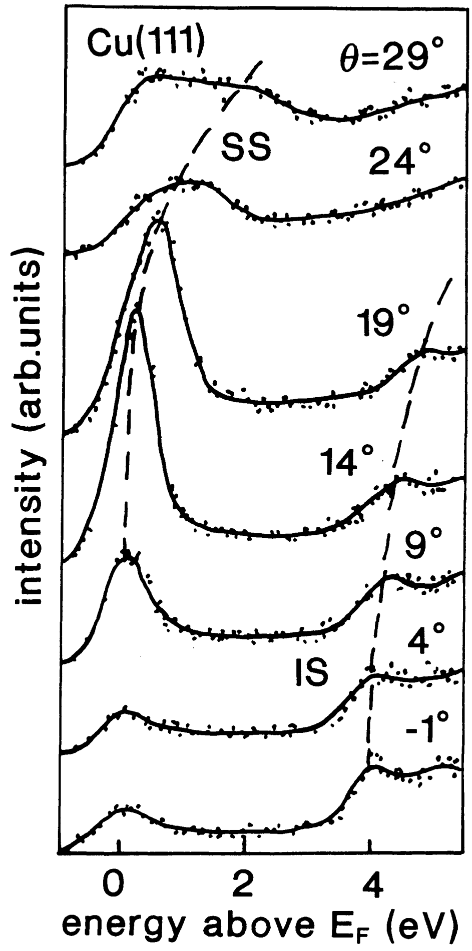

FIG. 8. KRIPES data taken from Cu(111) at a photon energy of 11.0 eV for different values of the angle of incidence Θ. The main features are labelled as IS (the $n=1$ image state) and SS (the Shockley state). After Hulbert *et al.* (1985).

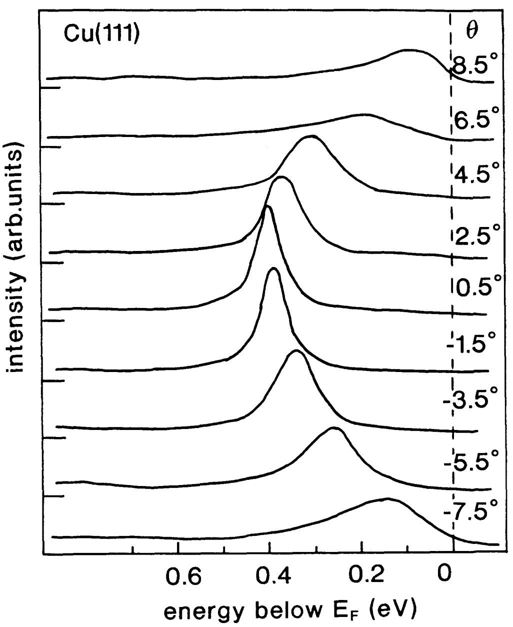

FIG. 9. High-resolution ARUPS of the Shockley state near the Brillouin zone center on Cu(111) recorded with a photon energy of 11.8 eV at different angles of emission, Θ. After Kevan (1983).

states which merge into an underlying edge. More of these higher states have been identified in separate higher-resolution two-photon photoemission experiments (in which the image-potential states are the intermediate bound states in the two-photon excitation from the occupied valence band to the vacuum continuum). Figure 10 summarizes the results of these experiments in the form of an experimental two-dimensional band structure onto which is superimposed the projection of the bulk occupied bands. Notice that both the Shockley and image-potential states which have been mapped lie in (or very close to the edge of) the bulk projected band gap.

Cu(111) also provides an example of a Tamm state which can be found at substantially larger values of $k_{\|}$. In addition to the rather free-electron-like *s-p* bands, the Cu valence bands contain the 3*d* electrons which, being far more strongly localized on the individual atoms, form very flat (weakly dispersing) fully occupied bands about 3 eV below the Fermi level (as may be seen in Fig. 3). Calculations of these *d* bands clearly require a more sophisticated treatment than the free-electron model we have discussed above, although they can be understood with a tight-binding model.

The usual way to calculate these bands is to perform a slab calculation in which the electronic structure of a small number of two-dimensionally periodic layers of the solid are stacked together. This allows one to use conventional three-dimensional band-structure methods to calculate the two-dimensional band structure of each layer, although the coupling between the layers must be dealt with differently. The slab has two surfaces, and these calculations are capable of providing a good description of the two-dimensional surface band structure, although the $k_{\perp}$ dispersion of the bulk bands is obviously not reproduced. The results of a calculation of this type are shown in Fig. 11 in a similar format to that of Fig. 10, but extended to lower energies. The dashed lines show the two-dimensional bands which are localized at the surface, and the upper such band is clearly the Shockley state which we have discussed previously. In addition, however, a rather flat band is seen some 2 eV below the Fermi level; for most values of $k_{\|}$, this surface band overlaps the bulk bands and so forms a surface resonance, but near the edge of the Brillouin zone it appears in a bulk band gap and becomes a true surface state. This band is associated with *d*-electron states in the surface atoms which experience a different local potential from those of the underlying bulk atoms and so are displaced in energy from the bulk *d* bands, a description which characterizes the Tamm surface states. These occupied surface states have also been observed (at energies a few tenths of an eV

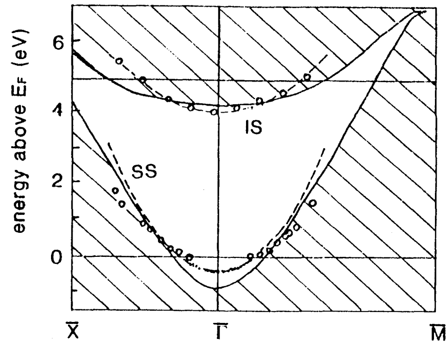

FIG. 10. Summary of the experimental surface band structure of Cu(111) based on the KRIPES (open circles) and ARUPS (small solid dots) results of Figs. 8 and 9. The hatched region is the projection of the bulk bands of copper.

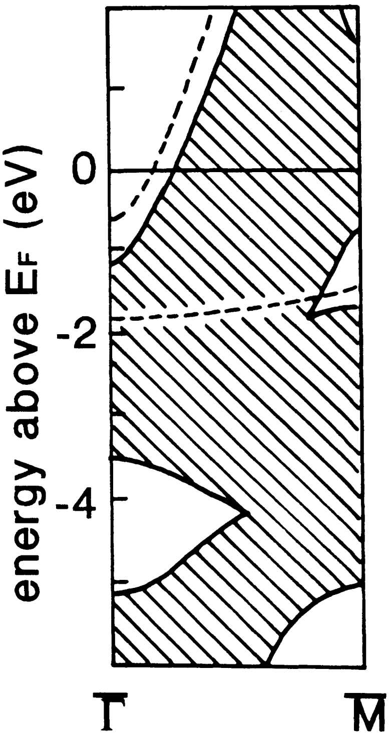

FIG. 11. Theoretical surface band structure for Cu(111) based on a slab calculation by Euceda *et al.* (1983) (after Zangwill, 1988).

below the calculated values) in ARUPS experiments performed at the appropriate higher values of $k_{\|}$.

Although this distinction between Shockley and Tamm states is rather clear in the case of Cu and quite a number of related noble and transition metals, this is not always true and evidently depends on the detailed hybridization schemes which determine the detailed electronic band structure. Nevertheless, this example serves to illustrate the main physical ideas involved in a particularly clear fashion.

We should also note here that in this section we have concentrated on a description of metal surfaces. Clearly covalently bonded semiconductors do not lend themselves to being described by a nearly-free-electron model, and a more appropriate simplification is a tight-binding approach; this highlights the fact that the electrons are far more localized in semiconductors so that we would expect mainly Tamm states. This subject is dealt with separately in Sec. 2.3.

2.2 Surface Core-Level Shifts

In the foregoing discussion we have concentrated on the use of photoemission, and particularly angle-resolved photoemission, as a direct probe of the valence electronic structure. Using higher photon energies to excite core-level photoemission, as typified by the XPS technique, provides primary information on the elemental composition of the surface region because the core-level binding energies provide a characteristic spectral signature of the emitting atoms. Small changes in these measured binding energies, however, do occur as a result of changes in the local valence electronic environment of the surface atoms, and indeed this sensitivity to the local "chemical" bonding state, and the associated "chemical" shifts in the measured binding energies, is one of the primary uses of the XPS technique in studies of surface chemistry. (Indeed, the technique was often, and is still sometimes, referred to as ESCA, or electron spectroscopy for chemical analysis.) This application of XPS is discussed further in Sec. 3.3 in regard to investigations of surface electronic structure associated with adsorption, but of interest in the context of clean surfaces is the extent to which the different electronic structure of the surface relative to the bulk is manifested in a change in the measured photoelectron binding energy even for an elemental solid. Indeed, one could view this effect as a rather special kind of Tamm surface state in that it is a binding-energy change in a localized state at the surface.

Before discussing the results of these surface core-level shift experiments, however, it is important to appreciate just what is measured in the XPS technique. In particular, photoemission from a highly localized core-level state of an atom leaves behind an ion with a localized core hole, and the time scale within which the surrounding valence electrons can respond to the appearance of this hole is sufficiently short that their effect must be considered in understanding the measured binding energy. Specifically, the loss of the core electron means that the nuclear screening effect of this electron is lost, and the remaining bound electrons will "relax" to lower binding-energy states; the effect of this relaxation is to make additional energy available to the escaping photoelectron which is measured to have a higher kinetic energy than would be expected from a simple "frozen orbital" emission process; the measured binding energy thus has a smaller magnitude than would be expected from a simple one-electron picture. This effect is important, not only because it modifies the absolute value of the measured binding energy, but because different valence electronic environments will lead to different degrees of extra-atomic relaxation, so that one component of any measured chemical or surface core-level binding-energy shift in XPS is associated with changes in the final-state ion as well as the initial-state neutral (ground-state) atom. Indeed, because removal of a core electron from an atom increases the effective nuclear charge "seen" by the valence electrons by one electronic charge, the valence electronic states in the final state can be likened to those of the next element in the periodic table (i.e., the atom having an atomic number one unit higher). As this atom may have a radically different bonding character (e.g., the difference between a halogen and an inert gas, or between an inert gas and an alkali), it is clear that this final-state effect can be substantial.

Returning now to the original question of the observability of surface core-level binding-energy shifts in photoemission, Fig. 12 shows examples of this effect in the form of W and Ta $4f_{7/2}$ photoemission energy spectra from W(111) and Ta(111) surfaces. In each case there are two clearly visible components to the spectrum, while more careful fitting of these curves reveals that three separate peaks, labeled S_1, S_2, and B, contribute to each spectrum. By applying various additional tests, such as studying the influence on the spectra of adsorbed species, these components are found to be associated with emission from top-layer atoms, second-layer atoms, and underlying bulk atoms, respectively. Note that these spectra, recorded at rather high resolution, were measured using quite low–photon-energy synchrotron radiation (70 and 66 eV, respectively) in order to maximize the surface sensitivity (by taking advantage of the lower inelastic-scattering mean free path at low kinetic energies) and to optimize energy resolution. These spectra illustrate the fact that in core-level photoemission from states which show sufficiently narrow intrinsic widths (such as these 4*f* states), the different electronic environment of surface atoms relative to bulk atoms can be distinguished, and indeed in this case even different shifts for differently coordinated near-surface atoms can be observed. One additional and rather striking feature of these data is that the surface core-level shifts of W and Ta are of opposite polarity.

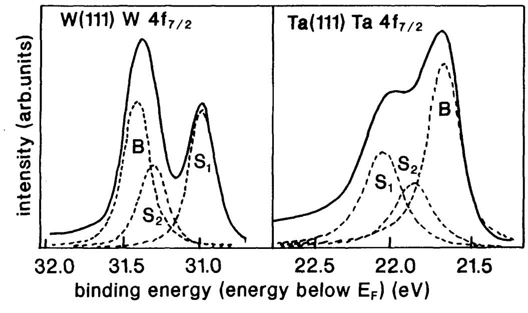

FIG. 12. W and Ta $4f_{7/2}$ photoemission spectra from clean W(111) and Ta(111) surfaces, also showing the component parts determined by peak fitting. After Eastman *et al.* (1982).

A rather simple theory of the effect of the different surface electronic environment on the one-electron binding energy (i.e., of only initial-state effects as in conventional Tamm valence states) can provide a qualitative description of this effect. It is based on the fact that the lower coordination of the surface atoms will lead to a narrowing of the associated 5*d* conduction band. If this band is other than exactly half-filled then a small amount of charge must flow into or out of the surface in order to balance the Fermi levels in the bulk and at the surface, and the resulting change in local electrostatic potential causes a change in the associated core-level binding energies of the surface atoms. This effect is illustrated schematically in Fig. 13 which shows that for a *d* band which is less than half-filled, the binding energy should increase, while for a band which is more than half-full the binding energy should decrease. The trend matches the experimental data in that W has one more (4) *d*-band electrons than Ta, so that the shift should be less positive, but the change in sign should actually occur one element to the right in the periodic table (at Re which has five 4*d* electrons) and not between Ta and W. One reason for this quantitative discrepancy is that the *d* bands are not symmetrical as assumed in the schematic of Fig. 13, and this asymmetry will change the *d*-band occupation required for the sign of the charge transfer to switch over.

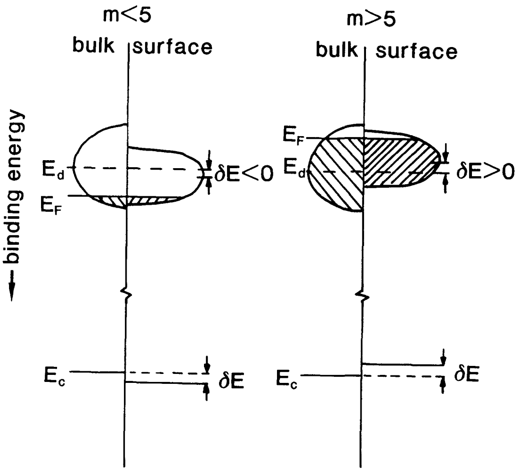

FIG. 13. Band-narrowing model of surface core-level shifts for a *d*-band metal, and an electronic occupation *m* either greater or less than 5 (half-filled). E_d is the energy of the center of the *d* band, E_c is the photoelectron binding energy of a core level of atoms in the bulk. δE is the displacement of the surface and bulk *d*-band centers and thus also the core-level shift. After Eastman *et al.* (1982).

Although this simple account of the initial-state energy change is qualitatively consistent with the results, another equally simple but more complete phenomenological theory highlights the fact that changes in the final-state energy are also likely to contribute to the observed results. In this picture we note that the key difference between photoemission of a core electron from a surface or a bulk metal atom is that in one case the final state has a core hole on a bulk atom, whereas in the other this hole is on a surface atom. We have already noted that the (relaxed) valence-electron environment around the core hole of the metal atom of atomic number Z is essentially equivalent to that around a neutral atom having an atomic number $Z+1$. The difference in energy is therefore that involved in moving a $Z+1$ atom from the bulk to the surface; i.e., the core-level shift is equal to the heat of segregation of a $Z+1$ atom in a Z-atom solid matrix.

2.3 Dangling-Bond States and Scanning Tunneling Microscopy

In introducing the idea of Tamm states one example that was mentioned was that of so-called dangling-bond states at semiconductor surfaces. Semiconductors comprise covalently bonded networks in which the valence electrons are rather highly localized in space between the atoms, in marked contrast to the highly dispersed electron density distribution of a simple free-electron-like metal. One consequence of creating a surface in such a structure is that localized electron orbitals appear at the surface which are unmatched by the atoms which were removed to create the surface. Clearly, these localized electron states have a very different electronic environment from that of a bulk atom and are likely to appear in the band gap. Another aspect to this picture makes this anticipated energetic location rather clear. If we consider, in particular, an elemental semiconductor such as Si, the bonding of two Si atoms causes the energy level of the bonding orbital (the sp^3 hybrid) to split into a bonding and antibonding orbital at higher and lower energies, respectively, and extending the Si—Si bonding to a solid network of Si atoms broadens these bonding and antibonding orbitals into the valence and conduction bands separated by the band gap, with the lower band just filled. If we now remove a Si atom from this network we can expect the energy of the unbound orbital to revert to an energy closer to its original atomic value, midway between the bonding and antibonding bands, and thus in the band gap.

Clearly a more rigorous approach is needed to establish the exact form and energy of the associated surface band, and in particular whether it should be occupied or unoccupied. Moreover, a very important complication in such a calculation is to take proper account of the reconstruction which such surfaces adopt in order to reduce the increased energy associated with these unsatisfied bonds. In the simplest case, such as the Si(100) surface, the main reconstruction is simply a "pairing" of adjacent atoms [which each have two dangling bonds on an ideally terminated Si(100) surface] with these atoms moving closer together; this movement of top-layer atoms causes distortions in several lower atomic layers because of the sensitivity of the total bonding energy to the nearest-neighbor bond lengths and relative bond angles. The atom-row pairing in the surface leads to a reconstructed surface having a surface unit mesh with dimensions equal to that of the substrate in one direction parallel to the surface, but twice as large in the direction of the other surface primitive translation vector—a so-called (2×1) structure. In the case of Si(111), the stable surface reconstruction involves atom pairing, top-layer stacking faults, and adatoms in a massive (7×7) reconstructed surface mesh, the structure of which has taken many years to solve. Nevertheless, the key conclusion concerning the surface electronic structure is that surface states are still expected to occur on this surface, and that they should be highly localized at specific surface atoms. The basic correctness of the existence of such surface states, both occupied and unoccupied, has been established using photoemission and inverse photoemission. A far more interesting experimental result in this context, however, is direct observation of the spatial localization of these surface states on the associated surface atoms.

This demonstration has been achieved using the technique of scanning tunneling microscopy (STM) (*q.v.*; see also FIELD EMISSION AND IONIZATION). The basic principle of the scanning tunneling microscope is illustrated in Fig. 14. If a fine metal tip is brought sufficiently close to a conducting surface, electrons can tunnel across the vacuum gap between them under the influence of a small voltage difference V. Clearly this quantum-mechanical tunneling can only occur when the separation is of atomic dimensions (less than about 1 nm), but under these circumstances electrons can tunnel either from occupied states in the tip to unoccupied states in the surface, or from occupied states in the surface to unoccupied states in the tip, depending on the polarity of the applied voltage. In the usual microscopic mode of the technique the tip is mounted on piezoelectric rods or a tube which allows the tip to be moved parallel and perpendicular to the surface, and as the tip is scanned parallel to the surface a feedback loop moves the tip in and out as required to maintain a constant tunneling current I_0. The voltage applied to the piezoelectric mounting to move the tip in and out can then be converted into a distance moved, so that a constant–tunneling-current contour map of the surface can be constructed. Because the quantum-mechanical tunneling current is exponentially dependent on the gap size, this technique is extremely sensitive, and the contour map can have a perpendicular spatial resolution of less than 10 pm, with a lateral resolution also well below atomic dimensions.

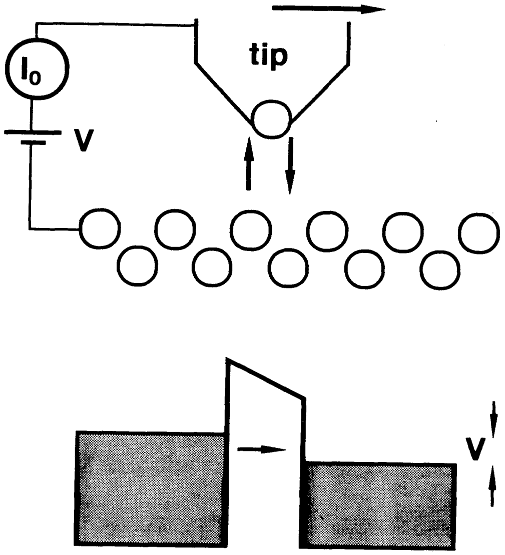

FIG. 14. Schematic of the principle of operation of a scanning tunneling microscope scanned at a bias potential difference V and a fixed tunneling current I_0.

Microscopies are generally regarded as probes of geometrical rather than electronic structure, but in the case of STM the nature of the probe means that it is extremely sensitive to the electronic structure; indeed, an approximate description of the contours actually followed in the microscope is that they correspond to constant valence-electron density contours at a rather low value of this density. The fact that the image typically appears as if it is an atomic picture of the surface is therefore potentially misleading in that there is no general theorem which connects peaks in these low-density charge contours outside the surface with underlying atomic positions (although such a correlation probably does exist for many surfaces). In this regard, the amplitude of the corrugations perpendicular to the surface in a typical STM image is found to be much larger at a semiconductor surface than at a metal surface, an effect which can be attributed to differences in the degree of localization of the valence charge in these materials. Specifically, however, in the situation in which we have dangling-bond states localized at particular atoms on the surface, we may expect that STM offers a means of spatially mapping these electronic states (with atomic resolution). This is, indeed, found to be the case, and a particularly clear example is provided by STM of the Si(111) surface [showing the (7×7) reconstruction]. Because the electronic states sampled by the tunneling experiment depend on the applied voltage difference *V*, and particularly on the polarity of this voltage, the STM images from this surface depend strongly on this parameter, as may be seen in Fig. 15.

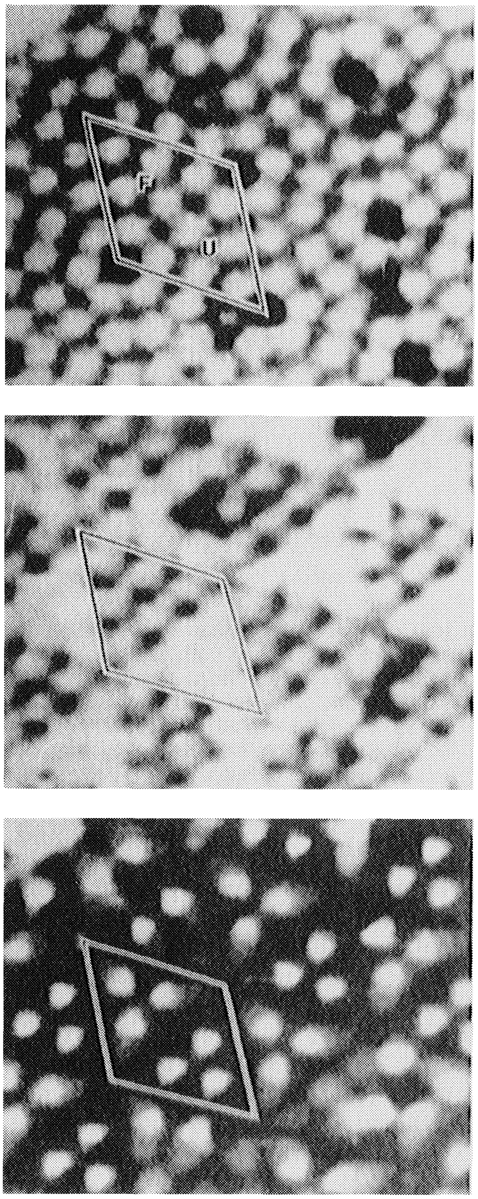

FIG. 15. STM images of Si(111) recorded with different bias voltages applied to the sample as follows: top, +2 V; center, +1.45 V; bottom, −1.45 V. The surface (7×7) unit mesh is superimposed on the micrographs for clarity. *F* and *U* refer to the two inequivalent ("faulted" and "unfaulted") halves of this unit mesh. After Hamers *et al.* (1986).

The sensitivity to electronic structure in STM can be exploited further by a modification of the usual imaging mode. In particular, if the tip is held at a fixed position above the surface, and the applied potential difference is scanned while measuring the changing tunneling current (now with the perpendicular positioning feedback loop switched off), the current voltage (*I*-*V*) characteristics should show steps associated with new tunneling channels being opened by appropriate occupied or unoccupied energy levels of the surface. By plotting a conductance versus applied voltage (*I*/*V*-*V*) graph these electronic energy levels can then appear as peaks similar to those seen in photoemission and inverse photoemission. This is confirmed by the data presented in Fig. 16, which shows conductance-voltage curves of this type recorded in both polarities and at various positions on the surface within a single surface unit mesh, as well as a spatially averaged spectrum. Also shown are (necessarily spatially averaged) photoemission and inverse photoemission spectra from this surface. It is clear that all of the main features of the occupied and unoccupied surface-state spectra produced by optical means are reproduced by the spatially averaged tunneling spectra, and also that each peak in the spectra is associated with a different part of the unit cell in real space. Indeed, direct spatial maps of these states can be obtained by building complete images based on the amplitude of specific features in the spatially resolved conductance-voltage spectra.

Although this example highlights the spatially localized character of semiconductor surface dangling-bond states (parallel as well as perpendicular to the surface), it also provides an elegant demonstration of the power of STM for electronic structure investigations of surfaces in suitable cases. Unfortunately, this restriction to "suitable cases" is an important one; although this technique has been applied to a number of other semiconductor surface problems with success, its broader applicability appears to be limited. For example, one might hope that it would be possible to map localized (Tamm) surface states on metal surfaces, but in the case of the transition and noble metals it appears that tunneling is dominated by the less spatially localized

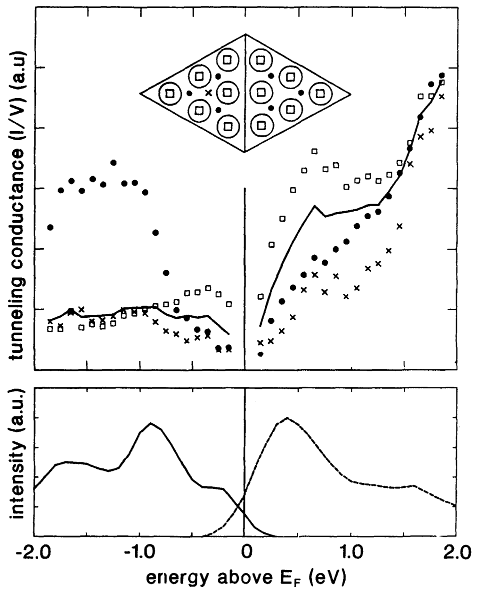

FIG. 16. Comparison of photoemission, inverse photoemission (lower part), and both spatially averaged (line) and spatially resolved (points) tunneling conductance-voltage spectra (upper part) from Si(111). The inset shows the areas sampled in the spatially resolved tunneling spectra, which are labeled by the same circles, squares, and crosses. After Hamers *et al.* (1986).

s-p electrons. Another potential limitation is that the tunneling process appears to favor predominantly transitions involving states at the surface Brillouin zone center (with $k_{\|} = 0$), although if no states exist here, strong features at other points in the zone can be observed. This selectivity in **k** clearly makes the technique complementary to the more conventional ARUPS and KRIPES methods.

Notice that one aspect of the existence of surface states on semiconductor surfaces, which often lie in the complete bulk band gap (i.e., not simply in a projected bulk gap, as on metal surfaces), is that it is then possible for the surface to be metallic, rather than semiconducting. In addition, the extent to which such surface states may be occupied can be strongly influenced by the type and extent of doping of the bulk semiconductor. The redistribution of charge between the surface and the bulk to balance the Fermi levels can then lead to interesting band-bending effects in the near-surface region. A proper quantitative description of surface states in semiconductors is far more complex than in metals, however, because of the essentially universal phenomenon of surface reconstruction (for III-V and II-VI, as well as elemental, semiconductors). In effect, the essential inevitability of dangling-bond states at ideally terminated semiconductor surfaces means that some rearrangement (both geometric and electronic) is necessary, but a quantitative modelling of the electronic structure requires an accurate geometrical structure as the starting point. This geometrical structure is not easily obtained because the covalently bonded network means that adjusting the position of one atom in the top layer causes movements of adjacent atoms in lower layers, typically down to 3 or 4 layers below the surface, and so there are many unknown structural parameters. Indeed, this intimate connection between the geometrical and electronic structure of the surface has meant that some progress in unraveling these structures has been made by measuring the electronic structure (with ARUPS and KRIPES) and comparing this with the results of model calculations based on different geometries. Further discussions of all of these effects may be found, for example, in Hansson and Uhrberg (1988), and in an article by the same authors in the book edited by Kevan (1992).

2.4 Surface Reconstruction

We have already remarked that semiconductor surfaces (almost invariably) have a local geometrical structure which is significantly different from that of an ideally terminated bulk solid, and that these reconstructions can be understood as a consequence of the rather local bonding in these materials and thus of the problem of reducing the excess energy associated with the dangling bonds present at an ideally terminated solid. It is now clear, however, that many metal surfaces also show substantial surface reconstructions, the origin of which is somewhat less clear. Early examples of these reconstructions were on W(100) and Mo(100), and it is tempting to suggest that even in these metallic systems a similar local bonding description based on the role of the localized valence *d* electrons can be used; indeed there has been some success in using local bonding models to explain the phenomenon.

An alternative picture of these reconstructions which has also found some favor, however, is related to the idea that a surface charge-density wave (CDW) may be associated with the reconstruction. This model relies on collective electronic effects rather than local bonding, and the reconstruction is seen as the freezing out of a particular surface phonon mode that has a surface wave vector spanning heavily nested portions of the two-dimensional Fermi surface. A necessary, if not sufficient, condition for this to occur is that the two-dimensional Fermi surface of the metallic surface does contain the required large parallel flat segments. In order to test this theory, therefore, ARUPS can be used to map out the two-dimensional Fermi surface by determining at which values of $k_{\|}$ surface states cross the Fermi level; each such crossing defines a point on the two-dimensional Fermi surface. This clearly requires very many ARUPS measurements to be made, ideally with good energy and angular (and thus $k_{\|}$) resolution, but this has been performed for a number of surfaces including the W and Mo(100) faces mentioned above.

The results for W(100) are summarized in Fig. 17 which shows the experimentally determined two-dimensional Fermi surface for this crystal face. Individual crossing points of the Fermi level are shown as circles, but there is also a large region which is hatched in which the ARUPS shows a surface state so close to the Fermi level that is difficult to be sure whether the Fermi surface is completely flat or not. Clearly these areas are heavily nested and provide strong support for some kind of charge-density-wave–driven reconstruction. Unfortunately, the nesting vectors are not quite in the expected range for the observed reconstruction [to a so-called $c(2\times2)$ surface periodicity]; a classic CDW reconstruction to this phase would require vectors joining nested regions along the $\bar{\Sigma}$ symmetry direction [the line joining the zone center ($\bar{\Gamma}$) and $\bar{M}$ points] with a length equal to the $\bar{\Gamma}$ to $\bar{M}$ distance. However, the largest vector in this direction joining the hatched (nested) regions is almost 10% shorter than this value. It appears, however, that these results are consistent with a further development of this basic theory in which electron-phonon effects are explicitly considered, indicating that a collective electronic effect does play a role in these reconstructions. A fuller discussion of these data, those on other surfaces, and their general significance can be found in a review by Smith and Kevan (1991).

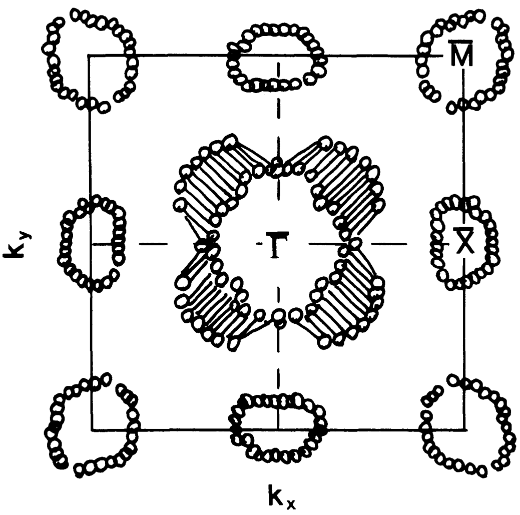

FIG. 17. Experimentally determined 2D Fermi surface of W(100) mapped in the first surface Brillouin zone. Data were recorded in one quarter of the zone only. The main crossing points of the Fermi level are marked by circles, but the hatched area also denotes regions in which the surface state is at, or very close to, the Fermi level. After Smith *et al.* (1990).

2.5 Magnetic Properties of Surfaces

Although the idea of surface magnetism in ferromagnetic materials has been discussed for many years, attempts to measure this frequently led to negative results, and the idea developed that the surfaces of such materials were magnetically "dead." It now seems clear, however, that this only true for contaminated surfaces, and that clean surfaces of ferromagnetic materials are, indeed, magnetic. Moreover, controlled studies of adsorption reveal that there is no simple universality to the destruction of the surface magnetism by adsorption, and indeed adsorbed species can themselves acquire magnetic electronic level splitting through hybridization with the underlying substrate.

The existence of magnetic surface states was inferred in quite early applications of ARUPS to the study of Ni surfaces by Plummer and Eberhardt (1979), through the observation of surface states appearing in regions of k space that only correspond to the bulk band gap for one spin state of the metal d electrons. More direct observation of the spin splitting of the d states, which produces the magnetism, has come from spin-resolved

ARUPS and KRIPES measurements. These techniques rely on the fact that not only energy and momentum, but also electron spin is conserved in the photoemission and inverse photoemission processes. This means that if the spin of photoemitted electrons is detected, or if the incident electron beam in an inverse photoemission experiment is spin-polarized, the occupied and unoccupied states of the near-surface region can be mapped in energy, momentum, and spin. Examples of such measurements on Ni(110) are shown in Fig. 18 for normal photoelectron emission and normal electron incidence inverse photoemission from Ni(110). The photoemission data clearly show the spin splitting of the occupied portion of the 3*d* bands, while the inverse photoemission shows that the unoccupied portion of the *d* bands is entirely of one (minority) spin; the unequal occupation of the two different spin states is the origin of the ferromagnetic behavior of this material.

Of course, we have already remarked in Sec. 1 that the ARUPS and KRIPES techniques are quite effective in mapping bulk band structure, in that the conservation of $k_\perp$ remains rather dominant despite the relatively small sampling depth of these methods. Although measurements such as those shown in Fig. 18 therefore provide valuable support for our understanding of bulk ferromagnetism, they do not necessarily demonstrate surface magnetism. Other measurements do, however. For example, it is possible to determine the temperature dependence of the spin polarization of electrons photoemitted from such a surface, and this is found to deviate very significantly from that to be expected for bulk magnetism, showing that at least part of the measured magnetic properties is surface specific.

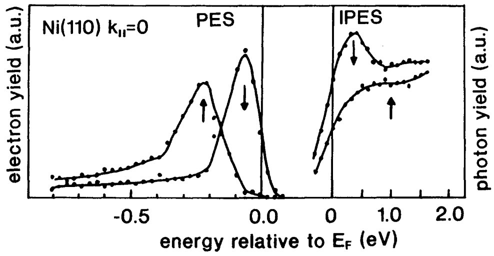

FIG. 18. Comparison of experimental results of spin- and angle- (momentum-) resolved photoemission and inverse photoemission data from Ni(110) recorded at normal emission and normal incidence, respectively. Taken from Schmitt *et al.* (1987) and Ungaris *et al.* (1982).

A small extension of studies of this type to the investigation of the magnetic properties of ultrathin metal films (i.e., of one to ten single atomic layers or so) is also proving extremely interesting, as is the study of metastable (constrained) phases of similarly thin films produced by epitaxial growth, such as of fcc Fe and Co by growth on copper surfaces. So far studies of such material by spin-polarized ARUPS and KRIPES have been limited (these experiments combining the problems of simultaneous energy, angle, and spin resolution with the small amounts of material available in monolayer films), but it is already clear that the magnetic properties of these layers can differ significantly from those of the bulk. For example, the fcc Fe films are found to be ferromagnetic, but the Curie temperature is thickness dependent (e.g., 230 K for one monolayer and 390 K for films of 3- and 5-monolayer thicknesses) (Stampanoni *et al.*, 1987).

3. ADSORBATE-INDUCED SURFACE ELECTRONIC STRUCTURE

A primary reason for studying the electronic structure of a surface in the presence of adsorbed species is to try to understand the nature of the adsorbate-substrate bonding together with any possible modification of the intrinsic electronic structure of the underlying surface and of the adsorbate itself (particularly for an adsorbed molecular species) which may help us to understand the chemical reactivity of the surface. A slightly different motivation also exists in the case of semiconductor surfaces for which the adsorbed species may be oxygen, a metallic species, or another semiconductor material; in this case one may wish to understand the early stages of semiconductor-insulator, semiconductor-metal (Schottky barrier) and semiconductor-semiconductor (heterojunction) interfaces of importance in fabricating semiconductor devices, particularly by ultrahigh-vacuum methods such as molecular beam epitaxy.

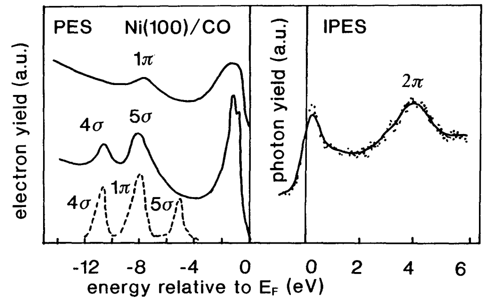

FIG. 19. Photoemission and inverse photoemission spectra recorded from CO adsorbed on Ni(100). Also shown as a dashed line is the gas-phase photoemission spectrum suitably aligned in energy. The photoemission spectra, taken from Allyn, Gustafsson, and Plummer (1977), are recorded in two different polarization conditions to separate out the different symmetry orbitals. The inverse photoemission spectrum is from Johnson and Hulbert (1987).

3.1 Molecular Bonding and Valence Electronic Structure

In the case of adsorbed molecules or molecular fragments, photoemission and inverse photoemission can provide a valuable spectral "fingerprint" of the molecular character of the adsorbate because of the characteristic energies of their valence orbitals. More careful inspection can also provide valuable information on the adsorbate bonding and molecular modification. One example of this is in studies of the adsorption of molecular carbon monoxide on transition-metal (and noble-metal) surfaces, a topic of great chemical interest in heterogeneous catalysts for processes as variable as methanol production, gasoline and methane production, and automobile exhaust-gas pollution control. Figure 19 shows valence-band photoemission and inverse photoemission spectra taken from a Ni(100) surface onto which CO has been adsorbed. The photoemission spectrum of the gas-phase molecule in this energy range contains three main features associated with the 4σ, 1π, and 5σ orbitals in order of decreasing binding energy, these orbitals being mainly derived from the C and O $2p$ atomic orbitals of the constituent atoms. In the adsorbed-molecular spectrum, however, one typically only observes two peaks (other than those associated with the underlying metal), although by the use of polarization selection rules in angle-resolved photoemission, combined with the fact that the C—O bond axis is almost always found to be perpendicular to the surface (thus preserving the symmetry of the situation), it is possible to show that the smaller-binding-energy peak actually comprises two overlapping peaks of different (π and σ) symmetries. The origin of this effect is that while the 4σ and 1π orbitals are largely undisturbed by the adsorption, the 5σ orbital is pulled down in energy by the interaction with the substrate to overlap the photoemission peak from the 1π state. This selective modification of the 5σ state is consistent with the fact that the molecule bonds with the C end against the metal, because the charge density associated with the 5σ orbital is most concentrated beyond this carbon end and so will overlap the metallic charge and hybridize with metal states of the appropriate symmetry. This hybridization is expected to form a CO-metal bonding–antibonding pair of levels, with the bonding level being lower in energy than either of the constituent levels. The displacement of the 5σ energy level can thus be assigned to this substrate bonding shift.

A more complete picture of the CO–transition-metal bonding picture in this molecular description is shown in Fig. 20 and illustrates two further important points. One is that the CO-5σ–metal d-band bonding actually only truly contributes to the adsorbate bonding if its associated antibonding level is at least partially unoccupied (it is shown above the Fermi level in Fig. 20). The second

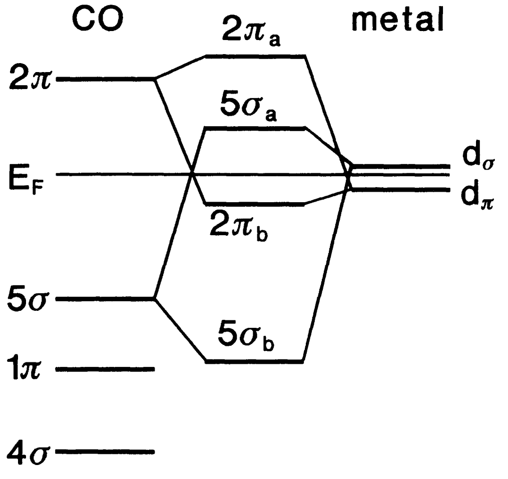

FIG. 20. Schematic energy level diagram showing the conventional (Blyholder) bonding scheme for CO adsorbed on a transition-metal surface.

feature is that a bonding interaction is also believed to occur between the unoccupied CO 2π orbital and the metal *d* band. The interaction is normally described in terms of CO charge donation to the metal from the 5σ orbital and backdonation of metal charge to the CO 2π. The involvement of the CO 2π orbital is of great importance in this picture because this orbital is antibonding with respect to the C–O bond and is completely unoccupied in the free molecule. If the surface bonding does donate charge to the CO 2π state this will therefore weaken the C–O bond making it easier to fracture, a process which is important in some of the CO chemistry which is aided by transition-metal catalysts. In this respect it is clear that the key issue is not the energetic location of the unoccupied 2π-derived level, which is also antibonding with respect to the CO-metal bond (although it is presumably this level which is responsible for the peak seen in the inverse photoemission spectrum), but rather the existence or otherwise of an occupied component of this state which is expected to be located close to the Fermi level. This is actually much more difficult to observe because it should occur in the energy range occupied by the substrate *d* band which typically dominates photoemission spectra. Nevertheless, there are some reported observations of this state in photoemission.

One rather different method that has been used to observe this feature (which is less troubled by the interfering influence of a dominant metal substrate signal) is based on the use of metastable He atoms, rather than ultraviolet photons, as the source of energy input to eject electrons from occupied states. In this technique, variously referred to as He metastable atom spectroscopy or surface Penning ionization spectroscopy, a metastable excited He-atom beam is directed at the surface and the emitted electrons are collected and energy analyzed as in photoemission. The excited He atoms used have one of the ground-state $1s$ electrons excited into a $2s$ state to form the metastable singlet 2^1S state (or the triplet 2^3S state) but can deexcite when they interact with the surface to give up their excess energy of 20.6 eV (or 19.8 eV for the triplet state, both being close to the 21.2 eV of the He I resonance source photons typically used in laboratory UPS). The form of the de-excitation can vary, but in the case of studies of adsorbed CO, appears to be by an Auger de-excitation process (see AUGER ELECTRON SPECTROSCOPY) in which an electron in the valence band of the surface tunnels into the $1s$ state of the He atom, and the He $2s$ electron is emitted with an energy characteristic of the total available energy in the metastable atom minus the binding energy of the valence electron involved. A key feature of this process is that the charge exchange is very localized, so that for a surface with adsorbed CO, the technique probes mainly the electronic states of the adsorbed molecule and not of the underlying substrate. This extremely high surface specificity makes it particularly useful for investigating the electronic states localized on adsorbed species rather than those associated with the underlying substrate, although the technique is clearly less simple and generally less applicable than UPS.

3.2 Atomic Adsorbates and Associated Two-Dimensional Bands

In studies of the electronic structure associated with adsorbed atomic species the valence electrons of the adsorbed atom no longer offer a particularly incisive fingerprint of the chemical identity of the adsorbate, but they still aid in understanding the adsorbate-substrate bonding, and for ordered overlayers the adsorbate-induced surface localized states form two-dimensional bands which disperse in $k_{\parallel}$ as a result of adsorbate-adsorbate interactions both through space (directly) and through interaction with the substrate. An example of data of this kind, in the form of experimental two-dimensional band structures obtained by ARUPS from ordered half-monolayer structures of C, N, and O on Ni(100), is shown in Fig. 21. Three main spectral regions may be seen in these data. The largest binding-energy bands [binding energies of about 12 eV (C) to 22 eV (O)] correspond to the adsorbate $2s$ electronic states and form rather flat bands because of their relatively high degree of localization; the upward dispersion away from the center of the surface Brillouin zone is as expected from a simple tight-binding model.

In the energy range around 4–8-eV binding energy are seen bands associated with the adsorbate $2p$ states. These states overlap the photoemission signal from the Ni substrate, and so the full extent of the adsorbate-induced bands cannot be followed reliably at all points in **k** space. Nevertheless, we can expect that at

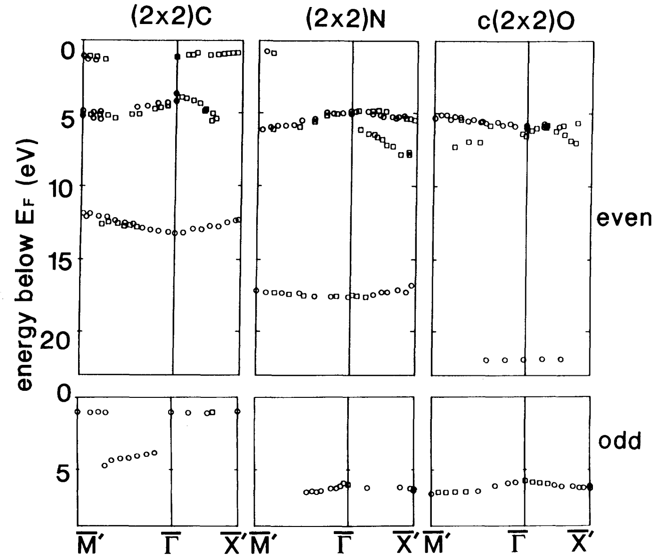

FIG. 21. Experimentally determined surface band structures of the adsorbate-induced states measured by ARUPS from half-monolayer structures of C, N, and O on Ni(100), plotted within the first surface Brillouin zone corresponding to a $c(2\times 2)$ overlayer mesh. After Kilcoyne *et al.* (1989).

the zone center the p_x and p_y states will be degenerate while the p_z-derived states (z perpendicular to the surface) will appear at a somewhat different energy, as a result of their different adsorbate-adsorbate and adsorbate-substrate interactions, even at this symmetry point. Note that the p_y states have odd parity relative to the mirror planes which contain the detector, and this difference in symmetry can be distinguished by polarization effects in photoemission; these states are plotted separately in the lower part of the figure. Different dispersion away from the zone center of the p_x-, p_y-, and p_z-derived states is expected to lead to three nondegenerate bands elsewhere in the two-dimensional Brillouin zone, although all three cannot always be discerned in the experimental data.

In addition, the C and N adsorption structures show some evidence of new surface localized states just below the Fermi level, although as these occur in an energy region overlapping the strong substrate d-band emission, the associated ARUPS peaks can only be reliably identified in some narrow regions of **k** space in which the d-band features are weak. These states close to the Fermi level are of particular interest, because although the half-monolayer coverage of O on Ni(100) appears to produce no significant distortion of the metallic substrate, both N and C do lead to a significant reconstruction. Following the arguments of Sec. 2.4 we might therefore expect to see electronic structure changes close to the Fermi level accompanying the geometrical reconstruction. The form of the reconstruction is illustrated in Fig. 22, in which the top-layer Ni atoms for an ideally terminated Ni(100) surface are shown as dashed circles, while the actual reconstructed sites are denoted by hatched circles; the adsorbed C or N atoms are shown as filled

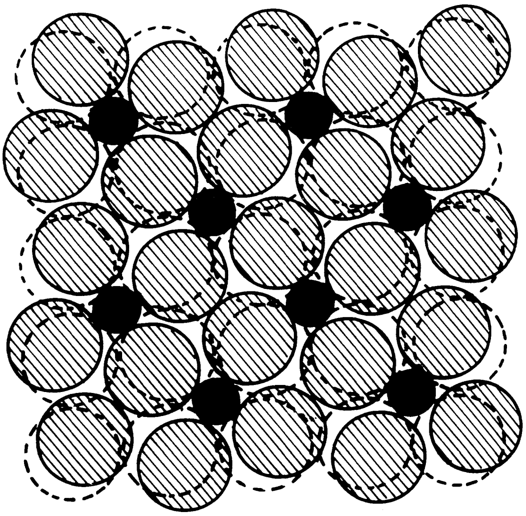

FIG. 22. Schematic diagram of the reconstruction induced by half-monolayer coverages of either C or N on a Ni(100) surface. The filled circles are the adsorbed atoms, the hatched circles are the top-layer Ni atoms, and the dashed circles show the positions of these top-layer Ni atoms for an ideally truncated surface.

circles. The origin of this adsorbate-induced substrate reconstruction is still far from clear but is of considerable academic as well as potential practical importance as a heterogeneous catalyst. The latter derives from the fact that the C adsorption structure appears to be the catalytically active surface phase in a methanation reaction conducted over this surface, implying that it is the electronic and chemical properties of this surface, rather than those of the clean metal, that are of chemical importance. In view of this, the small changes in the surface in the metal *d*-band region might be anticipated, but as yet the information available is too sparse to provide any real understanding of this problem.

3.3 Chemical Shifts in Core-Level Photoemission

As we have already remarked in Sec. 2.2, small shifts in the measured photoelectron binding energies of atomic core levels are well known to occur when the atom has its local valence electronic structure modified by different types of bonding, and these so-called chemical shifts (typically varying from a few tenths of an electron volt to several electron volts) provide an extremely valuable fingerprint of local bonding interactions at surfaces as well as in molecules and bulk compounds. The intrinsic surface sensitivity of the XPS method, which derives mainly from the short inelastic-scattering mean free path for electrons in the 10–1500-eV energy range appropriate to the method, means that it is particularly well suited to these surface studies.

A quantitative understanding of the magnitude (and even direction) of the observed chemical shifts is not at all straightforward because of the dual role of initial- and final-state effects, as described in Sec. 2.2. It is tempting to assign these chemical shifts to simple initial-state charge-transfer effects, but final-state relaxation energy shifts can be at least as large as these initial-state energy changes, and can be either of the same sign or the opposite sign as the initial state effects. For example, calculations of these two effects for O, Na, Si, and Cl, on an ideal free-electron surface (jellium) with an electron density appropriate to that of Al, yield initial-state energy shifts for adsorbate core levels of approximately +3.0, −1.0, +1.8, and +1.4 eV, respectively, but final-state shifts due to adsorbing these species of +7.8, +4.6, +5.2, and +4.8 eV (Williams and Lang, 1977). One possible quantitative route to the use, rather than interpretation, of these chemical shifts, is via the equivalent hole picture described earlier (Sec. 2.2) in which one recognizes that core ionization leaves behind a relaxed valence electronic environment equivalent to that of a neutral atom of the next element of the periodic table. It is therefore possible, by the construction of thermodynamic Born-Haber cycles (in which the energy changes in ionizing, adsorbing, and transmuting an atom of atomic number Z to one of $Z+1$ are followed around a closed loop), to relate core-level shifts to heats of adsorption (or segregation) at surfaces (Johansson and Mårtensson, 1980; Rosengren and Johansson, 1981).

Far more common, however, is the use of chemical shifts as a fingerprint of changes in local electronic environment or "chemical state." In studies of basic surface chemistry one often uses the measured photoelectron binding energies in solids or molecules of known valency to help identify the valency of adsorbed species. In other cases, one may simply concentrate on the fact that different chemical shifts signal changes in chemical state which can be correlated with changes seen in other techniques (which could be electronic, vibrational, or structural probes). An example of this kind of application, which also highlights the fact that interesting chemical shifts may be seen in the substrate as well as the adsorbate atoms, is shown in Fig. 23. It is well known that the Al $2p$ core-level photoemission peaks (spin-split doublets with a separation of approximately 0.4 eV) show a large chemical shift of some 2.6 eV when an aluminum surface is oxidized. In the case of Al(111), this broad oxide-state peak is seen at large oxygen exposures [measured in Langmuirs, where one Langmuir corresponds to an exposure at a pressure of 10^{-6} Torr (1.33×10^{-4} Pa or 1.33×10^{-6} mbar) for 1 s], but at lower exposures three different, intermediately shifted pairs of peaks (with shifts of approximately 0.5, 1.0, and 1.5 eV) appear. Figure 23 shows the rich spectrum of features resulting from this effect, but although the surface sensitivity and energy resolution have been enhanced by using synchrotron-radiation photons of energy 120 eV, proper resolu-

tion of all these peaks requires simple quantitative curve fitting. The analysis of the data indicates that all of these extra peaks are associated with surface Al atoms bonded to a simple chemisorbed atomic oxygen overlayer, whereas the higher chemical shift oxide peak is associated with Al atoms in a thin surface oxide, probably involving both overlayer and underlayer oxygen. One surprising feature of this result is that it indicates that quite local Al–O bonding must occur even on this rather free-electron-like metal surface.

INTRODUCTION

"Transport in solids" covers quite a large number of phenomena, but obviously, transport in liquids and gases is not a part of these. In the present context, "electronic" transport in solids will be delimited as the transport of charge and heat in solid electrical conductors, i.e., metals, semimetals, and semiconductors. Insulators, with their vanishingly small conductivities, will not be treated.

The concept of charge, i.e., the elementary charge of the electron, is supposed to require no explanation. Transport of charge means an electric current and, as the electron carries a mass, a transport of mass. A heat current, on the contrary, is defined in a somewhat subtle way: when a particle enters or leaves a material, it gives to the surroundings, or takes from them, the work function of the material. Such a current of work function is just proportional to the electric current, and consequently it is not a new concept. The new concept, the heat current, appears when the current of work function is subtracted from the energy current.

The two concepts are illustrated in Fig. 1 in terms of velocity distributions for a definite direction, say x, i.e., the probability of finding electrons with velocity v_x is displayed as function of v_x. In 1(a) there are no currents at all. In 1(b) there is an electric current, but no heat current. Finally in 1(c) there is a heat current, but no electric current.

The units of the two currents are coulomb per second and joule per second, with the shorter names ampere (A) and watt (W), respectively. The current passing through a

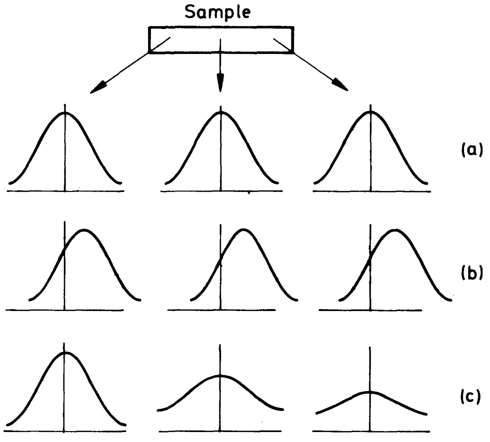

FIG. 1. Velocity distributions at three places in a sample, i.e., probabilities of finding the velocity v_x is displayed as function of v_x. In (a) the distribution is the same everywhere, and the average value of v_x is zero everywhere. In (b) the distribution is the same everywhere, but is shifted with respect to (a) so that it has a nonzero average value. Finally in (c) the average value of v_x is zero everywhere but the distributions become broader towards one end of the sample (the warm end).

unit square perpendicular to the direction of flow is denoted current density. The two current densities are thus measured in units A m^{-2} and W m^{-2}.

To produce a current, an external action is needed. This can be gradients of electrical potential, of temperature, or of electron concentration, i.e., spatial changes of these quantities. If a static magnetic field is applied to a sample in which a current flows, the nature of the flow is changed. By itself, a static magnetic field does not produce a current, and accordingly, in the equations describing the currents, such a field is treated differently from the gradients of electrical potential, temperature, or concentration. The very same remark holds for an applied static pressure.

The structure of the present article is largely historic, starting with the description used in the beginning of this century, and ending with a few of the last decades' discoveries. Quantum-mechanical features are treated, but without writing down the Schrödinger equation. The reader is assumed to be familiar with vectors and tensors, as well as with complex numbers.

For a deeper insight, the textbooks by Ziman (1960) and by Smith and Jensen (1989) are recommended, as well as cross references in the present encyclopedia, e.g., TRANSPORT PHENOMENA; HEAT TRANSFER; THERMAL CONDUCTION IN SOLIDS; SOLIDS, DIFFUSION IN; SUPERCONDUCTIVITY, LOW-TEMPERATURE; HIGH-TEMPERATURE SUPERCONDUCTIVITY.

1. CURRENTS, FIELDS, AND RELAXATION TIME; SYMBOLS

With two types of currents and three types of forces to drive the currents, plus the possibilities of an applied static magnetic field or pressure, the number of phenomena becomes large. Moreover, the actions inside the solid, the so-called scattering of electrons, need a level of description. For this, the most elementary one is in terms of a single parameter: the relaxation time τ. These concepts, with their symbols, are illustrated in Fig. 2.

2. THE DRUDE MODEL: OHM'S LAW

Already in 1900 P. Drude put forward a model that took account of relaxation effects. Drude's model consists mainly in describing the flow by the average velocity, $\mathbf{v}_a$, resulting from external forces and internal "frictional" forces, along with assuming that all carriers act independently. The Drude frictional force is

$$\mathbf{F}_{\text{Drude}} = -m\mathbf{v}_a/\tau\,; \tag{1}$$

and, in the very simplest case where the external force arises from an electric field **E**, the Newtonian equation of motion becomes

$$m\frac{d\mathbf{v}_a}{dt} = q\mathbf{E} - \frac{m\mathbf{v}_a}{\tau}\,. \tag{2}$$

The meaning of the Drude relaxation time τ is illustrated in Fig. 3, where a step function for the electric field is considered. The expression for $v_a(t)$ is the solution of Eq. (2), and from this the relaxation time appears as the time needed for the velocity to reach the fraction $1-e^{-1}$ of the steady state value $(q\tau/m)E_0$.

The electric current density in the steady state of Fig. 3 is

$$\mathbf{j} = nq\mathbf{v}_{a,\infty} = (nq^2\tau/m)\mathbf{E}_0 = \sigma_0\mathbf{E}_0, \tag{3}$$

where σ_0 is the electric conductivity in the Drude model,

$$\sigma_0 = nq^2\tau/m. \tag{4}$$

FIG. 2. Symbols (units) used in the present article. The carrier charge q can be either $-e$ (electrons) or $+e$ (holes), e being the elementary charge: $e=1.602\times10^{-19}$ C. The effective mass **m** is different from the mass of a free electron; it has a value characteristic for each solid. It can be anisotropic like the relaxation time τ.

The linear relation between current density and electric field expressed by Eq. (3) displays Ohm's law.

2.1 Optics

If, instead of the step function, an alternating electric field of frequency f is applied,

$$\mathbf{E}=\mathbf{E}_0 e^{-i2\pi ft}, \tag{5}$$

then there is no steady state, $dv_a/dt=-i2\pi f v_a$, and the conductivity becomes

$$\sigma=\sigma_0(1-i2\pi f\tau)^{-1}. \tag{6}$$

For $2\pi f\tau=1$, the imaginary and the real parts of σ are identical.

The link to optical properties is provided by the Maxwell equation for the curl of the magnetic field strength:

$$\nabla\times\mathbf{H}=\mathbf{j}+\epsilon_L\frac{\partial\mathbf{E}}{\partial t}=\epsilon\frac{\partial\mathbf{E}}{\partial t}. \tag{7}$$

The quantity ϵ so defined is denoted permittivity, and using $j=\sigma E$ the following relation results:

$$\epsilon=\epsilon_L-\sigma/i2\pi f, \tag{8}$$

where ϵ_L is the permittivity related to the ion cores.

Figure 4 illustrates the application of the Drude model to gold. The high-frequency part of the data was obtained from measurements of reflectance versus frequency; the low-frequency part, from waveguide transmission.

2.2 dc Electric and Magnetic Fields

When electric as well as magnetic fields are applied, the term $q\mathbf{E}$ in Eq. (2) is replaced by the Lorentz force, i.e.,

$$\mathbf{m}\cdot\frac{d\mathbf{v}_a}{dt}=q(\mathbf{E}+\mathbf{v}_a\times\mathbf{B})-\frac{\mathbf{m}\cdot\mathbf{v}_a}{\tau}, \tag{9}$$

where **m** allows for an anisotropic mass. In the steady state the solution for $\mathbf{v}_a$ is

$$\mathbf{v}_a=[(\mathbf{m}/\tau)+q\boldsymbol{B}]^{-1}\cdot q\mathbf{E}. \tag{10}$$

Here $\boldsymbol{B}$ is the tensor representation of the magnetic flux density,

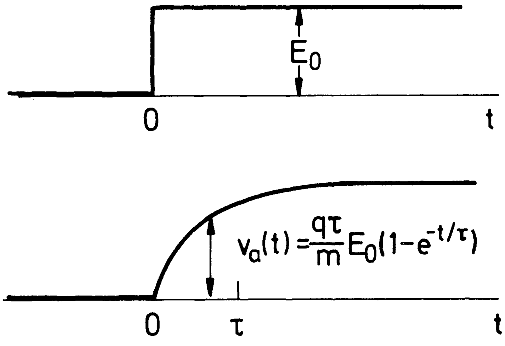

FIG. 3. Step function of the electric field and the velocity resulting from Eq. (2) as function of time.

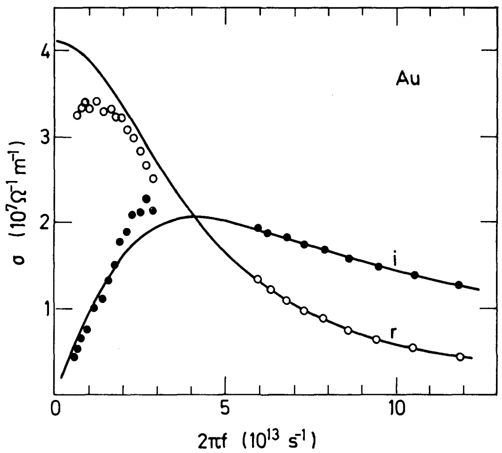

FIG. 4. Real (*r*) and imaginary (*i*) parts of the conductivity of gold in the infrared as function of the frequency. The high-frequency part represents a fit to data of reflectance vs frequency with $\sigma_0=4.09\times10^7\ \Omega^{-1}\ \mathrm{m}^{-1}$, $\tau=2.46\times10^{-4}$ s. The continuous curve is based on these values and Eq. (6). The low-frequency part was obtained from measurements of waveguide transmission (Smith and Jensen, 1989, p. 103).

$$\boldsymbol{B}=\begin{pmatrix} 0 & -B_z & B_y \\ B_z & 0 & -B_x \\ -B_y & B_x & 0 \end{pmatrix}, \tag{11}$$

and the expression (10) for $\mathbf{v}_a$ is found using the identity

$$\mathbf{v}_a\times\mathbf{B}=-\boldsymbol{B}\cdot\boldsymbol{v}_a\,. \tag{12}$$

From Eq. (10) the expression for the conductivity becomes

$$\sigma=\sigma_0\cdot\,(\mathbf{1}+q\tau\boldsymbol{B}\cdot\boldsymbol{m}^{-1})^{-1}, \tag{13}$$

$$\sigma_0=nq^2\tau\mathrm{m}^{-1}. \tag{14}$$

2.2.1 Hall Effect, Magnetoresistance, and Mobility. The concepts of Hall effect and magnetoresistance refer to the inverse of the conductivity tensor, the resistivity tensor $\boldsymbol{\rho}$. With $\boldsymbol{\sigma}$ given by Eq. (13) the resistivity tensor becomes

$$\rho=\sigma^{-1}=(\mathbf{1}+q\tau\boldsymbol{B}\cdot\boldsymbol{m}^{-1})\cdot\rho_0=\rho_0+(1/nq)\boldsymbol{B}. \tag{15}$$

The ways in which the elements of $\boldsymbol{\rho}$ and $\boldsymbol{\sigma}$ can be measured are discussed in Sec. 7. At present it is just noted that Hall effect and magnetoresistance are described by, respectively, the nondiagonal and diagonal elements of $\boldsymbol{\rho}$.

If the direction of $\mathbf{B}$ is chosen as the z direction, it follows from Eqs. (11) and (15) that

$$\rho_{xy}=-\rho_{yx}=-B/nq. \tag{16}$$

The Hall coefficient is defined as

$$R_{\mathrm{H}}=\rho_{yx}/B. \tag{17}$$

The expression for R_{H} finds extremely widespread use in determination of the carrier density, and, as the charge q appears to the first power, also of the type of carriers, i.e., electrons or holes. In contrast to this, the diagonal elements—being independent of B—do not explain the experimentally well-known phenomenon of magnetoresistance. The reason for this failure can be understood from the fact that the average velocity $\mathbf{v}_a$ was assumed to be the same for each carrier. Consequently, the force $q\mathbf{v}_a\times\mathbf{B}$ is the same for each carrier and is balanced by the electric field from the surface charge, cf. Fig. 20. Hereby, the effect of $\mathbf{B}$ on $\mathbf{v}_a$ is cancelled. From this argumentation a nonzero magnetoresistance is to be expected whenever different carriers, or groups of carriers, have different $\mathbf{v}_a$'s. This is especially the case for semiconductors and semimetals with two types of carriers: negatively charged electrons ($q=-e$) and positively charged holes ($q=e$). Here Eq. (13), when used for each of the two types, gives in most cases a fair description of the Hall effect as well as of the magnetoresistance. For metals more subtle ideas have to be invoked.

In the expressions for $\boldsymbol{\sigma}$ and $\boldsymbol{\rho}$ the factor $q\tau\mathbf{m}^{-1}$ appears on the magnetic flux density. This factor is denoted as mobility, μ. Usually a positive value is meant, i.e.,

$$\mu=e\tau\mathrm{m}^{-1}. \tag{18}$$

Mobilities are measured in units of inverse magnetic flux density: $[\mu]=(\mathrm{V\ s\ m^{-2}})^{-1}$.

2.2.2 Multicarrier Systems: Semiconductors and Semimetals. In semiconductors and semimetals, electrons as well as holes can be carriers of the electric current density. To distinguish the two, subscripts e and h will be used. Thus the equation

$$\mathbf{j}=\mathbf{j}_e+\mathbf{j}_h \tag{19}$$

expresses the idea on which transport in multicarrier systems is based: the current density is found by adding the contributions from each group. In fields sufficiently weak, Ohm's law will be valid for each group, i.e.,

$$\mathbf{j}_e=\boldsymbol{\sigma}_e\cdot\mathbf{E},\quad \mathbf{j}_h=\boldsymbol{\sigma}_h\cdot\mathbf{E}. \tag{20}$$

This means that the conductivity is the sum of $\boldsymbol{\sigma}_e$ and $\boldsymbol{\sigma}_h$:

$$\boldsymbol{\sigma}=\boldsymbol{\sigma}_e+\boldsymbol{\sigma}_h\,. \tag{21}$$

Although the idea presented by these three equations is simple, it takes some algebra to carry out the calculations when a magnetic field is applied. Thus, whereas Eq. (15) could be obtained from Eq. (13) with no calculations at all, it is now necessary to evaluate $(\mathbf{1}+q\tau\boldsymbol{B}\cdot\boldsymbol{m}^{-1})^{-1}$ in Eq. (13) before the two parts $\boldsymbol{\sigma}_e$ and $\boldsymbol{\sigma}_h$ can be added together, and finally the inverse of their sum, i.e., $\boldsymbol{\rho}$, can be found. Only some results for the case of isotropic mass and z axis along **B** will be presented.

The inversion that appears on the right-hand side of Eq. (13) gives

$$\sigma_{xx}=\sigma_{yy}=\frac{\sigma_0}{1+(q\tau/m)^2B^2}\,, \tag{22}$$

$$\sigma_{zz}=\sigma_0\,, \tag{23}$$

$$\sigma_{xy}=-\sigma_{yx}=\frac{\sigma_0}{1+(q\tau/m)^2B^2}\,\frac{q\tau}{m}\,B, \tag{24}$$

$$\sigma_{xz}=\sigma_{zx}=\sigma_{yz}=\sigma_{zy}=0. \tag{25}$$

When electrons as well as holes are present, every element of $\boldsymbol{\sigma}$ becomes a sum of an electron and a hole contribution. As $\boldsymbol{\sigma}$ gets the symmetry of $\boldsymbol{\sigma}_e$ and $\boldsymbol{\sigma}_h$, its inverse can be found from the relations

$$\rho_{xx}=\rho_{yy}=\sigma_{xx}/[(\sigma_{xx})^2+(\sigma_{xy})^2], \tag{26}$$

$$\rho_{zz}=1/\sigma_{zz}\,, \tag{27}$$

$$\rho_{yx}=-\rho_{xy}=\sigma_{xy}/[(\sigma_{xx})^2+(\sigma_{xy})^2], \tag{28}$$

$$\rho_{xz}=\rho_{zx}=\rho_{yz}=\rho_{zy}=0. \tag{29}$$

The resulting resistivity tensor is most conveniently considered in very weak or very strong magnetic fields, where "weak" and "strong" refer to μB being smaller or larger than one.

To zeroth order in μB, i.e., with no magnetic flux density applied, $\boldsymbol{\rho}$ simply becomes a scalar:

$$\boldsymbol{\rho}=(\sigma_{0e}+\sigma_{0h})^{-1}\mathbf{1}\quad\text{for}\quad B=0. \tag{30}$$

To first order in μB the result is

$$\boldsymbol{\rho}=(\sigma_{0e}+\sigma_{0h})^{-1}\begin{pmatrix}1 & -\tilde{\mu}B & 0\\ \tilde{\mu}B & 1 & 0\\ 0 & 0 & 1\end{pmatrix}, \tag{31}$$

where $\tilde{\mu}$ is short for

$$\tilde{\mu}=\frac{\sigma_{0h}\,\mu_h-\sigma_{0e}\,\mu_e}{\sigma_{0e}+\sigma_{0h}}\,. \tag{32}$$

Magnetoresistance only appears when second-order terms in μB are included. In this case,

$$\rho_{xx}=\rho_{yy}=\frac{1}{\sigma_{0e}+\sigma_{0h}}\left(1+\frac{\sigma_{0e}\sigma_{0h}(\mu_e+\mu_h)^2}{(\sigma_{0e}+\sigma_{0h})^2}\,B^2\right), \tag{33}$$

$$\rho_{zz}=1/(\sigma_{0e}+\sigma_{0h}), \tag{34}$$

$$\rho_{yx}=-\rho_{xy}=\frac{\sigma_{0h}\,\mu_h-\sigma_{0e}\,\mu_e}{(\sigma_{0e}+\sigma_{0h})^2}\,B, \tag{35}$$

$$\rho_{xz}=\rho_{zx}=\rho_{yz}=\rho_{zy}=0. \tag{36}$$

For very strong magnetic fields, expansions in $(\mu B)^{-1}$ and $(\mu B)^{-2}$ are made. This gives

$$\rho_{xx}=\rho_{yy}=\frac{(n_e/\mu_e)+(n_h/\mu_h)}{e(n_h-n_e)^2}\quad\text{for}\quad \mu B\gg 1, \tag{37}$$

$$\rho_{zz}=1/(\sigma_{0e}+\sigma_{0h}), \tag{38}$$

$$\rho_{yx}=-\rho_{xy}=\frac{1}{e(n_h-n_e)}\,B, \tag{39}$$

$$\rho_{xz}=\rho_{zx}=\rho_{yz}=\rho_{zy}=0. \tag{40}$$

Thus the transverse magnetoresistance saturates while the Hall element becomes independent of the mobilities.

The appearance of n_h-n_e in the denominators of Eqs. (37) and (39) means that these equations do not apply for compensated materials, i.e., when the densities of electrons and holes are equal. In this case it can be shown that the transverse magnetoresistance increases as B^2 while the Hall element is still linear in B, but with a prefactor that depends on the mobilities.

As an example of the application of the multicarrier concept, Figs. 5(a) and 5(b) display respectively the Hall effect and the resistivity in p-type InSb. The experimental results

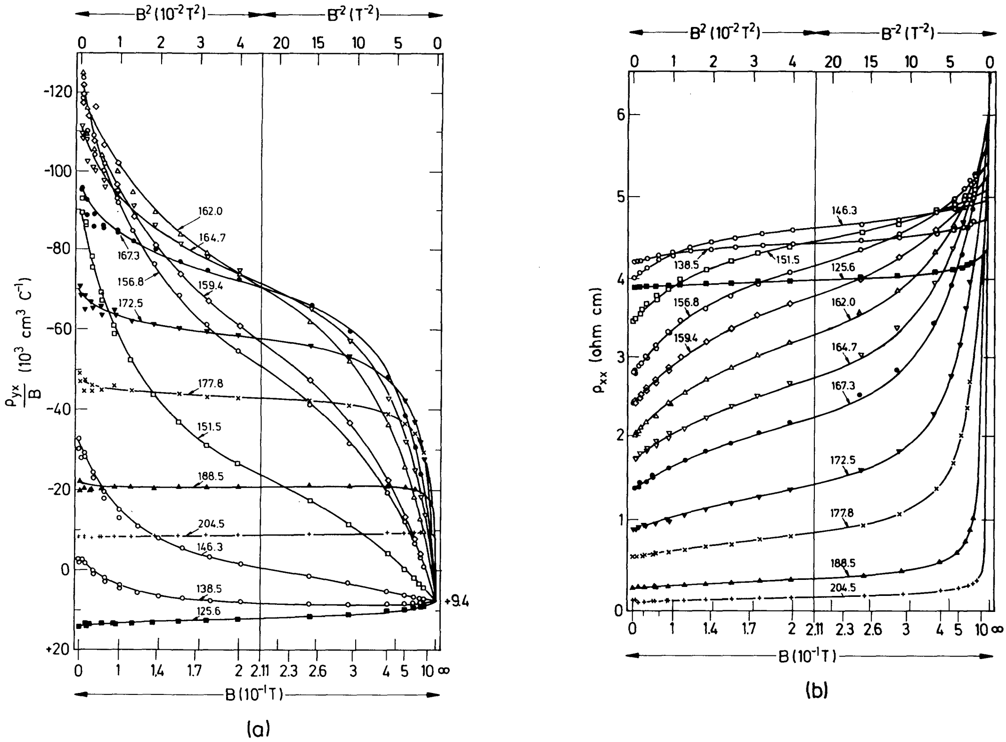

FIG. 5. (a) Hall coefficient and (b) magnetoresistance vs magnetic field for a single crystal of p-type InSb at various temperatures. The points display experimental values and the continuous curves display the results of calculations based on a three-carrier model (Blatt, 1968, p. 293).

were interpreted by a three-carrier model: electrons, heavy holes, and light holes. Extension of the two-carrier model to this case is straightforward. The six parameters, three densities and three mobilities, were determined such that the experimental points were reproduced as well as possible. Obviously the multicarrier formulas display sufficient complexity to allow for the fairly extensive field variations of Hall effect and magnetoresistance.

2.2.3 Metals. It might be expected that metals would be single-carrier systems, electrons being the only type of carrier. However, because of the complexity of the Fermi surface it turns out that transport can be mediated also by holes (See ELECTRON STRUCTURE OF SOLIDS). In such cases, the multicarrier concepts presented in the preceding section find applications also for metals.

As an example, the Fermi surface of aluminum is shown in Fig. 6. Out of the three valence electrons per Al atom, two fill up completely the first Brillouin zone. The one electron left is shared between the second and third zone. Figure 6(a) shows portions of the free-electron sphere when translated back into the first zone. The convex surface encloses holes, and, as each zone has two states per atom, the sum of electron and hole densities equals twice the density of Al atoms:

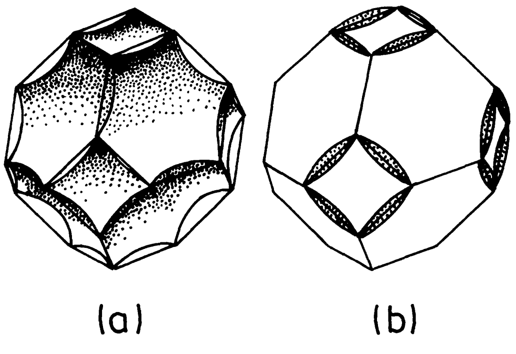

FIG. 6. (a) First Brillouin zone of Al with the parts of the free-electron sphere in the second zone translated back into the first. (b) As in (a) but now for the parts in the third zone (Ashcroft and Mermin, 1976, p. 301).

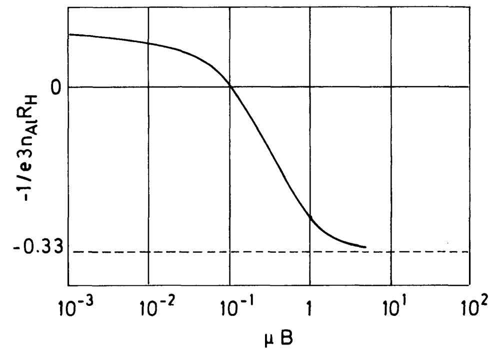

FIG. 7. Experimental values of Hall effect in polycrystalline Al (Ashcroft and Mermin, 1976, p. 15 and Lück, 1966). R_H denotes the measured Hall coefficient, and n_{Al} the density of aluminum atoms.

$$(n_e)^{II}+(n_h)^{II}=2n_{Al}\ . \qquad (41)$$

Figure 6(b) shows parts of the free-electron sphere in the third zone when translated back into the first zone. As only one electron per atom was left after filling the first zone, the electron densities in the second and third zone must sum up to the density of Al atoms:

$$(n_e)^{II}+(n_e)^{III}=n_{Al}\ . \qquad (42)$$

Thus according to Eqs. (41) and (42) the difference between hole and electron densities becomes

$$(n_h)^{II}-(n_e)^{III}=n_{Al}\ . \qquad (43)$$

Within the multicarrier concept this gives an expected strong-field limit of the Hall coefficient:

$$R_H=\frac{1}{e}\frac{1}{(n_h)^{II}-(n_e)^{III}}=\frac{1}{en_{Al}}\ . \qquad (44)$$

This is precisely what is observed; i.e., the strong-field Hall coefficient of polycrystals as well as single crystals has a value consistent with one positive carrier per Al atom; see Fig. 7.

In contrast to the strong-field limit of the Hall coefficient, the magnetoresistance has features that are not explainable in terms of the multicarrier concepts. Figure 8 displays results on single crystals of Al; the saturation in strong fields predicted by Eq. (37) is obviously not observed. Instead the magnetoresistance increases linearly, and the strength of this linear increase depends on the orientation of the magnetic field.

The horizontal variable in Fig. 8, B/ρ_0, is commonly used when magnetoresistance data are presented. With the simple expression $m/ne^2\tau$ for ρ_0 [cf. Eqs. (14) and (15)], B/ρ_0 becomes

$$B/\rho_0=\mu Bne. \qquad (45)$$

Materials for which the magnetoresistance depends on B only through B/ρ_0 are said to obey Kohler's rule.

The nonsaturation of magnetoresistance, exemplified above by the case of Al, is observed as well in other metals with closed

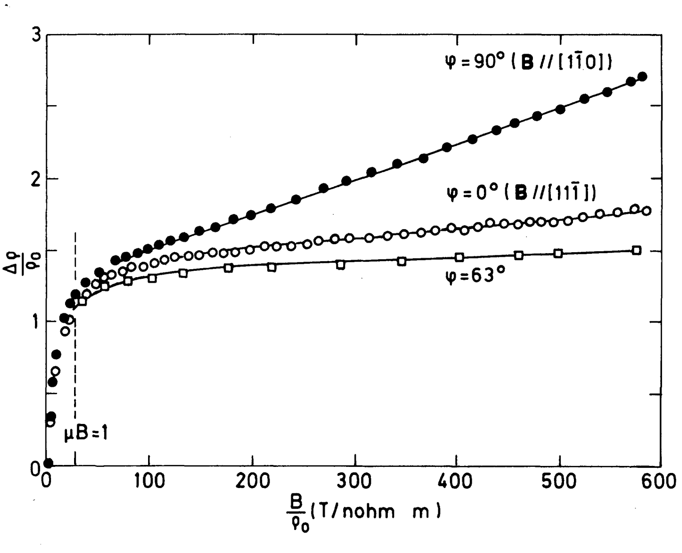

FIG. 8. Magnetoresistance of single-crystalline Al vs the Kohler variable B/ρ_0; $\rho_0=0.60$ nΩ cm (Kesternich *et al.*, 1975).

Fermi surfaces, such as In, Na, and K. Many proposals have been offered to explain this, among them magnetic breakdown (Kesternich *et al.*, 1975) and surface imperfections (Bruls *et al.*, 1981).

Aluminum belongs to a large group of metals having closed Fermi surfaces. However, metals with open Fermi surfaces exist, and in this case ranges of **B** directions can give rise to open carrier orbits. A typical example is the crimped cylinder, shown in Fig. 9. For this, open carrier orbits appear when **B** is perpendicular to the cylinder axis. The metals Cu, Ag, and Au belong to this category.

A theory based on the geometry of the Fermi surface was worked out by Lifshitz *et al.* (1957). The result was saturation of magnetoresistance for closed orbits and quadratic increase for open orbits. As the appearance of open orbits depends on the field direction, magnetoresistance for this case is expected to be strongly anisotropic.

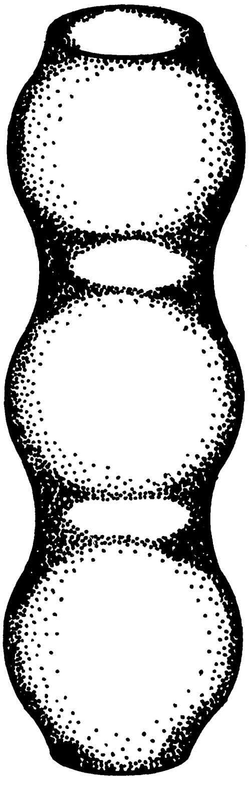

FIG. 9. Crimped cylinder (Lifshitz *et al.* 1957).

2.3 Magneto-optics: Cyclotron Frequency

The generalization of Eq. (10) to the case of an oscillating electric field, as in Eq. (5), is straightforward. The result for the conductivity becomes

$$\sigma=\sigma_0[(1-i2\pi f\tau)\mathbf{1}+(q\tau/m)\boldsymbol{B}]^{-1}. \qquad (46)$$

Free carriers, besides giving rise to the conductivity, also modify the applied field. This is especially so for metals, where the large density of free carriers screens out the electric field. Oppositely, for semiconductors with small densities of free carriers, the electric field inside the material can to a first approximation be taken as the vacuum field.

Thus for semiconductors the power absorption per unit volume can be approximated by

$$P_{\mathrm{av}}=\tfrac{1}{2}\,\mathrm{Re}(\mathbf{j}_0\cdot\mathbf{E}_0^*), \qquad (47)$$

where the subscript av means time average, Re means real part, the asterisk denotes complex conjugation, and $\mathbf{E}_0$ is the amplitude of the electric field as given by Eq. (5).

Figure 10 illustrates a common configuration: The electromagnetic wave propagates parallel to the static magnetic flux density and perpendicular to the sample surface (Faraday configuration). When the wave equation for this configuration is solved, it turns out that the solutions for **E** are in the form of a circularly polarized wave. With coordinates chosen as in Fig. 10 this means x and y components of the electric field related by

$$E_{0x}=\pm iE_{0y}, \qquad (48)$$

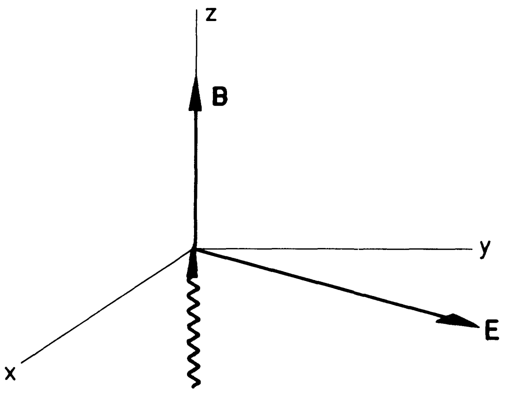

FIG. 10. Faraday configuration of a static magnetic flux density **B** and the electric field **E** of an electromagnetic wave propagating in the direction of **B**, which is perpendicular to the sample surface.

where the upper (lower) sign is for right (left) polarization. When used in Eq. (47), the power absorption of the two polarizations becomes

$$P_{\mathrm{av}}^{\pm}=(E_{0x})(E_{0x})^{*}\mathrm{Re}(\sigma_{xx}\mp i\sigma_{xy}). \tag{49}$$

The expressions (22) and (24) for σ_{xx} and σ_{xy} then give

$$P_{\mathrm{av}}^{\pm}=(E_{0x})(E_{0x})^{*}\frac{\sigma_0}{1+(2\pi f\pm 2\pi f_c)^2\tau^2}. \tag{50}$$

This has a maximum for either right or left polarization when the frequency equals the cyclotron resonance frequency f_c:

$$f_c=\pm(1/2\pi)(eB/m), \tag{51}$$

where the upper (lower) sign is for electrons (holes).

Cyclotron resonance was discovered in the semiconductor germanium in 1953 by Dresselhaus, Kip, and Kittel [see the review by Lax and Mavroides (1960)]. From measurements of the frequency at resonance, the carrier mass can be calculated using Eq. (51). The results of such measurements and calculations are displayed in Fig. 11 for the case of germanium. Three resonances were observed for each direction of the magnetic flux density. The resulting masses are seen to be strongly anisotropic.

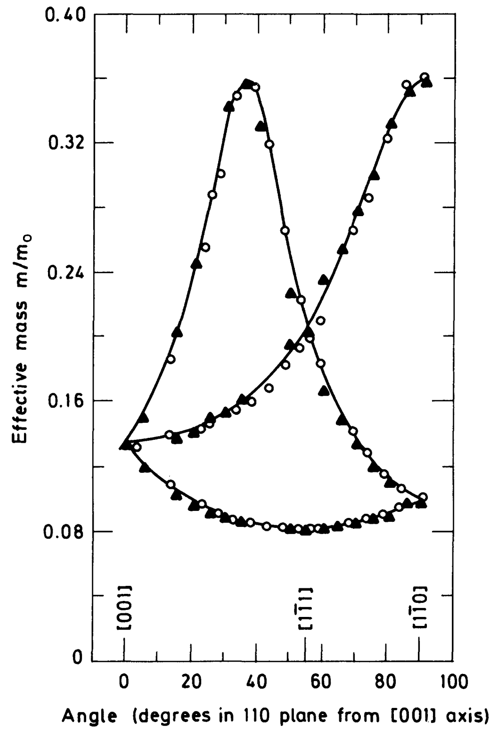

FIG. 11. Effective electron masses of germanium vs angle of magnetic flux density (Lax and Mavroides, 1960).

2.4 Thermal Conductivity, Fourier's Equation, and Thermal Diffusivity

The concept of heat current was illustrated in Fig. 1(c). The sample has a warm end and a cold end; i.e., a temperature gradient ∇T exists. The relation between ∇T and the heat current can be found by considering a particle traveling with velocity $\mathbf{v}_a$ from one region to another. To keep in thermal equilibrium with its immediate surroundings it energy has to change at a rate

$$\frac{\partial E}{\partial t}=c\mathbf{v}_a\cdot\nabla T, \tag{52}$$

c being the heat capacity per particle. As the particle moves a distance $v_a\tau$ without scattering, it contributes to the heat current by $v_a\tau\partial E/\partial t$. Taking the average over all directions of the velocity and summing over all particles, the heat-current density becomes

$$\mathbf{u}=-\tfrac{1}{3}Cv_a^2\tau\nabla T, \tag{53}$$

C being the heat capacity per volume.

The proportionality between heat-current density and the temperature gradient is often referred to as Fourier's equation, the constant of proportionality being the thermal conductivity κ:

$$\mathbf{u}=-\kappa\nabla T,\quad \kappa=\tfrac{1}{3}Cv_a^2\tau. \tag{54}$$

The diffusive nature of heat conduction is displayed when the time derivative of the energy is written as $C\partial T/\partial t$. Then energy conservation can be expressed by

$$C\frac{\partial T}{\partial t}+\nabla\cdot\mathbf{u}=0, \tag{55}$$

which together with Fourier's equation, leads to the diffusion equation for T:

$$\frac{\partial T}{\partial t}-\frac{\kappa}{C}\nabla^2 T=0. \tag{56}$$

The quantity κ/C is denoted thermal diffusivity. It is a main parameter for the description of heat pulse propagation in solids (*q.v.*).

2.5 Limitations

Although quite successful in describing a number of phenomena pertaining to electric and thermal conduction, the Drude model suffers from the lack of quantum-mechanical features. First, the particle quantum statistics is lacking, i.e., there is no way to include the Pauli principle for electrons. Also, the special quantization of electron orbits when a magnetic field is applied is absent, as is the whole concept of band structure of solids. The scattering should be given a quantum-mechanical description as well; however, a relaxation-time approximation can often be used.

3. WAVE FEATURES AND *k* SPACE

If scattering is described by a relaxation time, then the only nonclassical features that need to be introduced are the wave nature of moving particles and the Pauli exclusion principle.

The wave nature is expressed by the de Broglie relation:

$$k=2\pi/\lambda=mv/\hbar, \tag{57}$$

where k is the wave number, λ is the wavelength, and $\hbar$ is Planck's constant divided by 2π. Wave numbers are quantized according to the rule of periodic boundary conditions, i.e., along each of the three spatial dimensions, there should be an integer number of wavelengths. This rule selects discrete values of the wavelength:

$$\lambda\times\text{integer}=\text{spatial dimension}; \tag{58}$$

and according to (57) this means **k** values that are discrete and equally spaced.

This property of **k** values makes the **k** space a very useful concept. It is illustrated in Fig. 12(a). The discrete **k** values are denoted **k** states. According to Eqs. (57) and (58) they are spaced by $2\pi/L$; i.e., in the volume $(2\pi)^3/L_xL_yL_z$ there is just one **k** state, which means that the density of states in **k** space is $(2\pi)^{-3}$ per unit volume.

The Pauli principle is accounted for by the Fermi-Dirac distribution function—see Fig. 12(b)—which gives the probability of actually finding an electron in a state **k**:

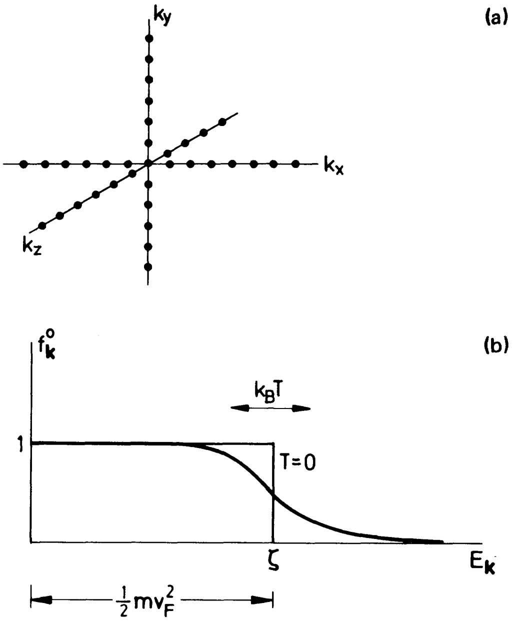

FIG. 12. Quantum-mechanical features. (a) Wave-number space, or **k** space. The spacings are $2\pi/L$, L being the (x,y,z)-edge lengths of the sample. (b) The Fermi-Dirac distribution function; ζ is the Fermi level.

$$f^0_{\mathbf{k}}=\{\exp[(E_{\mathbf{k}}-\zeta)/k_BT]+1\}^{-1}. \tag{59}$$

Here $E_{\mathbf{k}}$ is the energy of the state **k** and ζ is the energy at the Fermi level.

The wave vector **k** changes in time according to

$$\hbar\frac{d\mathbf{k}}{dt}=q(\mathbf{E}+\mathbf{v}\times\mathbf{B}). \tag{60}$$

As was the case for the Drude model, it is the Lorentz force that determines the dynamics of the system; cf. Eq. (9).

3.1 Metal-Insulator Transitions

The transition from a metallic, conducting state to an insulating state may be viewed in two ways: the starting point can be the metal or it can be the insulator.

Let the starting point be the metal, and let this be described by the mobility $\mu=e\tau/m$. As the mean free path $l=\tau v_F$ may be more easily visualized than τ, the mobility is written alternatively as $\mu=el/mv_F$. The question is then the following: Is there a lower limit of the mean free path below which the description breaks down? Ioffe and Regel (1960) have argued: Yes, if the mean free path, calculated from the ordinary mobility formulas, becomes less than the interatomic distances, then the mechanism of mobility itself must be altogether different, and the concept of a mean free path has no meaning. Thus, with symbols,

$$a \leqslant l. \tag{61}$$

which is known as the Ioffe-Regel rule.

If, on the contrary, the starting point is the insulating state, then the electrons are orbiting the atoms within a distance of the order of the Bohr radius

$$r_B = \frac{h^2 \epsilon_0}{m_0 \pi e^2} \frac{\epsilon}{m/m_0}. \tag{62}$$

In this case the question is: How close can neighboring atoms be before electrons start to become itinerant? An early estimate was made by Mott [see Mott (1982) for a review] of the critical value of the lattice constant a_c:

$$a_c \leqslant 4.5 r_B. \tag{63}$$

As an example of this, consider a semiconductor being doped with increasing concentration of donor atoms. A transition will then occur to a conducting metallic state. Experimental results for silicon doped with phosphorus is shown in Fig. 13. Here the metal-insulator transition takes place at a density $n_c = 3.74 \times 10^{18}$ cm^{-3}. If phosphorus is taken to be a monovalent donor in silicon, then a_c can be estimated as

$$a_c \sim n_c^{-1/3} = 0.64 \times 10^{-6} \text{ cm}.$$

The Bohr radius in silicon is approximately 20 Å, which gives $a_c \sim 3.2 r_B$, i.e., the order of magnitude expected from the Mott criterion.

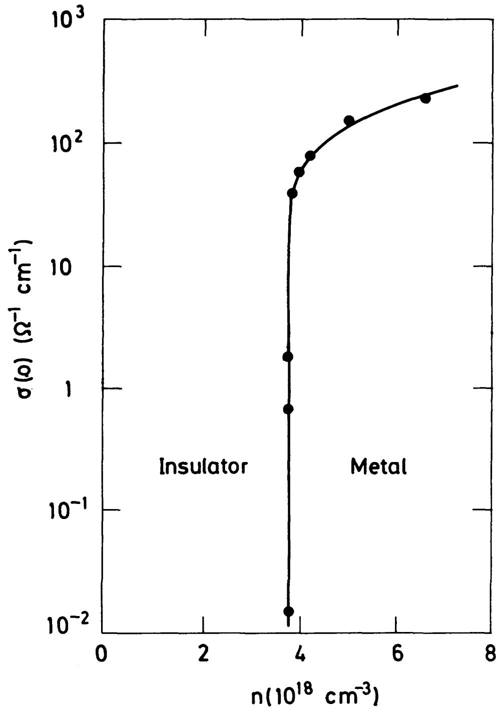

FIG. 13. Semilogarithmic plot of observed "zero temperature" conductivity $\sigma(0)$ vs donor concentration n for phosphorus donors in silicon (Kittel, 1986, p. 269).

Situations where either Eq. (61) or (63) is not fulfilled will not be treated in the present article. The reader may consult ELECTRON STATES, LOCALIZED and SEMICONDUCTORS, AMORPHOUS—ELECTRONIC PROPERTIES.

4. THE BOLTZMANN EQUATION

The Boltzmann equation describes the evolution in time of $f_\mathbf{k}$ as $\mathbf{k}$ changes according to Eq. (60) and the $\mathbf{k}$ states get scattered:

$$\frac{\partial f_\mathbf{k}}{\partial t} = \left(\frac{\partial f_\mathbf{k}}{\partial t}\right)_{\text{scatt}} - \frac{d\mathbf{k}}{dt} \cdot \nabla_\mathbf{k} f_\mathbf{k} - \frac{d\mathbf{r}}{dt} \cdot \nabla_\mathbf{r} f_\mathbf{k}, \tag{64}$$

where $(\partial f_\mathbf{k}/\partial t)_{\text{scatt}}$ is the rate of change of $f_\mathbf{k}$, due to scattering alone, and $d\mathbf{r}/dt$ is the carrier velocity. The inclusion of the last term, with the spatial gradient of $f_\mathbf{k}$, provides in one and the same equation a unified description of the effects of electric and magnetic fields and temperature gradients.

Various approximations have been devised to solve the Boltzmann equation. Let it be solved; then the current densities can be obtained as integrals over $\mathbf{k}$ states:

$$\mathbf{j} = \frac{2}{(2\pi)^3} \int q \mathbf{v}_\mathbf{k} f_\mathbf{k} d^3k, \tag{65}$$

$$\mathbf{v} = \frac{2}{(2\pi)^3} \int (E_\mathbf{k} - \zeta) \mathbf{v}_\mathbf{k} f_\mathbf{k} d^3k. \tag{66}$$

The factor of 2 in front of the integrals arises from the spin degeneracy of $\mathbf{k}$ states. The subtraction appearing in Eq. (66) accounts for the current of work function, as described in the Introduction.

4.1 Scattering of Charge Carriers

The scattering term in the Boltzmann equation describes the change in the occupation of the state **k**. This occupation increases when carriers in other states, **k**′, are scattered into **k**, and decreases with scattering out of **k**. The result can be written as an integral over the other states:

$$\left(\frac{\partial f_{\mathbf{k}}}{\partial t}\right)_{\text{scatt}}=\frac{V}{(2\pi)^3}\int [w(\mathbf{k},\mathbf{k}')f_{\mathbf{k}'}(1-f_{\mathbf{k}}) -w(\mathbf{k}',\mathbf{k})f_{\mathbf{k}}(1-f_{\mathbf{k}'})]d^3k, \qquad (67)$$

where V is the sample volume, $w(\mathbf{k},\mathbf{k}')$ is the transition probability per unit time from a filled state $\mathbf{k}'$ to an empty state $\mathbf{k}$, and the factors with $f_{\mathbf{k}'}$ and $1-f_{\mathbf{k}}$ account for the probability of finding the state $\mathbf{k}'$ occupied and the state $\mathbf{k}$ empty, respectively.

An immediate consequence of Eq. (67) is the principle of detailed balance: In equilibrium, with no fields and temperature gradients, the scattering term in the Boltzmann equation must vanish for every conceivable scattering process. This means that the integrand must vanish:

$$w(\mathbf{k},\mathbf{k}')f^0_{\mathbf{k}'}(1-f^0_{\mathbf{k}})-w(\mathbf{k}',\mathbf{k})f^0_{\mathbf{k}}(1-f^0_{\mathbf{k}'})=0, \qquad (68)$$

which by use of Eq. (59) leads to the principle of detailed balance:

$$\frac{w(\mathbf{k},\mathbf{k}')}{w(\mathbf{k}',\mathbf{k})}=\exp\left(\frac{E_{\mathbf{k}'}-E_{\mathbf{k}}}{k_BT}\right). \qquad (69)$$

For elastic scattering this means that $w(\mathbf{k},\mathbf{k}')=w(\mathbf{k}',\mathbf{k})$.

The complexity of the scattering integral can be avoided by simply writing the scattering term as

$$\left(\frac{\partial f_{\mathbf{k}}}{\partial t}\right)_{\text{scatt}}=-\frac{f_{\mathbf{k}}-f^0_{\mathbf{k}}}{\tau}. \qquad (70)$$

Whether or not this expression will follow strictly from Eq. (67) depends on the scattering process considered. When approximations have to be used, Eq. (70) is called the relaxation-time approximation.

4.1.1 Charged Impurities. When carriers are scattered against impurities, the large impurity mass makes the scattering elastic, and it turns out [Smith and Jensen (1989), p. 97] that for metals the relaxation rate can be written

$$\tau_{\text{imp}}^{-1}=\pi^3 n_{\text{imp}}v_F/k_F^2, \qquad (71)$$

where n_{imp} is the density of impurities, and where v_F and k_F are the Fermi velocity and the Fermi-sphere radius, respectively. The result in Eq. (71) is valid under the assumption that the impurity potential can be taken as a δ function. Through screening of the impurity charge by the mobile carriers—a positively charged impurity will attract a cloud of electrons—its bare Coulomb potential becomes modified by an exponential factor:

$$\phi_{\text{imp}}=-\frac{e}{4\pi\epsilon_0 r}e^{-k_s r}, \qquad (72)$$

where k_s^{-1} is the screening length, given by

$$k_s^2=\frac{e^2}{\epsilon_0}\int\left(-\frac{\partial f^0}{\partial E}\right)D(E)dE, \qquad (73)$$

$D(E)$ being the density of states.

The screening in metals is markedly different from screening in semiconductors. For metals the energy derivative of f^0 is a δ function and k_s^2 becomes

$$(k_{s,\text{TF}})^2=(e^2/\epsilon_0)D(E_F)=3e^2n/2\epsilon_0E_F\,. \qquad (74)$$

The quantity $(k_{s,\text{TF}})^{-1}$ is denoted as the Thomas-Fermi screening length. Contrary to this, for semiconductors $\partial f^0/\partial E=-f^0/kT$, and the integral of Eq. (73) leads to

$$(k_{s,\text{D}})^2=e^2n/\epsilon_0k_BT, \qquad (75)$$

where $(k_{s,\text{D}})^{-1}$ is denoted as the Debye screening length.

When, for metals, k_s is much larger than k_F, the impurity potential can be taken as a δ function, and Eq. (71) gives the resistivity due to impurity scattering:

$$\rho_{\text{imp}}=\frac{m}{ne^2\tau_{\text{imp}}}=\frac{\pi^2}{2}\frac{h}{e^2}\frac{1}{k_F}\frac{n_{\text{imp}}}{n} \qquad (76)$$

for impurities with a single charge.

4.1.2 Lattice Vibrations. Carriers are being scattered also against the vibrating ions of the solid. The energy of these vibrations is quantized in units of $\hbar\omega_{\mathbf{q}}$, so-called phonons, where $\omega_{\mathbf{q}}$ is the frequency of a vibration with wave vector $\mathbf{q}$. This type of scattering is principally inelastic, as the carrier absorbs or emits one or more phonons. For single-phonon processes energy conservation means

$$E_{\mathbf{k}'} = E_{\mathbf{k}} \pm \hbar\omega_{\mathbf{q}}. \tag{77}$$

This type of scattering dominates the transport phenomena at high temperature where phonons are many in number.

Several modes of lattice vibrations exist. In acoustic modes, known also as sound waves, the frequency is proportional to the wave number q:

$$\omega_{\mathbf{q}} = v_s q, \tag{78}$$

where v_s is the sound velocity. In optical modes the frequency is to a first approximation independent of **q**. Optical modes appear in crystals with two or more atoms per primitive basis and can be visualized as these atoms vibrating against each other. If the atoms in the basis carry a charge there will be an associated electric polarization wave, and the mode is denoted as polar optical. All these modes have transverse and longitudinal forms according to whether the motion of the atoms is at right angles or parallel to the direction of **q**. Below, only a few qualitative remarks pertinent to acoustic phonons will be made.

The density of phonons with wave vector **q** is given by

$$n_q = \frac{4\pi q^2}{\exp(\hbar v_s q/k_{\mathrm{B}}T) - 1}\,\frac{3}{(2\pi)^3}, \tag{79}$$

where the factor of 3 accounts for one longitudinal and two transverse modes. It has a maximum at $\hbar v_s q = 1.6 k_{\mathrm{B}}T$. In Debye's model an upper value of $\omega_{\mathbf{q}}$ is introduced by requiring that the total number of modes should equal the number of degrees of freedom:

$$\frac{3V}{(2\pi)^3}\int_0^{\omega_{\mathrm{D}}} 4\pi q^2 dq = 3N, \tag{80}$$

N being the number of atoms and ω_{D} the Debye frequency. For a cubic lattice $Na^3 = V$, a being the lattice constant, and Eq. (80) gives

$$\omega_{\mathrm{D}} = v_s q_{\mathrm{D}} = v_s(6\pi^2)^{1/3}/a \approx 1.2 v_s(\pi/a). \tag{81}$$

The Debye temperature T_{D} is defined by

$$k_{\mathrm{B}}T_{\mathrm{D}} = \hbar\omega_{\mathrm{D}}. \tag{82}$$

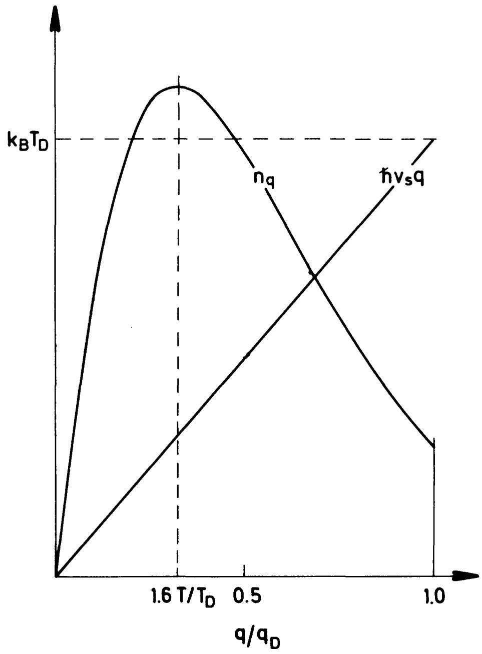

FIG. 14. Illustration of concepts in Debye model for phonons: Phonon density $n_{\mathbf{q}}$ (arbitrary units), according to Eq. (79) for $T/T_{\mathrm{D}} = 0.2$, and phonon energy $\hbar v_s q$, both vs reduced phonon wave vector q/q_{D}. The maximum in $n_{\mathbf{q}}$ occurs at a phonon energy of $1.6 k_{\mathrm{B}}T$.

The concepts introduced above are illustrated in Fig. 14. The density of phonons is

$$n_{\text{phonon}} = \int_0^{q_{\mathrm{D}}} n_q dq. \tag{83}$$

For $T \gg T_{\mathrm{D}}$, n_{phonon} increases linearly with T, while for $T \ll T_{\mathrm{D}}$ its temperature dependence is T^3.

Although electron-phonon scattering is principally inelastic, analysis of the scattering integrals shows that, provided $\hbar\omega_{\mathbf{q}} \ll |E_{\mathbf{k}} - \zeta|$, it can be treated as quasielastic.

In metals $|E_{\mathbf{k}} - \zeta| \approx k_{\mathrm{B}}T$, and as the phonon energy is less than $k_{\mathrm{B}}T_{\mathrm{D}}$, the requirement for quasielastic scattering becomes $T_{\mathrm{D}} \ll T$. Furthermore, for cubic metals with lattice constant a, and one conduction electron per atom, the Fermi-sphere radius is

$$k_{\mathrm{F}} = (3/\pi)^{1/3}(\pi/a) \approx 1.0(\pi/a) \tag{84}$$

and electron-phonon scattering can be illustrated as in Fig. 15. The geometry of momentum conservation gives

$$q \approx 2k_{\mathrm{F}} \sin \tfrac{1}{2}\theta, \tag{85}$$

and a relative change $\Delta k/k$ of the wave vector in the direction of **k**:

$$\Delta k/k \approx 1-\cos\theta = 2\sin^2(\tfrac{1}{2}\theta) = 2(q/2k_F)^2. \tag{86}$$

Above T_D the phonon wave vector $\mathbf{q}$ can be replaced by its maximum value q_D, which, along with the estimates of q_D and k_F in Eqs. (81) and (84), gives a $\Delta k/k$ of the order of 1. This means that a single electron-phonon scattering destroys completely the direction of **k**. For $T<T_D$ the situation is different. Here q may be replaced by its most probable value $1.6q_D(T/T_D)$, in which case $\Delta k/k \approx 1.8(T/T_D)^2$.

Besides being proportional to $\Delta k/k$, the scattering rate is further proportional to the phonon density and to the density of carrier states. In metals the density of carrier states will have to be taken at the Fermi level and is thus independent of temperature, whereas the phonon densities have the dependences T and T^3, as already explained. When put together, the result for the scattering rate becomes

$$\tau^{-1}_{\text{phonon,metal}} \sim \begin{cases} T & \text{for} \quad T>T_D\,, \\ T^5 & \text{for} \quad T<T_D\,. \end{cases} \tag{87}$$

Equation (87) gives the limiting behaviors of the so-called Grüneisen-Bloch law. Experimental data for a wide range of metals fit this remarkably well; cf. Fig. 16.

In semiconductors, the low carrier density means that small-angle scattering is of no relevance, and furthermore, that the electron density of states becomes temperature dependent as $T^{1/2}$. This leads to a scattering rate

$$\tau^{-1}_{\text{phonon,semicond.}} \sim \begin{cases} T^{3/2} & \text{for} \quad T>T_D\,, \\ T^{7/2} & \text{for} \quad T<T_D\,. \end{cases} \tag{88}$$

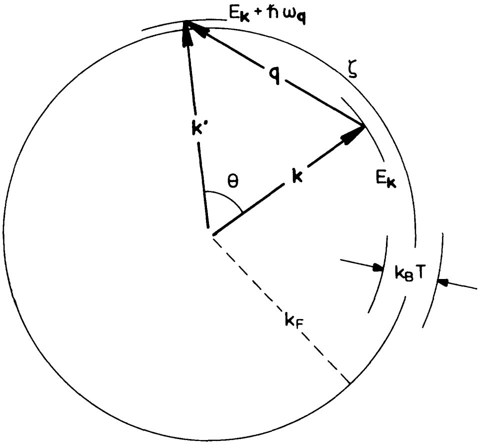

FIG. 15. Electron-phonon scattering: Electron with wave vector **k** and energy E_k absorbs a phonon with wave vector **q** and energy $\hbar\omega_q$. Fermi energy and Fermi-sphere radius are denoted ζ and k_F; θ is the scattering angle.

Figure 17 shows agreement between detailed calculations of mobility in germanium and experimental data gathered over two decades of years. Below 60 K the dependence is $T^{-3/2}$ in accordance with the high-temperature part of Eq. (88). The detailed derivation giving the $T^{-3/2}$ dependence is due to Bardeen and Shockley.

4.1.3 Mixed Scattering. When more than one scattering process is present, the combined effect is to a first approximation described by adding the scattering rates. Thus if the processes are those just considered, the total scattering rate is

$$\tau^{-1} = \tau^{-1}_{\text{imp}} + \tau^{-1}_{\text{phonon}}. \tag{89}$$

For metals, the impurity scattering rate is independent of temperature, and, as the phonon scattering vanishes at low temperatures,

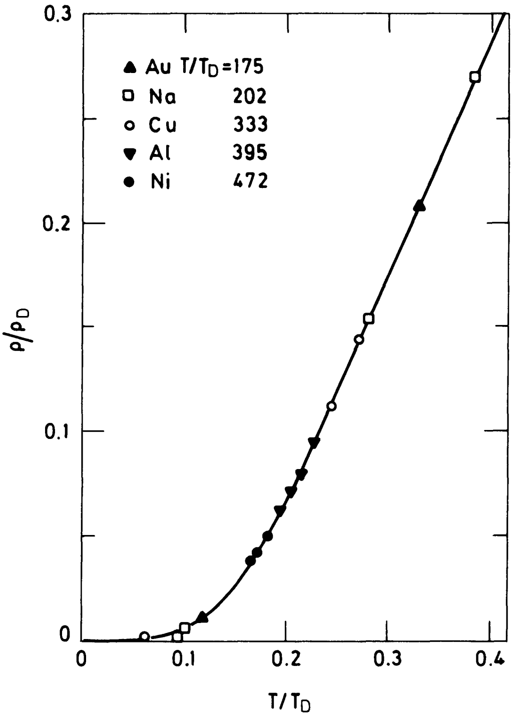

FIG. 16. The Grüneisen-Bloch law fitted to experimental data on the resistivity of metals, T_D and ρ_D being the Debye temperature and the resistivity at this temperature (Ziman, 1960, p. 366).

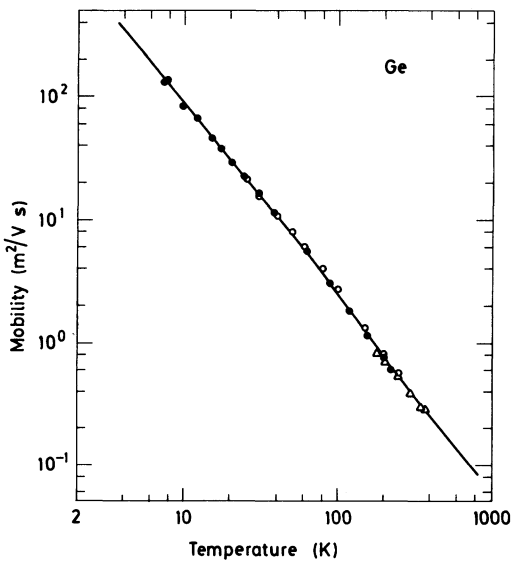

FIG. 17. Theoretical electron mobility of germanium (solid curve) and measured values: △, 1953; ○, 1954; ×, 1971; and ●, 1973 (Rode, 1975, p. 83).

Eq. (89) gives rise to a resistivity with a nonzero limiting value at low temperatures. This behavior is found experimentally for a large number of metals. It is known as Matthiessen's rule.

For the experimental data in Fig. 16 the measured resistivities were analyzed in accordance with Eq. (89), such that the resistivity ratio displayed pertains to the phonon scattering part only, and similarly for Fig. 17. But here, in addition to the scattering by acoustic phonons, scattering by nonpolar optical modes and scattering from one electron valley to another were considered. Willardson and Beer (1975) is recommended for further reading.

4.2 The Wiedemann-Franz Law

Within the relaxation-time approximation the Drude results (4) and (54) for the electric and thermal conductivities are retained—but with a different interpretation of the average velocity v_a: This should be the velocity v_F at the Fermi level. Furthermore, the expression for the heat capacity is not the one of classical particles, $C_{\text{classical}}=\frac{3}{2}k_B n$, but reflects that only the fraction $\sim k_B T/\frac{1}{2}mv_F^2$ of the electrons is taking part in thermal excitations. This gives rise to a heat capacity

$$C=\pi^2 n k_B^2 T/m v_F^2, \qquad (90)$$

and, according to Eqs. (4) and (54), a thermal conductivity

$$\kappa=(\pi^2/3)(k_B/e)^2 T\sigma. \qquad (91)$$

In the Drude model a similar result is obtained but with $\frac{3}{2}$ instead of $\pi^2/3$ as the numerical prefactor.

The independence on temperature of the ratio $\kappa/\sigma T$ is known as the Wiedemann-Franz law:

$$\kappa/\sigma T=\mathscr{L} \quad \text{independent of } T. \qquad (92)$$

From Eq. (91) the ratio is found to be

$$\begin{aligned}\kappa/\sigma T&=(\pi^2/3)(k_B/e)^2\\ &=\mathscr{L}_0\\ &=2.443\times10^{-8}\ \text{V}^2\ \text{K}^{-2},\end{aligned}$$

which is the so-called Lorenz number. Values of $\mathscr{L}$ at 0 and 100 °C for some metals are given in Table 1. Note that the numerical values are unambiguously in favor of the quantum description, the Drude value being 1.114×10^{-8} $(\text{V/K})^2$.

Table 1. Lorenz numbers for some metals (Mott and Jones, 1958, p. 307).

Metal	Lorenz number $\mathscr{L}$ [10^{-8} (V/K)^2] 0°	100°	Metal	Lorenz number $\mathscr{L}$ [10^{-8} (V/K^2)] 0°	100°
Mg	···	2.31	Pt	2.51	2.60
Al	···	2.23	Cu	2.23	2.33
Mo	2.61	2.79	Ag	2.31	2.37

Figure 18 displays the thermal conductivity of Au at temperatures below 150 K. Three regions can be seen: a linear dependence on T at the lowest temperatures, a constant value above ~100 K, and a maximum at intermediate temperatures. This behavior can be qualitatively understood from the discussion of electron-impurity and electron-phonon scattering in Secs. 4.1.1 and 4.1.2: The Wiedemann-Franz law, Eq. (91), was obtained through cancellation of the relaxation time appearing in the expressions for σ and κ. However, when small-angle scattering is important, i.e., for $T<T_D$, these relaxation times are no longer identical. In other words, the relaxation-time approximation is not valid. Energy is more easily relaxed than wave number, and below T_D the Wiedemann-Franz law could not be expected to be valid.

At the lowest temperatures the impurity scattering becomes dominating; let it be below a temperature T_i. At these temperatures the relaxation-time approximation is again valid, the conductivity is independent of temperature, and the Wiedemann-Franz law is obeyed. The characteristic temperature dependences of σ, κ, and $\mathscr{L}$ for metals are displayed in Fig. 19.

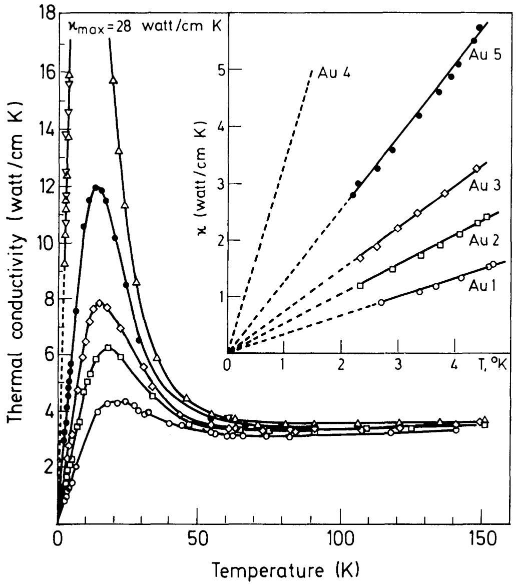

FIG. 18. Thermal conductivity of gold in varying states of physical and chemical purity, ○, Au 1, 99.9% pure, unannealed; □, Au 2, 99.9% pure, annealed; ◇, Au 3, JM3226, freshly drawn; △, Au 4, JM3226, annealed; ▽, Au 4, JM3226, annealed—second run; ●, Au 5, JM3226 redrawn (Olsen, 1962, p. 50).

5. LINEAR TRANSPORT EQUATIONS: PELTIER AND THERMOELECTRIC TENSORS

Despite the complicated scattering term in the Boltzmann equation, the expressions for the current densities will, to a first approximation, always be linear functions of the electric field and the temperature gradient:

$$\mathbf{j}=\mathbf{L}_{EE}\cdot\mathbf{E}+\mathbf{L}_{ET}\cdot\nabla T, \tag{93}$$

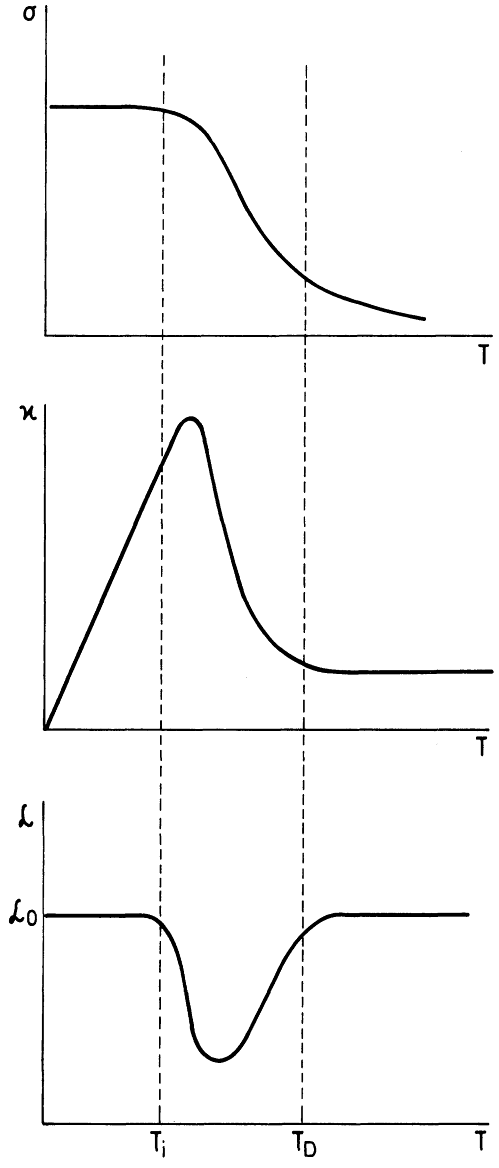

FIG. 19. Characteristic temperature dependences of the electric and thermal conductivities, and of $\mathscr{L}=\kappa/\sigma T$, for metals.

$$\mathbf{u}=\mathbf{L}_{TE}\cdot\mathbf{E}+\mathbf{L}_{ET}\cdot\nabla T. \tag{94}$$

The experimental conditions imposed in transport measurements are conveniently discussed with reference to these equations. These conditions are primarily the following two: no temperature gradient or no electric current.

When the temperature is everywhere the same, Eq. (93) is the basis for describing measurements of electric conductivity:

$$\boldsymbol{\sigma}=\mathbf{L}_{EE}\,. \tag{95}$$

Some details pertaining to the measurement of elements of $\boldsymbol{\sigma}$ and of its inverse, the resistivity $\boldsymbol{\rho}$, are given in Sec. 7. Equation (94) describes a flow of heat proportional to the electric field, or, by Eq. (93), to the electric current density:

$$\mathbf{u}=\mathbf{L}_{TE}\cdot\mathbf{L}_{EE}^{-1}\cdot\mathbf{j}=\boldsymbol{\Pi}\cdot\mathbf{j}; \tag{96}$$

The tensor in front of **j** is the Peltier tensor **Π**.

The other condition means that the sample should be electrically insulated. In this case, one end of the sample is clamped to a block which is maintained at a constant temperature, while a heater at the other end imposes a heat current through the sample. Equation (93) then tells that along with the temperature gradient, there will be an electric field:

$$\mathbf{E}=-\mathbf{L}_{EE}^{-1}\cdot\mathbf{L}_{ET}\cdot\nabla T. \tag{97}$$

The tensor in front of ∇T is the thermoelectric tensor **Q**:

$$\mathbf{Q}=-\mathbf{L}_{EE}^{-1}\cdot\mathbf{L}_{ET}\,. \tag{98}$$

The relation between the heat-current density and the temperature gradient is found by inserting the expression for **E**, Eq. (97), into Eq. (94):

$$\mathbf{u}=(\mathbf{L}_{TT}-\mathbf{L}_{TE}\cdot\mathbf{L}_{EE}^{-1}\cdot\mathbf{L}_{ET})\cdot\nabla T=-\boldsymbol{\kappa}\cdot\nabla T, \tag{99}$$

where $\boldsymbol{\kappa}$ is the thermal conductivity tensor.

6. SYMMETRY RESTRICTIONS

Two types of symmetry restrictions exist. One is linked to time reversal, the other one to spatial rotations. For a detailed understanding, the textbook by Smith *et al.* (1967), Chaps. 2 and 4, is recommended.

6.1 Onsager Relations

The Onsager relations deal with transport under time reversal. For the magnetic flux density—being produced by a circulating current—time reversal means a change of direction:

$$\mathbf{B}\rightarrow-\mathbf{B}\quad\text{for } t\rightarrow -t. \tag{100}$$

The Onsager relations tell how the transport tensors behave when the direction of **B** is changed. They are the following:

$$\mathbf{L}_{EE}(\mathbf{B})=\tilde{\mathbf{L}}_{EE}(-\mathbf{B}), \tag{101}$$

$$\mathbf{L}_{TE}(\mathbf{B})=-T\tilde{\mathbf{L}}_{ET}(-\mathbf{B}), \tag{102}$$

$$\mathbf{L}_{TT}(\mathbf{B})=\tilde{\mathbf{L}}_{TT}(-\mathbf{B}). \tag{103}$$

where the tilde means transposition. Applied to the transport tensors $\boldsymbol{\sigma}$, $\boldsymbol{\rho}$, $\boldsymbol{\kappa}$, **Π**, and **Q**, Eqs. (101)-(103) lead to

$$\boldsymbol{\sigma}(\mathbf{B})=\tilde{\boldsymbol{\sigma}}(-\mathbf{B}),\quad \boldsymbol{\rho}(\mathbf{B})=\tilde{\boldsymbol{\rho}}(-\mathbf{B}), \tag{104}$$

$$\boldsymbol{\kappa}(\mathbf{B})=\tilde{\boldsymbol{\kappa}}(-\mathbf{B}), \tag{105}$$

$$\boldsymbol{\Pi}(\mathbf{B})=T\tilde{\mathbf{Q}}(-\mathbf{B}). \tag{106}$$

6.2 Point-Group Symmetry

Suppose a crystal is placed in an apparatus that measures some macroscopic property. If a space-group symmetry operation is physically performed on the crystal but not on the apparatus, the atoms of the crystal will be brought back into their original positions with respect to the measuring apparatus, and there will be no change in the value of the quantity measured. The space-group translations associated with glide planes and screw axes involve atomic dimensions. They are therefore unobservable at the macroscopic level, and it is the point-group operations that give information about the symmetry of macroscopic crystal properties. The forms of the resistivity tensor and of the thermoelectric tensor for all 32 point groups can be found in the two papers by Akgöz and Saunders (1975). The effects of the Onsager relations are included in these papers as well.

7. SAMPLE GEOMETRIES

In the measurement of transport quantities a decisive role is played by the geometry of the sample and the way in which it is connected to the measuring circuit. As an example, consider the equation for the electric current density when the sample has everywhere the same temperature: $\mathbf{j}=\sigma\cdot\mathbf{E}$. The measurements can be performed in two ways: by control of the electric current density or by control of the electric field. Specific sample geometries are required for the two cases. They are named after their inventors: Hall (1880) and Corbino (1911). A mixed geometry, van der Pauw (1958/1959), mainly reflects technical convenience.

7.1 Hall Geometry

The Hall geometry is displayed in Fig. 20. The sample is in the form of an elongated, rectangular bar. The current enters and leaves the sample through the end faces, and its direction is along the long dimension. Let this be denoted by x. By this geometry the direction of the current is fixed:

$$\mathbf{j}=(j,0);\tag{107}$$

and the electric field is to be found from

$$\mathbf{E}=\rho\cdot\mathbf{j},\tag{108}$$

which means

$$E_x=\rho_{xx}j,\quad E_y=\rho_{yx}j.\tag{109}$$

These field components are measured between potential probes placed along the long dimension of the sample. The component E_y results from charges deflected by the field $\mathbf{B}$ and residing at the y surfaces. It is called the Hall field.

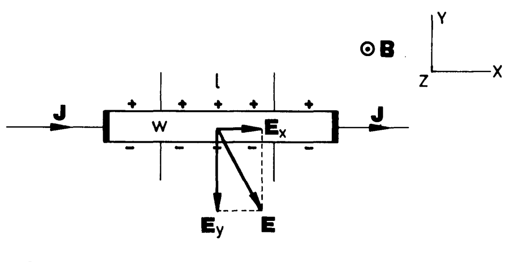

FIG. 20. Hall geometry. A magnetic flux density **B** is applied perpendicular to the paper plane. Spacings between potential probes are denoted *l* and *w*.

If only one type of charge carrier is present—let it be electrons of density n—then ρ_{yx} depends in a simple way on the density. The dependence can be found from the following considerations: In the steady state, the total force in the y direction is zero, meaning

$$\mathbf{E}_y=-\mathbf{v}\times\mathbf{B},\tag{110}$$

and the velocity $\mathbf{v}$ is related to the current density through

$$\mathbf{j}=-en\mathbf{v},\tag{111}$$

which along with (109) and (110) gives

$$\mathbf{E}_y=\frac{1}{ne}\,\mathbf{j}\times\mathbf{B}=R_{\mathrm{H}}\mathbf{B}\times\mathbf{j},\tag{112}$$

where

$$R_{\mathrm{H}}=-1/ne=\rho_{yx}/B\tag{113}$$

is called the Hall coefficient.

The components ρ_{xx} and ρ_{xy} of the resistivity tensor are found from measurements of the transverse and longitudinal voltages, E_yw and E_xl, respectively.

7.2 Corbino Geometry

Figure 21 illustrates an imaginary transformation from Hall geometry in Fig. 21(a) to Corbino geometry in Fig. 21(c): One of the current contacts is stretched until the two y faces meet, whereby this contact forms a ring, while the other one becomes a disk. The meeting of the two y faces means a short circuit of the Hall field, and this leaves the radial component of the electric field as the only component. Thus, the Corbino geometry fixes the direction of the electric field.

The current–field relation for the Corbino geometry can be expressed in cylindrical coordinates (r,θ) by

$$\mathbf{E}=(E,0),\tag{114}$$

$$\mathbf{j}=\sigma\cdot\mathbf{E},\tag{115}$$

from which

$$j_r=\sigma_{rr}E,\quad j_\theta=\sigma_{\theta r}E.\tag{116}$$

The potential difference V_{Corbino} between the disk and the ring is the radial integral

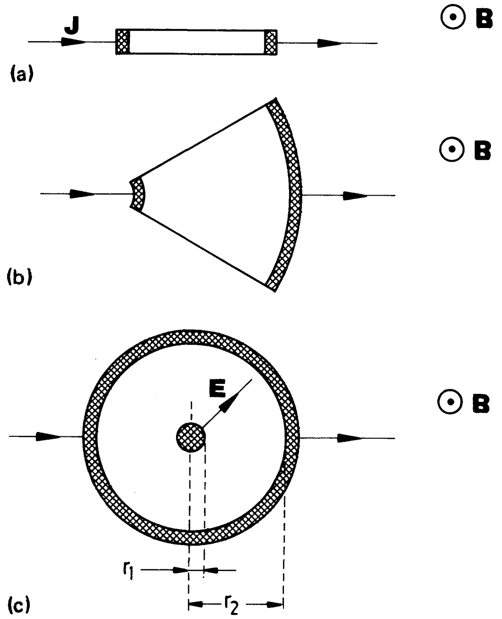

FIG. 21. Imaginary transformation from (a) Hall to (c) Corbino geometry.

$$V_{\text{Corbino}} = \int_{r_1}^{r_2} \mathbf{E}(r)\cdot d\mathbf{r}, \tag{117}$$

and the field $E(r)$ is determined by the requirement that, in the steady state, the current I entering the disk passes through every concentric circle:

$$2\pi r_1 j(r_1) = 2\pi r j(r) = I/t, \tag{118}$$

t being the thickness of the sample; or, by Eq. (116),

$$E(r) = j(r)/\sigma_{rr} = I/2\pi r t \sigma_{rr}\,. \tag{119}$$

Inserting this expression in the integral of Eq. (117) gives

$$V_{\text{Corbino}} = \frac{I}{2\pi t \sigma_{rr}} \ln \frac{r_2}{r_1} = R_{\text{Corbino}} I, \tag{120}$$

where

$$R_{\text{Corbino}} = \frac{I}{2\pi t \sigma_{rr}} \ln \frac{r_2}{r_1}\,. \tag{121}$$

Thus the Corbino geometry allows a genuine determination of the diagonal component σ_{rr}.

The current circulating in the Corbino sample, I_θ, is determined by both components σ_{rr} and $\sigma_{\theta r}$:

$$I_\theta = t \int_{r_1}^{r_2} j_\theta(r)\,dr = t \int_{r_1}^{r_2} \sigma_{\theta r} E(r)\,dr$$
$$= t\sigma_{\theta r} V_{\text{Corbino}} = \frac{I}{2\pi} \frac{\sigma_{\theta r}}{\sigma_{rr}} \ln \frac{r_2}{r_1}\,. \tag{122}$$

7.3 van der Pauw Method

The Hall and Corbino geometries are distinguished by parallel current streamlines and radial electric field, respectively. These features make the interpretation of the measured quantities easy, but are paid for by the difficulties in sample and contact preparation. In the van der Pauw method a slab of arbitrary shape, and with four point contacts along its edge, is used. This is sketched in Fig. 22. To find the resistance, two measurements have to be made: One of these is the potential difference V_{OP} between contacts P and O, using M and N as current contacts. The ratio between V_{OP} and the current is denoted $R_{MN,OP}$:

$$R_{MN,OP} = V_{OP}/I_{MN}\,. \tag{123}$$

The other one is the potential difference V_{PM}, using N and O as current contacts. This gives

$$R_{NO,PM} = V_{PM}/I_{NO}\,. \tag{124}$$

The square resistance $R_\square$ is then found from

$$R_\square = \frac{\pi}{\ln 2} \frac{R_{MN,OP} + R_{NO,PM}}{2} f, \tag{125}$$

where f is a geometrical factor of the order 1. The square resistance is the resistivity divided

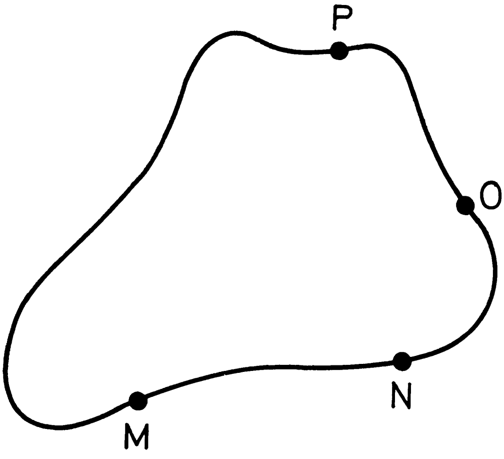

FIG. 22. van der Pauw geometry: slab of arbitrary shape with four contacts along its edge.

by the thickness of the slab. The Hall effect may be measured by this method as well. For the derivation of Eq. (125) the original paper of van der Pauw (1958/59) should be consulted.

8. LANDAU QUANTIZATION

In the previous sections the influence of quantum mechanics on electronic transport has been treated at the very simplest level: the de Broglie relation and the Pauli exclusion principle (Fermi-Dirac distribution function). This type of treatment does not account for a number of oscillatory phenomena observed when an electronic sample is placed in a strong magnetic field at low temperatures.

The theory as well as the experimental observations appeared in 1930. The Leningrad physicist L. D. Landau worked out the theory of diamagnetism in metals while visiting Cambridge University. At the same time at the University of Leiden, de Haas and van Alphen observed oscillatory susceptibility, and Shubnikov and de Haas observed oscillatory magnetoresistance.

The Landau quantization appears in the plane perpendicular to an applied magnetic flux density. It restricts the **k**-space areas to the following values:

$$A_{\mathbf{k}\perp}=(p+\tfrac{1}{2})(2\pi/\hbar)eB, \quad p=0,1,2,\ldots . \qquad (126)$$

The period of oscillatory phenomena is found from this expression by equating $A_{\mathbf{k}\perp}$ to the **k**-space area actually occupied by electrons. Thereby, a series of equidistant values of the inverse field, B^{-1}, appears, their spacing being the period $P(B^{-1})$:

$$P(B^{-1})=\frac{2\pi}{\hbar}\,e\,\frac{1}{A_{\mathbf{k}\perp,\text{occupied}}}\,. \qquad (127)$$

In the simplest case the **k**-space volume occupied by electrons has the shape of a sphere with radius k_F. The area $A_{\mathbf{k}\perp}$ and the carrier density is then expressed as

$$A_{\mathbf{k}\perp,\text{occupied}}=\pi k_\text{F}^2 \qquad (128)$$

and

$$n=2\,\frac{1}{(2\pi)^3}\,\frac{4}{3}\,\pi k_\text{F}^3=\frac{1}{3\pi^2}\,k_\text{F}^3\,. \qquad (129)$$

From measured periods $P(B^{-1})$ the carrier density n can be calculated, as from Eqs. (127)–(129):

$$P(B^{-1})=(2e/\hbar)(3\pi^2 n)^{-2/3}. \qquad (130)$$

The review of Landwehr and Rashba (1991) is recommended for further reading.

8.1 Shubnikov–de Haas Oscillations

The oscillatory period given by Eq. (127) is observed in a variety of solid-state phenomena. In electronic transport its most conspicuous effects show up in the magnetoresistance. An example is shown in Fig. 23.

9. TRANSPORT IN LOW-DIMENSIONAL SYSTEMS

The quantization of wave numbers was mentioned in Sec. 3: The wave-number spacings are $2\pi/L$, L being the spatial dimension along (x,y,z). If one of these dimensions is reduced—let it be z—then the k_z spacing increases. As **k** states are occupied in accordance with their energy, which depends on **k** as k^2, the large k_z values mean that ultimately only states in one (k_x,k_y) plane, the one having the smallest k_z, are occupied. This is sketched in Fig. 24(a). The occupied area in **k** space, which in the three-dimensional sample was a sphere, now becomes a disk. The system is said to be two-dimensional. The density of **k** states in the plane is $(2\pi)^{-2}$ per unit area.

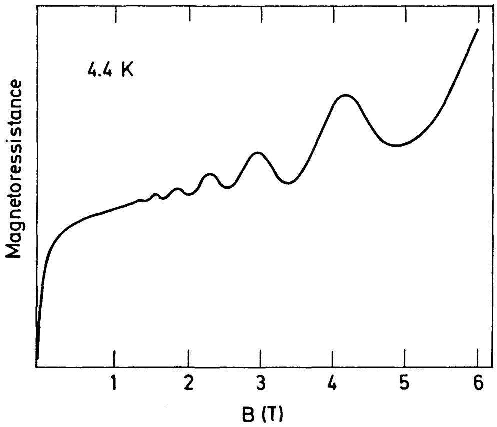

FIG. 23. Magnetoresistance of bismuth doped slightly with Sn.

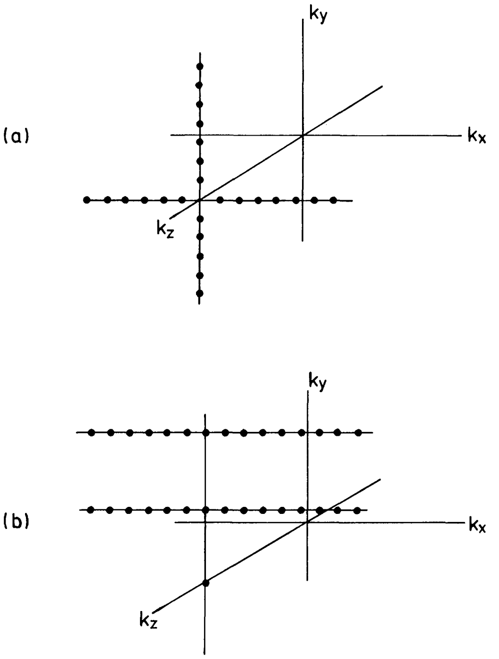

FIG. 24. **k** space for (a) a two-dimensional system and (b) a one-dimensional system.

If, in the two-dimensional system, one of the spatial dimensions is reduced—let it be y—then the k_y spacings increase, and the occupied **k** states will be on k_x lines. The system is then said to be one-dimensional. [See Fig. 24(b)].

The improvement within the last two decades of crystal-growing techniques to the limit where growth can be controlled at the level of atomic layers has opened up the possibility for studying a large variety of two-dimensional systems. Along with this, the techniques for making patterns in the two-dimensional systems have given access to one-dimensional systems as well.

9.1 The Quantum Hall Effect

Within the two-dimensional systems the discovery by von Klitzing in 1980 of the quantum Hall effect was a most remarkable event, for which the Nobel prize was awarded in 1985. An example of quantized Hall resistance is shown in Fig. 25 along with Shubnikov–de Haas oscillations. Instead of the linear dependence of Hall voltage on B, expected from Eqs. (16) and (109), a series of steps appears. The values of these transverse resistance steps can be obtained by the following considerations: With the notation used in Fig. 20 the Hall voltage V_H is written as

$$V_H = E_y w = \rho_{yx} j w = (B/ne) j w. \qquad (131)$$

The Landau levels are circles in the (k_x, k_y) plane in Fig. 24(a). The number of **k** states in each of these circles equals the area $(2\pi/\hbar)eB$ between them [cf. Eq. (126)], multiplied by the density of states $(2\pi)^{-2}$ per unit area, i.e., $(e/h)B$. Thus if ν circles are filled up with electrons, there will be $\nu(e/h)B$ electrons per unit area. On multiplying numerator and denominator in Eq. (131) by the thickness t of the two-dimensional layer, nt becomes the density per unit area and jwt becomes the current I, and so

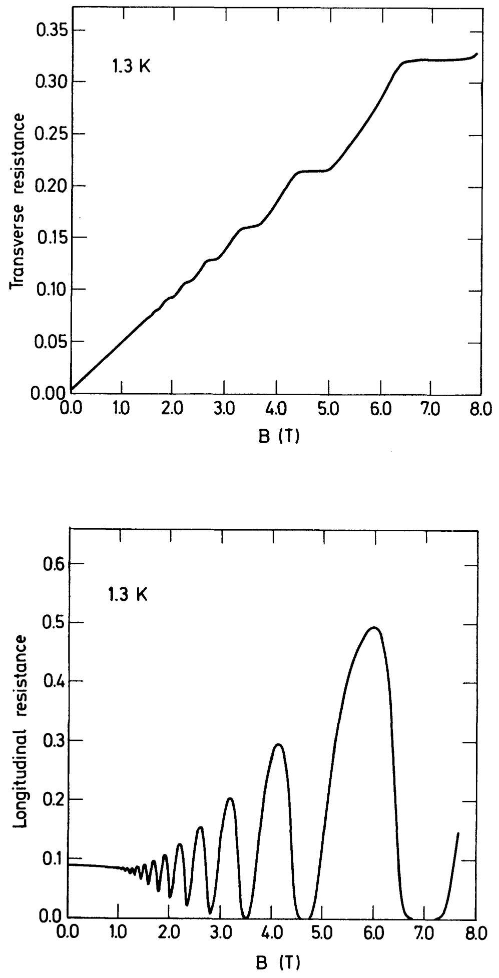

FIG. 25. The transverse and longitudinal resistances of a GaAs/GaAlAs heterostructure (two-dimensional electron system).

$$V_{\mathrm{H}}=\frac{1}{\nu}\frac{h}{e^2}I. \tag{132}$$

Measurement of the transverse resistances at the plateaus thus gives access to the important combination of fundamental constants, h/e^2. The values are so accurately given by Eq. (132) that in 1988 the Comité International des Poids et Mesures recommended that from 1 January 1990 the ohm should be represented by means of the quantum Hall effect, assigning the value 25 812.807 Ω to the von Klitzing constant, that is to say, to the quotient of the Hall voltage divided by the current for the plateau $\nu=1$ (see CONSTANTS, FUNDAMENTAL).

The number ν is called the filling factor because it tells how many Landau levels are filled. The very intense research that followed the discovery in 1980 led in 1982 to the observation of a step also at $\nu=\frac{1}{3}$, and soon after at a number of fractional fillings. After this, the names integer quantum Hall effect (IQHE) and fractional quantum Hall effect (FQHE) were used for the two phenomena. They have been and are still a challenge to theory. For further reading the following is recommended: QUANTUM HALL EFFECT, the book *The Quantum Hall Effect,* edited by Prange and Girvin (1987), and the review by MacDonald (1992).

9.2 Size-Quantized Conductivity

Figure 26 shows the conductance of a so-called point contact, which is an example of a one-dimensional constriction in an otherwise two-dimensional system. The quantization may be qualitatively understood as follows: For each of the k_x lines in Fig. 24(b) the current is written as an integral over the energy:

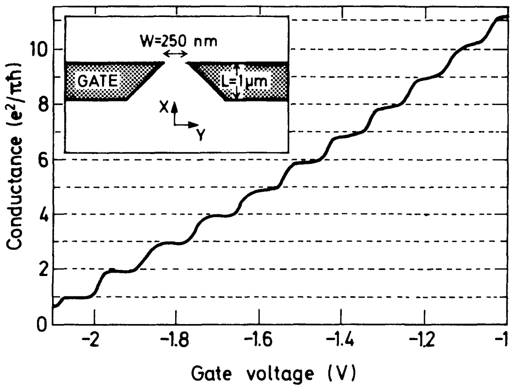

FIG. 26. Point-contact conductance as a function of gate voltage. Temperature: 0.6 K. Inset: Point-contact layout (van Wees *et al.*, 1988).

$$I=e\int_0^{eV}\nu\frac{dn}{dE}\,dE, \tag{133}$$

where V, in the upper limit of the integral, is the voltage across the point contact. The way in which one-dimensionality is distinguished is by its density of states per unit energy:

$$\frac{dn}{dE}=\frac{dn}{dk}\frac{dk}{dE}. \tag{134}$$

Only for the one-dimensional case is dn/dk a constant, $(2\pi)^{-1}$. For the velocity the general $\nu=\hbar^{-1}(dE/dk)$ is used, and the following expression for I results (the factor of two accounts for the spin degeneracy):

$$I=(2e^2/h)V. \tag{135}$$

The steps in Fig. 26 arise when the size of the constriction is changed. Such change is accomplished by the horizontal variable of Fig. 26, the gate voltage. The gate is the hatched area in the inset of Fig. 26. Applying a negative voltage to this increases the energy of the two-dimensional electron gas underneath, and thereby creates a saddle-point potential for the electrons. The gate voltage determines the width of the "saddle," and this in turn determines the number of k_x lines by which electrons can cross the constriction. Changing this number by 1 creates a step in Fig. 26.

The two phenomena considered in this last section are just examples, very important ones though, of electronic transport in solids in which the Drude assumption, that all carriers act independently, is no longer valid. This invalidation has been brought about by improved crystal-growing and lithographic techniques. In the small spatial dimensions thus created, electron waves can keep coherence, and as a result interference effects appear. The word mesoscopic, indicating a range between micro and macro, is being used to designate this whole field. (See MESOSCOPIC SYSTEMS.)

INTRODUCTION

The electrorheological (ER) response is characterized by a large change in suspension mechanical properties upon exposure to electric fields. Viscosity changes of several orders of magnitude commonly occur. Suspensions displaying an ER response are typically composed of polar solids suspended in low–dielectric-constant oils, and, as a result, have low conductivities. As a consequence, field strengths of 0.5–5 kV/mm employed to achieve large responses do not result in prohibitive power consumption, opening the possibility for a wide range of technologies. While the ER response has been known for over 40 years, a recent resurgence of interest can be traced to the availability of control instrumentation made possible by solid state electronics. The ability to rapidly alter and continuously vary stress transfer properties plays an important role in applications of the ER response in devices such as dampers, shock absorbers, clutches, and actuators. Despite the length of time the response has been known, much remains poorly understood, and the study of ER systems is very active from both a fundamental and a technological perspective. Here a review of current (up to the beginning of 1991) understanding of the ER response will be provided, and directions that future research and development are likely to take are discussed.

The ER response was discovered by Winslow in 1947 (Winslow, 1947, 1949) and patents were issued at that time on applications involving stress-transfer devices. Winslow identified much of the underlying physics giving rise to the ER response and investigated a number of fluid formulations. Klass and Martinek (1967) and Uejima (1972) provided the most comprehensive rheological and suspension characterization of ER fluids published until late in the 1980s. Klass and Martinek questioned Winslow's contention that the ER response was due to interactions between particles produced by differences in polarizability of the solid and continuous phases and, on the basis of the short response times, suggested that the ER mechanism involved polarization of electric double layers. Uejima, working with suspensions of microcrystalline cellulose, demonstrated that dramatic increases in response can follow from the addition of small quantities of water to ER suspensions. The effects of water are still poorly understood and continue to plague commercialization of ER technologies. In the 1970s an active program investigating electrorheology was established in the Soviet Union, where a variety of formulations were explored and careful rheological characterization of ER fluids was initiated (Shulman *et al.*, 1981). From the mid 1960s to the late 1970s, Mason and co-workers at McGill University supplied some of the first fundamental data on particle interactions in the presence of shear and electric fields and demonstrated that rates of structure formation and degradation could be determined from a summation of electrically induced polarization forces developed between particles in the presence of an electric field and the viscous drag provided by the suspending solvent (Zia *et al.*, 1975).

What might be called a modern era of ER research and development was initiated in the late 1970s in the U.K., culminating in the publications of Stangroom and co-workers,

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

who developed polymer-based suspensions displaying large ER responses (Stangroom, 1978, 1983). This work stimulated automotive industry interest in developing active suspensions and engine mounts. Since the early 1980s research programs in industrial and academic laboratories have begun to elucidate the fundamental character of the ER response. These efforts have spanned a broad spectrum of interests ranging from device design to physical properties of polarized suspensions. A poor understanding of the links between field strength, shear rate, current density, and material properties contribute to the limited applications of ER technologies. In this article, the effects of large electric fields on nonaqueous suspensions will be described from a phenomenological perspective in Sec. 1 followed in Sec. 2 with a development of the polarization model of the ER response. In recent years, novel applications of the ER response have been described, and these will be discussed in Sec. 3. Reviews discussing the ER response have been written by Block and Kelly (1988), Gast and Zukoski (1989), and Jordan and Shaw (1989).

Table 1. Characteristics of electrorheological suspensions.

Suspending Fluid Properties	
Relative permittivity	$\epsilon_c=2-15$
Low-field conductivity	$\sigma_c=10^{-7}$–10^{-13} s/m
Viscosity	$\eta_c=0.01$–10 Pa s
Density	$\rho_c=0.6$–2 g/cm^3
Particle Properties	
Shape	Roughly spherical
Size	$\sigma=0.1$–100 μm
Relative permittivity	2–60
Suspension Properties	
Zero-field viscosity	$\eta_\infty=0.1$–10 Pa s
Volume fraction	$\phi=0.05$–0.50
Conductivity	$\Sigma=10^{-6}$–10^{-13} s/m
Typical field strengths	$E=0.5$–5 kV/mm

1. THE ELECTRORHEOLOGICAL RESPONSE

Suspensions displaying large electrorheological responses are typically composed of a polar solid suspended in a low–dielectric-constant oil. Continuous phases of chlorinated hydrocarbons and silicon, mineral, and vegetable oils have been reported. Properties of importance in the continuous phase are low conductivity, high dielectric breakdown voltage, and ability to disperse the solid phases. Typical physical properties are given in Table 1.

The dispersed phase is composed of particles in the 0.1 to 100-μm-diam range with polarizabilities much larger than that of the continuous phase. For example, when containing 0.5–4 wt% water (based on solid-phase mass), suspensions of microcrystalline cellulose and wheat flour produce very effective ER suspensions. On the other hand, if the solid phase is dried at 80°–100 °C for several hours, suspensions of the same materials have small ER responses. The change in activity is associated with increases in polarizability produced by hydrating the solid phase. Besides starches and cellulosics, polar solids such as titania, barium titanate, charge-transfer salts, conducting polymers, hydrated polymeric systems, and zeolites have been reported as giving rise to large ER responses. Water is often identified as an agent which activates many solid phases. Particles are often roughly spherical and few studies have systematically explored the effects of anisotropic shapes. Typical physical properties of the dispersed phase are given in Table 1.

ER suspensions are made up at 1–50 volume% solids and, in the absence of an electric field, display the properties expected of nonaqueous suspensions. The particles tend to flocculate because of long-range van der Waals interparticle forces and thus to settle out of suspension. This poses problems for devices which are called upon to respond in an intermittent manner. As a result, stabilizing agents are commonly incorporated in fluid formulation. Surfactants and grafted or adsorbed polymeric materials have been investigated, but the effects of these agents are complex and poorly understood, even in the absence of an external electric field. As discussed in more detail below, the choice of stabilizer is made difficult by the need for the electric field to hold particles at small pair separations without irreversibly trapping them in a deep potential energy minimum produced by van der Waals forces (for a discussion of colloidal interactions see Russel *et al.*, 1989). Thus a balance of stabilizer size and the softness of the resulting interparticle potential must be sought in suspension formulation.

Depending on volume fraction and degree of dispersion, in the absence of an externally applied field, ER suspensions may display a yield stress (i.e., a stress below which the materials respond as an elastic solid rather than as a fluid). Most formulations aim to reduce the yield stress in the absence of a field to as low a value as possible. As the shear rate is raised, unelectrified ER suspensions are shear thinning and, at elevated shear rates, reach a Newtonian shear viscosity of η_∞ which depends primarily on suspension volume fraction and can be estimated from

$$\eta_\infty/\eta_c=(1-\phi/\phi_m)^{-2}, \tag{1}$$

where η_c is the viscosity of the continuous phase and ϕ_m is a maximum packing fraction often taking a value between 0.63 and 0.71 (Russel *et al.*, 1989).

Devices employing the ER response hold the suspension between two electrodes. Because of the large field strengths required to achieve the desired viscosity changes (on the order of 0.5–5 kV/mm), gaps on the order of 0.5–5 mm are commonly encountered. The ratio of the gap width to particle size, l/σ, ranges from 5 to 100 in most devices. To date, no systematic studies have been carried out to explore the effects of l/σ on the resulting ER response.

When the electric field is applied to the quiescent suspension, the particles rearrange from an initially random microstructure to one where fibers or columns of particles are seen to span the electrode gap (Fig. 1). At very low volume fractions the fibers tend to be one particle wide and form slowly (over the course of tens of minutes depending on the field strength; see below for a more detailed description of the time dependencies). As the volume fraction is raised, the columns thicken and become branched.

If one electrode is moved parallel to the other so as to produce a small strain in the field-induced structures, the strands respond in an elastic manner, showing that they are capable of sustaining a stress without rupturing, and thus they display solid-like characteristics. At small steady rates of deformation, the strands break and reform in a continuous manner. The strands remain attached to each electrode and the strands thicken until a characteristic, steady-state size distribution is reached. At higher shear rates, the strands rupture completely such that there are solid-like regions attached to each electrode separated by a fluid-like zone. The fluid-like zone expands until it occupies the entire gap (Klingenberg and Zukoski, 1990) (Fig. 1) as the shear rate is still further raised. At these shear rates the electrified suspension viscosity approaches η_∞.

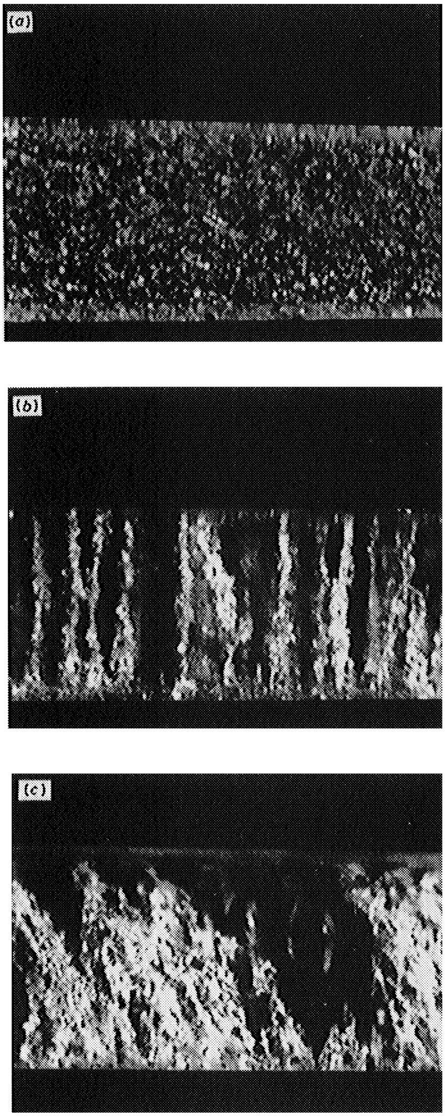

FIG. 1. 100-μm-diam hollow silica spheres suspended in corn oil between two metal electrodes spaced 3 mm apart, at (a) 0 V/mm, (b) 750 V/mm with a zero shear rate, and (c) 750 V/mm and a shear rate of 0.5 s^{-1} (reproduced from Klingenberg and Zukoski, 1989).

In slit or pipe flows at pressure drops below those required to break the strands held in place by a given field, the strands act as weakly extensible elastic solids. At low to intermediate volume fractions, the network behaves like an excellent deep bed filter with particles being captured in the fibrous structure and clear fluid being expressed at the low-pressure outlet. As the pressure drop is raised the fibers bend and then break, giving rise to plug flow at just above the yield pressure. At still larger pressure drops, the field-induced structures are completely destroyed.

The current passed by the ER suspensions typically increases faster than linearly with the electric field and depends on both the continuous- and dispersed-phase conductivities. At a constant field strength the current drops at shear rates near those required to form a fluid-like zone and increases again upon cessation of flow when the percolating strands reform. With increases in the degree of hydration of the dispersed phase, the ionic character of dispersant, or operating temperature, currents increase. Not only do increasing power losses place economic constraints on ER suspensions with elevated conductivities, but the resulting Joule heating degrades the ER response.

The shear behavior of ER fluids is characterized by a field-strength–dependent dynamic yield stress, shear thinning with increasing shear rates, and a high–shear-rate viscosity that is independent of field strength. These features are conveniently captured in a Bingham type of constitutive equation,

$$\tau=\tau_y+\eta_\infty\dot{\gamma}, \tag{2}$$

where τ is the stress, $\dot{\gamma}$ is the shear rate, and τ_y is the field-strength–dependent dynamic yield stress. In a plot of stress versus $\log\dot{\gamma}$, a plateau stress is observed at low $\dot{\gamma}$ and a slope of unity at elevated $\dot{\gamma}$ (Fig. 2). The stress extrapolated to zero shear rate defines τ_y. Here τ_y increases with field strength E, but the stress transferred by the suspension becomes independent of E at elevated $\dot{\gamma}$ [as expected from Eq. (2)] suggesting that one of the key parameters of interest in understanding ER suspension behavior and designing devices is τ_y. The shear rate where τ lifts off the low–shear-rate plateau corresponds well with the appearance of the fluid-like regions seen in flow visualization experiments, indicating that the transition to Newtonian flow behavior at high $\dot{\gamma}$ is associated with degradation of field-induced structures.

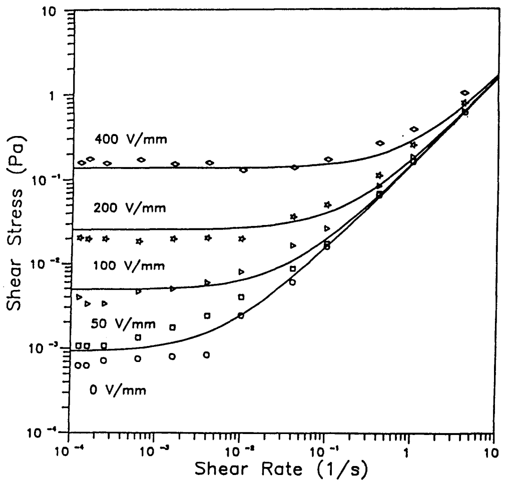

FIG. 2. Shear stress in pascals as a function of shear rate at various field strengths for an ER suspension composed of hydrated polymethylacrylate particles in a chlorinated hydrocarbon. Solid lines drawn from Eq. (2) with τ_y proportional to E^2.

For many ER suspensions, a critical field strength is required to break up the flocculated network produced by colloidal forces, and the overall yield stress is well approximated as the sum of a yield stress observed when $E=0$ and a field-dependent yield stress (Gow and Zukoski, 1990). For suspensions with small yield stress at $E=0$, τ_y is found to scale as E^n. For many suspensions up to field strengths of 1–2 kV/mm, n is found to lie near 2. At higher field strengths n often approaches unity. In addition, τ_y/E^2 is found to increase linearly at low volume fractions, but to saturate at volume fractions near 0.3. τ_y/E^2 is a function of the material properties of the dispersed and continuous phases, as discussed in more detail below.

The kinetics of stress-transfer changes with variations in field strength or shear rate are poorly understood, but appear to be dominated by two characteristic times: that required to produce electrode-spanning structures and that required for the shear to rearrange these structures. The time to produce percolating strands depends primarily on particle polarization properties, volume fraction, and the square of the field strength, while shear degrades the strands in a time characterized by $\dot{\gamma}^{-1}$. The result is that at intermediate shear rates and/or field strengths there is a large stress overshoot before the steady-state stress is reached. The stress overshoot is of importance in the design of control algorithms for situations where rapid deceleration is required.

The dynamic response of ER suspensions has been less well studied. In the presence of an electric field, the suspensions have a substantial elastic modulus and a small limiting strain above which they display nonlinear responses. As a result, examination of the linear viscoelastic properties is somewhat instrumentation limited. However, interest in applications such as acoustic dampers will result in continued studies of the small-strain dynamic response of ER materials.

2. ORIGINS OF THE ER RESPONSE

In his original publications, Winslow (1947, 1949) identified strand formation as a key process in successful ER fluids, and postulated that these structures were formed as the result of the interactions of particles polarized in the external field. Increases in viscosity were then associated with breaking polarization-induced interparticle "bonds." Klass and Martinek (1967) did not observed strands in their fluids and postulated that the increases in viscosity could arise from polarization of double layers that surround the slightly charged particles. Later, because of the apparent requirement of water to activate ER suspensions, Stangroom (1983) postulated that water migrated within particles by electroosmosis, and that interparticle bonds were formed by a water bridging mechanism.

By far the most successful approach to understanding and codifying the ER response lies in the polarization model as first suggested by Winslow. Here, particles of different dielectric constant than the continuous phase polarize when the suspension is exposed to an external electric field. To a first approximation, the spherical particles of diameter σ interact as point dipoles which feel forces attempting to align pairs along the lines of electrical force. The magnitude of the polarization force is given by $(3/16)\pi\epsilon_0\epsilon_c\sigma^2\beta^2E^2$ where $\beta[=(\epsilon_p-\epsilon_c)/(\epsilon_p+2\epsilon_c)]$ is the relative polarizability of the particles, with ϵ_p and ϵ_c being the particle and continuous-phase dielectric constants. Here, the permittivity of free space is ϵ_0.

If the particles are small and feel negligible colloidal interaction forces, and the field is adjusted such that $(3/16)\sigma^3\beta^2E^2/kT$ is of order unity, the suspensions display phase behavior of dipolar materials. Here, kT is the product of Boltzmann's constant and the absolute temperature. At low volume fractions and modest field strengths, the particles establish a cluster length distribution that can be predicted from a balance of thermal and polarization forces using classical statistical mechanics. As the volume fraction or field strength is raised, a percolation transition is approached where chains of infinite length are formed (Gast and Zukoski, 1989).

Typical ER suspensions consist of large particles where the ratio of polarization to thermal forces is large [i.e., $(3/16)\pi\sigma^3\beta^2E^2/kT \gg 1$]. Under these conditions, low-temperature approximations are valid and suspension structures are determined by kinetic rather than equilibrium considerations. Through polarization interactions, particle columns and fibers are formed, percolate across the electrode gap, and reach a steady-state width distribution. If one electrode is moved parallel to the second, stress is transferred through a combination of viscous and electromechanical mechanisms. Within the polarization-model framework, time scales for structure formation can be found by balancing the viscous drag on particles moving in the continuous phase against the characteristic polarization interaction. The characteristic time for percolating structures to form when an initially random suspension of non-Brownian particles is exposed to an electric field is predicted to vary as $t^*=16\eta_c/\epsilon_0\epsilon_c\beta^2E^2$ and to be dependent on volume fraction. Simulation studies, which have been confirmed experimentally, have demonstrated that the average time to produce percolating structures, $\langle t_p\rangle$, scales as $\langle t_p\rangle/t^*\sim\phi^{-4.5}$ for $\phi<0.5$. This result demonstrates that the polarization model can predict measured response times reported in the millisecond range. In the design of ER devices, while stress-transfer properties plateau as volume fraction is raised, response times can be easily varied over a wide range through changes in ϕ (Klingenberg *et al.*, 1989).

With growing concerns for shorter response times, the rate of particle polarization becomes an important parameter. The characteristic particle polarization time may be estimated from $\epsilon_p \epsilon_0 / K_p$, where K_p is the particle conductivity. As K_p increases, dipoles are formed more rapidly when the electric field is applied. Few studies have investigated the role of particle conductivity on ER suspension response time. As a result, the role of particle response time (and thus K_p) in the ER response is poorly understood and subject to debate (Uejima, 1972; Block *et al.*, 1990; Gow and Zukoski, 1990).

In the polarization model, the continuous shear behavior of ER suspensions results from a balance of polarization and viscous interaction forces, such that the relative viscosity of the electrified suspension will be a function of the Mason number, $Mn = \eta_c \dot{\gamma} / 2\epsilon_c \epsilon_0 \beta^2 E^2$. As exemplified by Fig. 3, this scaling works well for many ER suspensions. Essentially the model predicts that at low Mn (i.e., high field strengths or low shear rates), polarization forces dominate suspension structure and stress is transferred by electromechanical means through the percolating particle strands. At large Mn, the viscous forces dominate, and the polarization-induced structures are degraded. Thus the suspension behaves as if no field were applied (i.e., $\tau/\dot{\gamma} = \eta_\infty$). The Bingham constitutive equation can be rearranged to yield

$$\eta/\eta_\infty = (Mn^*/Mn) + 1, \tag{3}$$

where Mn^* becomes a volume-fraction- and material-dependent, dimensionless yield stress. This constitutive equation for the steady shear behavior of ER suspensions is found to be quite accurate at small and large Mn. At intermediate values, Eq. (3) under-predicts the ER response because it does not account for synergistic effects between electromechanical and viscous stress-transfer mechanisms (Marshall *et al.*, 1989).

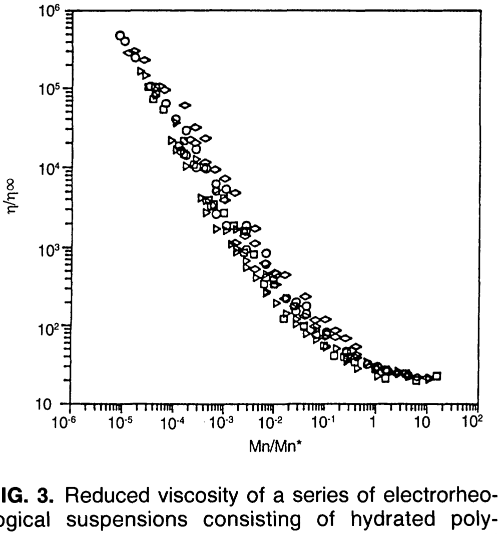

FIG. 3. Reduced viscosity of a series of electrorheological suspensions consisting of hydrated polymethacrylate particles suspended in a chlorinated hydrocarbon for volume fractions ranging from 0.07 to 0.35 for shear rates between 10^{-4} and 10 s^{-1} and field strengths of 50–400 kV/m. $M_n^* = 0.45\ \phi$.

Detailed simulation studies of hard particles suspended in a viscous continuous phase accounting for exact hydrodynamic and electrostatic interactions have shown that the polarization mechanism is capable of capturing both the qualitative features of the continuous flow behavior and the magnitude of the ER response based on particle volume fraction, continuous-phase viscosity, and the dielectric constants of the two phases (Bonnecaze and Brady, 1990; Heyes and Melrose, 1990; Klingenberg *et al.*, 1991).

As observed experimentally for $E \leqslant 1$–3 kV/mm, the polarization model predicts that yield stress scales, $\tau^* = (3/16)\pi\epsilon_0\epsilon_c\beta^2E^2$. However, quantitative prediction of the yield stress is very sensitive to particle interactions at small surface-to-surface separations. Thus details of the electrostatic interaction accounting for large ratios of ϵ_p/ϵ_c (i.e., outside the point dipole limit) and multiparticle interactions play an important role in setting the magnitude of the ER response. In addition, the nature of the short-range repulsive interactions provided by stearic stabilizers or surface roughness will determine how close particle cores may approach and thus have impact on the magnitude of the yield stress. In keeping with experimental observations, for fixed short-range repulsive interactions, the polarization model predicts a large increase in dimensionless yield stress (τ_y/τ^*) as β approaches unity.

As the volume fraction is raised, molecular-dynamics simulations predict that the dimensionless yield stress will saturate at a volume fraction near 0.4. This is due to the formation of dense clusters of particles that transfer stress less efficiently than the single-particle chains that dominate at lower volume fractions, a result well supported by experimental evidence (Klingenberg *et al.*, 1990) (Fig. 4).

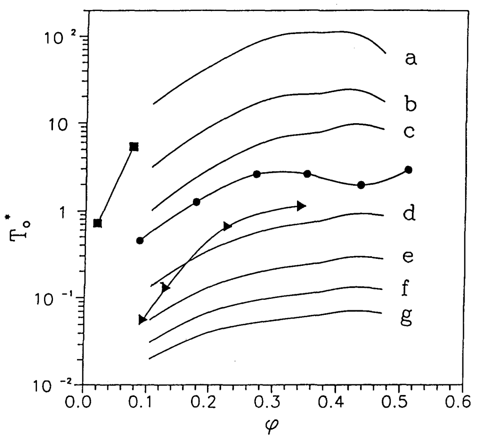

FIG. 4. Dimensionless yield stress $T_0^* = \tau_{yE}/(3/16)\pi\beta^2 E^2$ predicted from simulations of sheared ER suspensions. Solid lines are predictions for conducting particles with minimum surface-to-surface separations of (a) $10^{-5}\sigma$, (b) $10^{-4}\sigma$, and (c) $10^{-3}\sigma$, and dielectric spheres which come into contact for ϵ_p/ϵ_c of (d) 10.0, (e) 4.0, (f) 2.0 and (g) 1.0 (limit form). Experimental points are for (squares) polyaniline in silicone oil with $\epsilon_p/\epsilon_c = 36$; (circles) hollow silica spheres in corn oil with $\epsilon_p/\epsilon_c = 3.9$; and (triangles) hydrated polymethacrylate particles in a chlorinated hydrocarbon with $\alpha = 3.2$. (Reproduced from Klingenberg *et al.*, 1991).

As $\epsilon_p/\epsilon_c \to \infty$, the polarization model predicts that the yield stress will grow without bound for particles in contact. This picture is altered by chemical limitations of the systems under study. For example, conducting particles are observed to form chains when exposed to electric fields and thus a large ER response is expected. However, the chains also conduct electricity and the power requirements to maintain the field across the gap are unacceptable. Even if the electrodes are coated such that no loss current can flow, if conducting particles are held at too small a separation and the field strength is raised, the dielectric breakdown voltage of the continuous phase is reached and the ER response is severely degraded. However, the polarization model predicts that conducting particles held apart by a thin insulating layer suspended in a dielectric continuous phase represent upper bounds on the ultimate strengths of ER suspensions. Based on a model of conducting particles suspended in a continuous phase of dielectric constant 4 at a volume fraction of 0.37, and a minimum pair surface-to-surface separation of $1 \times 10^{-5}\sigma$, a yield stress of 240 kPa is predicted at 10 kV/mm (Klingenberg *et al.*, 1990). This is a response that, if available, would open a host of technologies. Unfortunately, an experimental yield stress of this magnitude has not yet been reported.

The successes of the polarization model lie in its ability to reproduce time scales, magnitudes of yield stresses, and dependence of the viscosity on field strength, shear rate, and volume fraction. However, models based solely on electrostatic mechanisms are not yet able to account for all experimental observations. First, the models make no attempt to predict the current-carrying capacity of ER suspensions. This is a problem of great technological importance as energy consumption limits ER device economic viability, and the resulting Joule heating produces excessive temperature changes and degrades the response. Second, there is debate about the requirements of a loss current for there to be an observable ER response. Third, the polarization model cannot yet explain why some materials with large bulk dielectric constants do not produce suspensions with large ER responses. Much of the uncertainty over the origin of this failure of the polarization model revolves around the details of the electrochemical system under investigation, how current is transferred through the suspension, and the dispersed-phase polarization mechanisms. Fourth, the effects of temperature on ER suspensions are not fully understood in terms of the polarization model. Some suspensions appear to respond well at high temperature and poorly at low temperature while in others, the reverse is observed. To meet the needs of the automotive industry, the effects of temperature will need to be characterized and controlled.

The polarization model is largely a linear description of the ER response. Often the field strengths used in ER devices exceed the limits of linearity, and then descriptions of the physics and chemistry of nonpolar suspensions subjected to large field strengths are poorly characterized. Understanding many of the failings of the polarization model requires more experimental study. Advances in understanding of the ER response will also be aided by studies of how current is transferred in highly nonpolar continuous phases.

In conclusion, the polarization model has been successful in establishing the bounds where linear behavior can be expected and what materials should produce high-quality ER responses. As a consequence, the way is paved for detailed and rigorous research and development activities. For example, studies of the effects of particle size, shape, and polarization time will lead to greater understanding of how material properties control the ER response. In addition the influence of continuous-phase conductivity and chemistry occurring at the electrode surfaces is likely to influence ER fluid development. Finally, the role of thermal motion in controlling the field where percolating chains are produced, details of the microstructure, and the role of free charge in limiting the ER response are subjects of fundamental and technological interest worthy of further investigation.

3. APPLICATIONS OF ER DEVICES

Devices using ER fluids typically rely on the ability of the ER suspension to change viscosity in a reversible manner upon the application of an electric field. The continuous variability of stress-transfer capability, fast switching speeds, and ease of control offer tantalizing opportunities for device design. Clutches, shock absorbers, robotic actuators, and engine mounts are commonly considered applications for ER suspensions. Here, a series of parallel plates with alternating polarity contain the ER suspension. Plates of one polarity move relative to those of opposite polarity and stress is transferred. When the field is changed, the magnitude of the stress transferred is altered. Advantages of ER devices are rapid and continuously variable stress-transfer capability and the possibility of solid-state electronic control of stress transfer. Engine mounts and active suspensions are currently under consideration in the automotive industry. Power requirements, temperature limitations, and toxicity are considered to be the main stumbling blocks to commercialization (Shulman *et al.*, 1981; Block and Kelly, 1988; Jordan and Shaw, 1989).

In an alternative series of applications, ER fluids are used in hydraulic lines. Electrical valves are then used to control flow rates and pressure drops. Problems faced here are the heterogeneous nature of the ER suspensions. Structures capable of sustaining the required stresses can be generated in the electric field. However, the strands and columns are of limited utility in controlling flow of the continuous phase (Shulman *et al.*, 1981; Block and Kelly, 1988; Jordan and Shaw, 1989).

Control of flexural stiffness is also considered a potential application. For example, a plate-like member is constructed such that it contains compartments with electrodes and ER fluid. When the member is subjected to a load, the compartments can be stiffened in such a manner as to damp out vibrations.

While many applications of the ER response involve limiting the macroscopic motion of a solid surface, new applications under consideration include acoustic dampers and transducers where the modulus of the transducer and thus frequency range to which it is sensitive can be tuned with the electric field. Here, rather than being concerned with the ultimate strength of the ER fluid at some field strength as represented, for example, by τ_y, one is concerned with field-strength and volume-fraction dependences of the storage and loss moduli of the electrified ER suspension in the linear response region.

In another intriguing application, the continuous phase of an ER suspension is made of a chemically crosslinking material such as a silicon sealant, epoxy, or urethane. A mold is constructed of electrodes configured in the shape of the ultimate piece and dipped into the reactive suspension. When the electrified mold is lifted out, the suspension clings to the mold where the electrodes have a narrow separation and runs off the mold where the field is not intense. If the field is kept on the electrode configuration until the material has set, an "electroshaped" object will result. This type of technology has applications in rapid generation of spare parts and prototypes.

The ER response has been known for almost five decades. Few applications have reached the commercial stage because of a variety of problems. The ultimate strength, erosive properties, long-term chemical and colloidal stability, current-carrying capacity, and temperature range are problems which have plagued ER fluid formulation. Recent advances in understanding of the origin of the response and thus the types of chemical and physical characteristics that give rise to large ER responses are beginning to eliminate some of these problems. In addition to formulation problems, limited visibility of ER devices has led to a lack of experience in design, and thus there is little working knowledge of long-term device and fluid performance. A strong coupling between the device design, its applications, and fluid formulation will be required before successful commercialization is achieved.

Driving the interest in ER devices is the availability of solid state power supplies and circuits to control stress transfer. Advances in power supplies and in circuits that can survive extreme environments, coupled with design of new ER suspensions, hold promise for commercial products in the next 5–10 years.

INTRODUCTION

Maxwell's equations, constituting the foundation of electromagnetic theory, deal with three primary entities: the electric field **E**, the magnetic field **B**, and the current density *j*. Corresponding to these three entities are the three primary elements of modern electronic circuits: capacitors, for the storage of energy in the electric field; inductors, for the storage of energy in the magnetic field; and resistors,

which convert electric current into heat energy.

This article addresses the structure, technology, applications, and development of one of these primary electronic elements: the capacitor. To cope with the near infinity of capacitor designs, sizes, electrode–dielectric combinations, and electrical characteristics, a generic approach is adopted in Sec. 1, in which the anatomy of a capacitor is first illustrated with Nature's thunderhead. A brief historical sketch of the first manmade capacitor—or "condenser"—the Leyden jar, is followed by a description of the essential components of a capacitor, together with mathematical definitions of capacitance, dielectric permittivity and relative permittivity, and free-energy storage. An analysis of a typical *R-C-L* circuit introduces the circuit characteristics, which then form the basis of the technical evaluation of capacitor quality in terms of the equivalent series resistance (ESR), equivalent series inductance (ESL), and dissipation factor.

The relation of these gross electrical characteristics to the underlying physics is examined at two levels: first, Sec. 2 offers a field description of the dielectric polarization, induced bulk dipole moment, Maxwell's displacement field, permittivity, the general thermodynamics, and the Gibbs free energy, and how these determine the capacitor electrical characteristics; and second, Sec. 3 describes dielectric phenomenology at the molecular level, including the several types of polarizability, dielectric saturation, breakdown, and breakdown mitigation.

These fundamentals provide the basis of the discussion in Sec. 4 of the various types of capacitors, their structure and geometry, electrode types, and dielectric materials.

Section 5 singles out four illustrative capacitor applications: Energy storage, dc filters, timing circuits, and electromagnetic interference suppression.

The article concludes in Sec. 6 with a projection of the technology of high–energy-density capacitors.

1. CAPACITOR ANATOMY AND CIRCUIT CHARACTERISTICS

1.1 The Thunderhead: A Natural Geophysical Capacitor

On a warm summer day a rapidly moving mass of moisture-laden air sweeps northward from the Gulf of California, forming clouds by adiabatic expansion and cooling as it rises over the high country of northern Arizona. As the afternoon wears on and insolation from the waning sun declines, the cloud water droplets become supercooled. When freezing is finally spontaneously initiated in the droplets of a local volume or "cell" of the cloud, the heat liberated creates a sudden buoyancy, resulting in violent updrafts that propel the cell into a thunderhead towering far above the cloud deck. Accompanying this development is a separation of electrical charge of ill-understood mechanism but variously ascribed to "friction", which builds an enormous difference in the electrostatic potential Φ between the positively charged top and negative base of the thunderhead (Feynman *et al.*, 1964).

Nature thus produces an awesome electrical capacitor of geophysical dimensions, in which the two regions of accumulated charge near the thunderhead top and base serve as the electrodes, with the intervening air as the dielectric medium (Fig. 1). The underlying surface of the Earth acts as a third electrode, positively charged from induction by the negative cloud base.

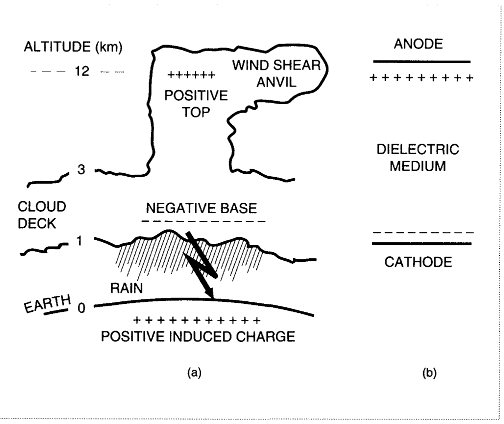

FIG. 1. (a) Charge distribution in a typical thunderhead. (b) Schematic capacitor analog.

If the electric field **E** ($\equiv -\mathrm{grad}\Phi$) reaches the breakdown strength of the air, ~3 MV/m, the capacitor discharges through a spectacular arc or lightning stroke. Lightning can occur between parts of a single cloud, between clouds, or between cloud and Earth. Because of the limited conductivity in the "electrodes," the stroke momentarily depletes the charge concentrations about the ends of the arc, reducing the potential difference, quenching the arc, and allowing the charge separation to resume its buildup.

Evidently to produce such high electric fields in thunderstorms requires a rate of charge separation far exceeding the charge neutralization rate due to conductivity. Conductivity is always present, accounting for a gradual "leakage" of electrode charge and eventual loss of the stored electrical energy.

These natural geophysical capacitors thus mirror on a grand scale not only the structure and general properties of manmade capacitors, but also their failure modes—conduction, leakage, energy loss, dielectric breakdown, and interelectrode arcing—and their recovery—arc quenching.

Collectively, the 2000 thunderstorms in progress worldwide drive a continuous power source of ~700 MW. But in the short duration (~2 ms) of a lightning stroke to Earth from a cloud at 1 km altitude, the power is much greater: ~10 kA at 3 GV produces 3×10^7 MW and an energy release ~6×10^{10} J or 15 tons of high-explosive equivalent! Fortunately, Benjamin Franklin did not tap into this enormous energy source efficiently when he performed his dangerous kite-flying experiment in June 1752. However, using his wet kite string as conductor, he was able to charge a Leyden jar—the forerunner of the modern capacitor.

1.2 Historical Sketch: The Leyden Jar "Condenser"

Electrification produced by friction on certain substances, notably amber and jet, was mentioned by Theophrastus (321 B.C.) and was said to have been familiar to Thales of Miletus (600 B.C.) (Fleming, 1910). The first electrostatic generating machine, employing a revolving ball of sulfur, was built by Otto von Guericke ca. 1663. In 1729, Stephen Gray, of the Greyfriars' School in England, discovered that static electricity is conducted by certain materials and soon was transmitting electrostatic charges around his house over "wires" made of such things as hempen string. The apparent flow of charge led to the belief that electricity was some sort of fluid, and prompted research into ways of collecting this electric fluid.

In 1745, Ewald Georg von Kleist, Bishop of Pomerania, theorized that electricity could be collected in a glass container, glass being already well recognized in the mid-1700s for its electrical insulating properties. A bottle partially filled with water was fitted with a brass nail inserted through a cork in the mouth and touching the water. Holding the bottle by hand, von Kleist presented the projecting nail head to the pole of an electrostatic friction generator. Upon removing it from the generator and touching the nail with his other hand, he received a strong electrical shock.

During the following year, Pieter van Musschenbroeck, Professor of Physics at the University of Leiden, conducted a similar experiment. He also started with water in a bottle, but soon discovered that the charge could be intensified by replacing the water with mercury. By outlining his experiment in a letter to a colleague, who presented it to the French Academy of Sciences, van Musschenbroeck received the credit, and the "Leyden jar" thus acquired its name. In later experiments the Leyden jar was improved by coating the inner and outer surfaces with tin foil (Fig. 2).

The Leyden jar was the original "condenser"—so designated for its ability to concentrate and store electric charge. Spectacular demonstrations of the condenser's power were carried out, including electrocuting birds and fish, and igniting gunpowder and ether. Sir William Watson conveyed the discharge of a Leyden jar over metallic wires for a distance of 2 miles, observing that the transmission appeared instantaneous. This gave rise to a proposal in 1753, now credited to Charles Morrison (Singer, 1958), for an electrostatic telegraph in which the successive charging of an appropriate sequence of the 26 alphabet wires connecting the transmitter and receiver could convey any message.

1.3 Capacitor Components and Structure

The essential elements of a capacitor in a circuit are schematically illustrated in Fig. 3. Upon the closing of switch S1, with S2 open, equal and opposite charges appear on the

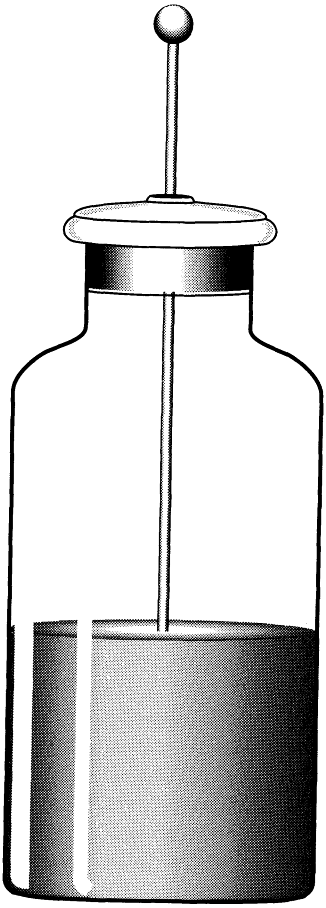

FIG. 2. Glass Leyden jar.

upper and lower plates. These charges result from the transfer of electrons, which continues until the potential difference between the electrodes is equal to the applied voltage—supplied, in the case shown, by a battery.

Modern capacitors operate on the same physical principles as the Leyden jar. As shown schematically in Fig. 1(b), a typical capacitor still utilizes some form of charged electrodes separated by a dielectric material, usually in a multiple-layer sandwichlike structure, in either planar or cylindrical geometry.

The most significant advances in capacitor technology have been made in new materials that permit the use of large areas of dielectric exposed to high electric fields, and in the design of the electrodes. Many common organic plastics, such as various polyesters, polycarbonates, polypropylene, polystyrene, etc., are currently used in film form as capacitor dielectrics. The electrodes of most capacitors are now either aluminum foils 4–12 μm thick, or extremely thin metal coatings—of the order of a few hundred angstroms thick—deposited directly on the surface of the dielectric film.

Inorganic compounds constitute the dielectric of "ceramic" capacitors (see DIELECTRIC PROPERTIES OF INSULATORS), which are today mass produced with such materials as barium titanate ($BaTiO_3$) and lanthanum-doped lead zirconate/titanate (PLZT). Aluminum and tantalum oxides are used as dielectric media in another class, the electrolytic capacitor.

1.4 Capacitance

The measure of the ability of a capacitor to store electric charge, denoted by its capacitance C, is usually expressed as the ratio of charge Q to potential difference V (see ELECTRODYNAMICS, CLASSICAL):

$$C=Q/V. \tag{1}$$

This definition is adequate for low voltages where the capacitance is essentially constant, but is inconvenient for higher voltages where the capacitance may become voltage dependent. In that case it is desirable to use the more general definition of capacitance $C(V)$ as the differential coefficient

$$C(V)=dQ/dV, \tag{2}$$

which, of course, includes a constant capacitance as a special case.

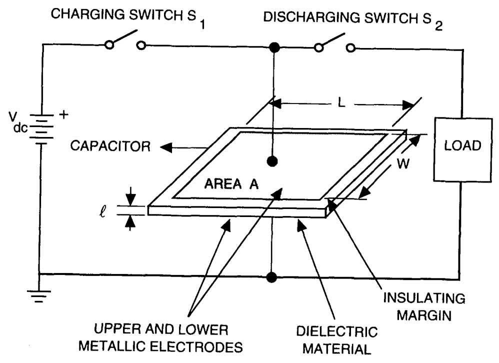

FIG. 3. Essential elements of a capacitor in a circuit.

Capacitance depends not only upon the geometric factors of electrode area A and separation distance l, but also and particularly upon the permittivity ϵ of the dielectric medium. Within the dielectric between electrodes bearing charges $\pm Q$, increasing the charge by dQ causes a corresponding increase in the electric field E of magnitude

$$d\mathsf{E} = dQ/A\epsilon, \tag{3}$$

and an increase in potential difference of

$$dV = l d\mathsf{E}. \tag{4}$$

By Eq. (2) the capacitance is thus

$$C = \epsilon A/l. \tag{5}$$

In the mks system with charge Q in coulombs and V in volts, C is in farads.

The farad, named after the nineteenth-century English physicist Michael Faraday, is generally too large a unit of capacitance for most practical applications. It is even much too large for the cloud-to-ground thunderstorm system of Fig. 1(a): an area of 10 km^2 and altitude 1 km, with air permittivity essentially the same as for the vacuum,

$$\epsilon_0 = 10^7/4\pi c^2 \text{ C/V m}, \tag{6}$$

where the speed of light $c = 3\times10^8$ m/s, has capacitance

$$C = (10^7/4\pi c^2)10^7/10^3 = 0.09\mu F. \tag{7}$$

The microfarad (μF), or 10^{-6} farad, is a more common unit of capacitance, although for the miniature capacitors used in integrated circuits the picofarad (or, in the older literature, the micromicrofarad, $\mu\mu$F) is sometimes more appropriate. However, modern capacitors for high density of energy storage and pulse-power delivery may have capacitances of the order of a farad, more than a millionfold greater than the geophysical capacitors of nature's thunderheads. The capacitance range of industrial capacitors thus spans at least 12 orders of magnitude!

1.5 Capacitor Circuit Analysis

In use, a capacitor must of course be connected to other circuit elements. The solder joints, electrode contacts, leads, and other "external" peripherals always have some series resistance R and inductance L that must be taken into account in time-dependent applications, whether ac of pulse operation.

With reference to Fig. 4(a), the applied voltage, in the complex form $V = V_0 e^{i\omega t}$, with ω $(=2\pi\nu)$ being the angular frequency, is the sum of the voltage drops across each of the series elements:

$$V = V_0 e^{i\omega t} = L dI/dt + RI + \frac{1}{C}\int I\,dt. \tag{8}$$

As shown in standard textbooks (Page, 1935), this equation is solved by the substitution of the time-dependent current,

$$I = I_0 e^{i\omega t}, \tag{9}$$

which yields

$$V = I[R + i(\omega L - 1/\omega C)] \equiv IZ. \tag{10}$$

In an ac circuit, the complex impedance Z thus occupies the role played by the resistance in a dc circuit:

$$\begin{aligned} Z &\equiv R + i(\omega L - 1/\omega C) \\ &= [R^2 + (\omega L - 1/\omega C)^2]^{1/2} \\ &\quad \times [R/Z_0 + i(\omega L - 1/\omega C)/Z_0] \\ &= Z_0 e^{i\delta}, \end{aligned} \tag{11}$$

where Z_0 stands for the modulus radical in the second line, and the "phase angle" δ is given by

$$\tan\delta = (\omega L - 1/\omega C)/R. \tag{12}$$

The relationships among V, I, and δ in the complex plane are shown in Fig. 5. The circuit "reactance" X is given by the numerator of Eq. (12):

$$X \equiv \omega L - 1/\omega C. \tag{13}$$

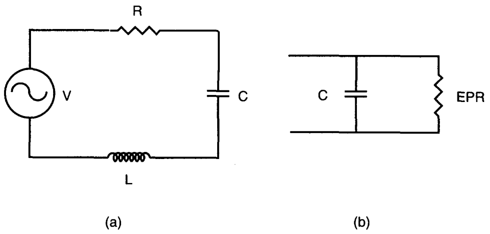

FIG. 4. (a) External series resistance R and Inductance L. (b) Equivalent parallel resistance (EPR).

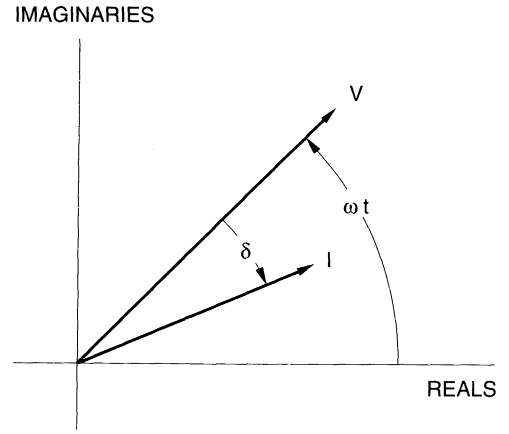

FIG. 5. Representation of V, I, and phase lag δ in the complex plane.

Maximum power is achieved under the resonant condition $\delta=0$ where, from Eq. (12), the resonance angular frequency ω_r is given by

$$\omega_r=1/\sqrt{LC}. \tag{14}$$

1.6 Dissipative Processes; The Equivalent Series Resistance

The conversion of electrical energy stored in a capacitor into heat not only reduces the energy efficiency but also may limit the number and repetition rate of cycles in pulsed operations because of intolerable temperature rise. Three principal mechanisms account for the loss of energy in capacitor operation:

1. Ohmic heating in the combined series resistance R_s of the metal conductors: the electrodes, the foils in wound capacitors, the soldered connections in extended-foil capacitors, the contact resistance in tabbed capacitors, etc.;
2. charge leakage and accompanying Ohmic heating due to the omnipresence of a nonzero conductivity of the dielectric medium, and a corresponding finite shunt or equivalent parallel resistance, R_p [Fig. 4(b)];
3. dielectric energy loss, arising from the conversion of the mechanical energy of atoms and molecules into heat as they try to follow the changes in the electric field.

In the absence of any series inductance L these three loss mechanisms can be accounted for by introducing an equivalent resistance in series with the capacitor—the equivalent series resistance (ESR) (Hall, 1978).

For each type of loss mechanism it is customary to define a dimensionless dissipation factor D as the ratio of the energy loss rate to the energy storage rate. If in Eq. (13) the series inductance L is essentially zero, the magnitude of the capacitor reactance is

$$X_c=1/\omega C. \tag{15}$$

Then, if I is the current through the capacitor, the rate of increase in the stored (free) energy G is

$$dG/dt=I^2X_c=I^2/\omega C. \tag{16}$$

The dissipation factor for a series resistance R_s, which carries the same current I as the capacitor, is evidently

$$D_s=I^2R_s/I^2X_c=\omega CR_s\,. \tag{17}$$

The dissipation factor for the parallel leakage resistance R_p that subtends the same voltage as the capacitor is

$$D_p=(I^2X_c/R_p)^2R_p/I^2X_c=1/\omega CR_p\,. \tag{18}$$

Similarly, dielectric loss can be attributed to an equivalent parallel resistance R_d that subtends the same ac voltage as that across the capacitor. This leads to the same form of dissipation factor as for D_p, Eq. (18):

$$D_d=1/\omega CR_d\,. \tag{19}$$

The total dissipation factor D is simply the sum of these three contributions:

$$D=\omega CR_s+(1/R_p+1/R_d)/\omega C. \tag{20}$$

Noting that D is essentially the ratio of energy lost to energy stored, the ESR becomes

$$R_{\text{ESR}}=D/\omega C=R_s+(1/R_p+1/R_d)/(\omega C)^2. \tag{21}$$

The reciprocal of the dissipation factor, $Q=1/D$, is known as the quality factor. Lumping the three loss mechanisms into the ESR has the virtue of allowing the familiar circuit analysis and language to be applied.

With reference to Fig. 6(a), the impedance, Eq. (11), becomes

$$Z=R+iX_c\,, \tag{22}$$

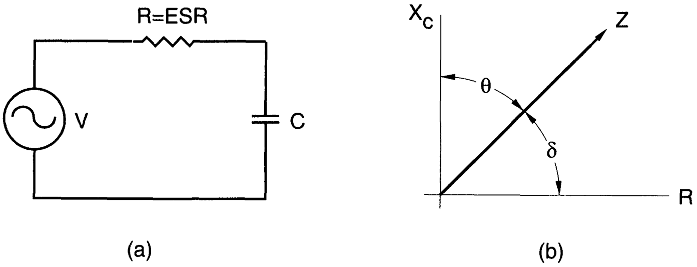

FIG. 6. (a) Capacitor circuit with equivalent series resistance. (b) Relationships in the complex plane.

The tangent of the phase angle δ is again given by the reactance/resistance ratio,

$$\tan\delta = X_c/R. \tag{23}$$

The "loss angle" θ is the complement of the phase angle δ; its tangent is the dissipation factor:

$$\tan\theta = \cot\delta = R/X_c = D. \tag{24}$$

The quality factor Q, being the reciprocal of D, is evidently

$$Q = \tan\delta = \cot\theta. \tag{25}$$

These relationships are shown in the complex plane, Fig. 6(b).

1.7 The Equivalent Series Inductance

As with the equivalent series resistance, each capacitor has a series inductance L, called the equivalent series inductance (ESL). This inductance is inherent in the geometry of the capacitive elements, the connections, the type of insulators or feedthrough used, the current return, etc.

The ESL of a capacitor can be determined by finding its resonant frequency. This test, known as the "standing-wave method", imposes a standing wave, generated by a variable-frequency oscillator, upon a transmission line terminated by the capacitor under test. The frequency at which a null voltage is detected at the capacitor by a high-impedance voltmeter is the resonant angular frequency ω_r of the capacitor, from which, according to Eq. (14):

$$L = 1/C\omega_r^2, \tag{26}$$

wherein L is the inductance in henries and C is the capacitance in farads. This method produces valid readings until the capacitor plates begin to operate as transmission lines, but this occurs only in extremely low-inductance designs where ESL < 10 nH.

2. MACROSCOPIC DIELECTRIC PHENOMENOLOGY

2.1 Dielectric Polarization **P**

An electric capacitor consists essentially of a dielectric medium sandwiched between a pair of metallic electrodes, usually in a parallel-plate configuration, that can be provided with charges of equal magnitudes but of opposite signs. Being supplied by an outside source and unattached to the dielectric medium, these electrode charges are referred to as "free" or "real." It will be shown that they constitute the source of the so-called *displacement field* **D** across the dielectric.

When the field of the electrode charges is applied to a dielectric medium, the positively charged nuclei of the constituent atoms experience a displacement along the field direction and the negatively charged electrons in the opposite direction, so that both signs of charge contribute in the same sense to the charge displacement. If we designate the amount of charge displaced—or charge "flux"—across a unit area normal to the direction of the displacement by the *polarization vector* **P**, and the resulting polarization charge density by ρ_{pol}, conservation of charge requires that

$$\text{div}\mathbf{P} = -\rho_{\text{pol}}. \tag{27}$$

As was already evident from Eq. (5), the greater the permittivity, ϵ, the greater the charge that can be stored on the electrodes for a given potential difference. The underlying physical reason is that the polarization charges induced on the surface of the dielectric material are of opposite sign to the charges on the electrodes, and thus reduce the potential difference.

2.2 The Induced Bulk Dipole Moment $\mathbf{M}$

The polarization vector $\mathbf{P}$ represents the dipole moment induced per unit volume, or the "induced dipole-moment density" (Landau and Lifshitz, 1960). Thus the total dipole moment induced in volume V of the dielectric is given by the volume integral

$$\mathbf{M} = \int_V d\tau\, \mathbf{P}. \tag{28}$$

2.3 The Displacement Field $\mathbf{D}$

From Eq. (27) the total charge density can be written as

$$\rho = \rho_{\text{free}} + \rho_{\text{pol}} = \rho_{\text{free}} - \operatorname{div}\mathbf{P}. \tag{29}$$

In the mks system, Maxwell's fundamental equation defining the electric field $\mathbf{E}$ as the field of *all* the charges takes the form

$$\operatorname{div}\mathbf{E} = \rho/\epsilon_0, \tag{30}$$

where ϵ_0 is the vacuum permittivity of Eq. (6), introduced for convenience of the mks units. Combining Eqs. (29) and (30), we obtain

$$\rho_{\text{free}} = \operatorname{div}(\epsilon_0\mathbf{E} + \mathbf{P}) \equiv \operatorname{div}\mathbf{D}. \tag{31}$$

Evidently the free charges constitute the source of the displacement field $\mathbf{D}$, defined by

$$\mathbf{D} \equiv \epsilon_0\mathbf{E} + \mathbf{P}. \tag{32}$$

In the cgs system, the corresponding relation takes the form

$$\mathbf{D} \equiv \mathbf{E} + 4\pi\mathbf{P}. \tag{33}$$

2.4 The Dielectric Permittivity ϵ

To obtain the connection between $\mathbf{P}$ and $\mathbf{E}$ for dielectric materials at low field strengths it is customary to eliminate $\mathbf{D}$ through the linear constitutive relation*

$$\mathbf{D} = \epsilon\mathbf{E}, \tag{34}$$

where ϵ is the permittivity. However, for high field strengths, the dielectric medium is no longer linear, and it is more useful to define the (nonconstant) permittivity ϵ as the differential coefficient,

$$\epsilon(\mathrm{E}) = d\mathrm{D}/d\mathrm{E} = \epsilon_0 k(\mathrm{E}), \tag{35}$$

where the *relative* permittivity k is defined as the ratio ϵ/ϵ_0 of the dielectric permittivity ϵ to the permittivity ϵ_0 of the vacuum. Although generally a function of E, in the low-field regime this ratio is independent of the field strength, and is called the dielectric constant k:

$$k \equiv \epsilon/\epsilon_0. \tag{36}$$

In the cgs–Gaussian system at low field strengths, $\mathbf{D}$ is simply proportional to $\mathbf{E}$ through the dimensionless dielectric constant k:

$$\mathbf{D} = k\mathbf{E}. \tag{37}$$

Table 1 lists the low-field relative permittivity k and approximate breakdown strength of common capacitor dielectric materials at low frequency and 25 °C.

2.5 Thermodynamics of the Capacitor System

A capacitor may be considered as a "closed" system to which the combined first and second laws of thermodynamics apply during the charging process. If we denote by w_{el} the electrical work done on the capacitor during charging, the Gibbs free energy G has the differential (cf. Guggenheim, 1950)

$$dG = V\,dP - S\,dT + \delta w_{\text{el}}, \tag{38}$$

where, as usual, V is volume, P pressure, S entropy, and T absolute temperature. Thus, for the charging process at constant pressure and temperature,

$$dG = \delta w_{\text{el}}. \tag{39}$$

For a parallel-plate capacitor containing a dielectric slab of area A and thickness l, the work done on the system in transporting charge dQ from the negative to the positive electrode across the interelectrode separation distance l against an existing field $\mathbf{E}$ (normal to the electrode plates) is

$$\delta w_{\text{el}} = \mathrm{E}l\,dQ = V\,dQ, \tag{40}$$

---

*For nonisotropic media the permittivity is a symmetrical three-dimensional tensor, for which generally $\mathbf{D}$ is parallel to $\mathbf{E}$ only along the principal axes. However, for liquids and amorphous solids, such as high polymers above their glass transition temperatures, as well as for crystalline materials of sufficiently high symmetry, the tensor ellipsoid reduces to a sphere so that the scalar relation (34) applies, at least for low field intensities where ϵ is constant.

Table 1. Typical properties of common dielectric materials (at 25 °C).

Medium	Relative permittivity, ϵ/ϵ_0	Breakdown strength (MV/m)^a
Vacuum	1	
Air (STP)	1.000 583	3.0
Polytetrafluoroethylene (Teflon)	2.0	80
Polypropylene	2.2	400
Polyethylene	2.2	140
Paraffin	2.25	
Polystyrene	2.5	180
Polycarbonate	2.7	300
Silicone oil	2.5	30
Polyester (Mylar)	3.2	300
Polyimide (Kapton)	3.3	275
Glass (Pyrex)	4.0	30
Castor oil	4.5	20
Bakelite	6.0	20
Kraft paper (impregnated)	6.6	230
Mica	7.8	120
Aluminum oxide (Al_2O_3)	8.0	
Polyvinylidenedifluoride	11.0	450
Tantalum oxide (Ta_2O_5)	27.0	
Water	80	10
Barium titanate ceramics	500–10 000	20

[a] Values of measured breakdown strengths are highly variable since these are sensitive not only to inhomogeneities and minor impurities but also to sample preparation and duration of exposure to the field.

where V is the potential difference (voltage) between the capacitor electrodes. Since $\mathbf{D}$ is the field of the real charges residing on the capacitor electrodes, its corresponding increment in magnitude is

$$d\mathsf{D} = dQ/A. \tag{41}$$

In what follows it will be convenient to regard the dielectric medium as uniform as well as isotropic. Thus any extensive thermodynamic property, such as the total energy, entropy, or free energy, can be obtained simply as the product of its *specific* (i.e., per unit volume) value—indicated by an overbar—with the total volume of the dielectric medium. Accordingly, combining Eqs. (40) and (41), the increment $d\bar{G}$ in the (Gibbs free) energy density is

$$\begin{aligned} d\bar{G} &= \mathsf{E} l A d\mathsf{D}/lA \\ &= \mathsf{E} d\mathsf{D} \\ &= [\epsilon(\mathsf{E})/\epsilon_0]\epsilon_0 \mathsf{E} d\mathsf{E} \\ &= k(\mathsf{E})\epsilon_0 \mathsf{E} d\mathsf{E}, \end{aligned} \tag{42}$$

where $k(\mathsf{E})$ is the relative permittivity of Eq. (36), generally a monotonically decreasing function of the field strength E.

The characteristics of bulk dielectric materials described above translate into the technical parameters of the manufactured capacitors. The connection between the potential-dependent capacitance C of Eq. (2) and the field-dependent relative permittivity $k(\mathsf{E})$ of Eq. (35) is evidently given by

$$C = dQ/dV = Ad\mathsf{D}/ld\mathsf{E} = (A/l)\epsilon_0 k(\mathsf{E}). \tag{43}$$

2.6 (Free-)Energy Storage

One of the principal applications of capacitors—particularly large capacitors—is the storage of electrical energy and its rapid delivery at high power. If the capacitor were ideal—i.e., a pure, voltage-dependent capacitance $C(V)$ with no conductivity and zero inductance—the Gibbs free energy G stored would be the integral of the voltage V times the charge increment dQ. But since from Eq. (2) $dQ = CdV$,

$$G = \int_0^V V\,dQ = \int_0^V C(V)V\,dV = \langle C\rangle V^2/2, \tag{44}$$

where $\langle C\rangle$ represents the average capacitance over the voltage range 0–V. Evidently if the capacitance has the constant value C_0 independent of voltage,

$$G = C_0 V^2/2. \tag{45}$$

In many applications the energy rating of a capacitor is not of primary concern but rather is determined only by the capacitance and working voltage required. In other cases, such as metal forming by high magnetic fields, the energy delivered to the work piece is critical. In low-energy applications, some capacitors may contain only a few microjoules of energy, while at the other extreme large capacitors can store up to 100 kJ or more—hence their designation as "energy-storage capacitors."

3. MOLECULAR* DIELECTRIC PHENOMENOLOGY

3.1 The Polarizability Tensor

Dielectric materials can be divided into two general classes, polar or nonpolar, depending upon whether or not they possess a permanent electric dipole moment in their ground state.

To describe the behavior of dielectric materials in capacitors, four types of fields must be distinguished:

1. the field **D** of the "real" charges on the electrodes;
2. the field due to the polarization **P**;
3. the electric intensity **E**, being the macroscopic force field averaged over the dielectric medium; and
4. the "local" (or effective) microscopic field **F**.

At the molecular level, the local field **F** that acts upon a molecular element of the dielectric medium is a self-consistent superposition of the externally applied field due to the charged capacitor electrodes, and the fields contributed by all the other charges in the medium, including those induced by the field **E**.

The response of an atom or dipolar group to the local field can be described in terms of its polarizability α, which gives rise to an induced dipole moment μ,

$$\mu=\alpha\mathbf{F}, \tag{46}$$

and polarization,

$$\mathbf{P}=n\alpha\mathbf{F}, \tag{47}$$

where n is the molecular number density. Since under some circumstances the induced moment μ is not parallel to **F**, the polarizability α is generally a (symmetrical) tensor whose operation on the vector **F** changes its direction, magnitude, and units into those of μ.

Three types of response contribute to the polarization:

1. *the electronic polarizability* α_e—measured by the dipole moment resulting from the induced displacement, under the local electric field, of the negative electrons relative to the positively charged atomic nuclei;
2. *the orientation polarizability* α_μ —resulting from the partial alignment of the permanent bond dipole moments along the local electric field; and
3. *the distortion polarizability* α_d —resulting from the bending and stretching of the chemical bonds within the molecules that tie together atoms bearing different formal charges, due to their different electronegativities.

Both the electronic and distortion polarizabilities may depend upon the orientation of the molecule or substituent group relative to the direction of the applied electric field, each being described by its respective polarizability tensor.

3.2 The Clausius–Mossotti Equation

In the cgs–Gaussian system the four fields **E, D, P,** and **F** are connected through the three equations (33), (37), and (47), so that a fourth equation is required for their complete determination. For low field strengths this is provided by the Lorentz–Lorenz field derived for a spherical cavity in the dielectric (Debye, 1945):

$$\mathbf{F}=\mathbf{E}+(4\pi/3)\mathbf{P}. \tag{48}$$

This leads to the Clausius–Mossotti equation,

$$(k-1)/(k+2)=(4\pi/3)n\alpha, \tag{49}$$

where α is the sum of the three polarizabilities:

$$\alpha=\alpha_e+\alpha_\mu+\alpha_d\,. \tag{50}$$

3.3 The Electronic Polarizability α_e

Since electrons in molecules have binding energies comparable with those of the constituent atoms but have masses thousands of times smaller, only they can respond to the high frequencies of visible light—which, of course, is itself generated by electronic oscillations. This provides a means of determining the electronic polarizability. For nonmagnetic materials the dielectric constant k reduces to the square of the refractive index n (not to be confused with the molecular number density used elsewhere):

---

*The subject of electrodynamics is plagued by a multiplicity of unit systems. The electromagnetic technology of capacitors, motors, etc., now usually employs the mks system, which has been used in the preceding section. In contrast, the physics and chemistry of molecules, atoms, and subatomic particles still generally employ the cgs–Gaussian system, which will be followed in this section. The main difference lies in the presence or absence of factors of 4π and ϵ_0 in various formulas.

$$k=n^2, \tag{51}$$

so that the Clausius–Mossotti equation (49) can be written in terms of the molar refraction R, defined by

$$R=V(n^2-1)/(n^2+2)=(4\pi/3)N_A\alpha_e, \tag{52}$$

where V is the molar volume and Avogadro's number $N_A=6.022\times10^{23}$. The electronic polarizabilities α_e^s for various atomic species s can then be expressed in terms of the corresponding atomic refractions, R_s:

$$\alpha_e^s=(3/4\pi)R_s/N_A=0.396R_s\ (\text{Å}^3), \tag{53}$$

where R_s is in cm^3.

Values of the atomic refractions are approximately additive and are found to be practically independent of molecular structure. For a polymer, the electronic polarizability α_e can thus be estimated in terms of the sum of the atomic refractions R_s of the individual atoms composing the typical monomer unit in the polymer film.

For calibrating the intuition, a useful limiting case is that of a perfectly conducting sphere of radius a, for which the electronic polarizability is simply the cube of the radius: $\alpha_e=a^3$ (Joos, 1951).

3.4 The Orientation Polarizability α_μ

The electronic polarizability is reasonably constant up to very high field strengths and is rapidly reversible with essentially no hysteresis or other dielectric loss, but in polar media contributes only a small fraction of the total polarization. By contrast, the rotation of the permanent bond dipoles towards alignment with the applied field involves relative and cooperative movement of the atoms in the dielectric medium, and thus encounters not only a kind of viscous resistance but also the opposing thermal agitation which tends toward randomized orientation. At very high field strengths these permanent dipoles approach complete alignment or "saturation," so that any further polarizability is reduced to the electronic contribution α_e.

Moreover, when the applied field is removed, the permanent dipoles do not "spring" back (as do in the electrons) to their original unaligned orientations but rather are much more gradually disaligned by the thermal agitation; as with the previous alignment, the relative atomic motions required in this disalignment encounter a viscous resistance that may give rise to some hysteresis. It is desirable to minimize hysteresis, since it leads to energy dissipation and heating, which may impose limits on the number and repetition rate of charge–discharge cycles of the capacitor.

At sufficiently low temperatures a polymer may exist in a quasicrystalline state, with a correspondingly rigid structure that strongly resists rotation of the bond dipole moments; upon heating above the "glass transition temperature," the crystallinity disappears in favor of a glasslike structure, which allows greater rotational freedom and thus increases the dielectric permittivity. It is therefore desirable to select a dielectric material whose glass transition temperature lies below the normal operating temperature of the capacitor.

In some dipolar materials the interaction between neighboring dipoles is sufficiently strong to maintain mutual alignment even in the absence of an external field (see DIELECTRIC PROPERTIES OF INSULATORS). When the preferential alignment between neighbors is parallel the material becomes ferroelectric; when antiparallel, antiferroelectric. In extreme cases, ferroelectric crystals can exhibit bulk dipole moments and are known as electrets. In capacitor technology ferroelectric materials can exhibit large hysteresis and correspondingly large dielectric loss.

The energy u of the interaction of a permanent dipole moment μ with the effective local field $\mathbf{F}$ depends upon the relative orientation according to the scalar product*

$$u=-\mu\cdot\mathbf{F}. \tag{54}$$

---

*Strictly speaking, **F** as used in this section is only that part of the local field that affects the dipole orientation. In a given orientation, the dipole induces in the surrounding medium a charge distribution whose "reaction field" acts back on the dipole. If this reaction field is parallel to the dipole and follows its reorientation, it plays no part in orienting the dipole itself.

By convention, the direction of the dipole moment vector $\boldsymbol{\mu}$ extends from the negative (tail) end to the positive (head) end, so that the orientation of lowest energy corresponds to $\boldsymbol{\mu}$ parallel to $\mathbf{F}$. The reference zero of the orientation energy evidently corresponds to $\boldsymbol{\mu}$ perpendicular to $\mathbf{F}$. If the only orientation-dependent energy of a dipolar group were its interaction, Eq. (54), with the local field $\mathbf{F}$, one could write the Hamiltonian function H_{F} for a typical dipole of moment $\boldsymbol{\mu}$ as

$$H_{\mathrm{F}} = H_0 - \boldsymbol{\mu}\cdot\mathbf{F}, \tag{55}$$

where H_0 is the Hamiltonian for the field-free case. This form is not quite equivalent to assuming that the dipoles are mutually independent, since the effective field $\mathbf{F}$ at one dipole contains contributions from the fields of all the other dipoles in its vicinity. In the absence of the external field there is no preferred direction against which to measure the orientation of the dipole, so that the relative orientation of $\boldsymbol{\mu}$ with respect to any specific direction is random. We can thus write the change in chemical potential (i.e., in the Gibbs free energy per molecule) upon applying the external field in terms of the ratio of the respective molecular partition functions q as

$$-\beta\bar{G}/n = \ln(q_{\mathrm{F}}/q_0), \tag{56}$$

where

$$\beta = 1/kT \tag{57}$$

and

$$\begin{aligned} q_{\mathrm{F}}/q_0 &= \oint d\Omega\, e^{\beta\boldsymbol{\mu}\cdot\mathbf{F}} \Big/ \oint d\Omega \\ &= \frac{1}{2}\int_0^{\pi} d\theta \sin\theta\, e^{\beta\mu\mathrm{F}\cos\theta} \\ &= (\sinh\beta\mu F)/\beta\mu\mathrm{F}. \end{aligned} \tag{58}$$

The average energy $\bar{E}/n$ per dipole is thus

$$\begin{aligned} \langle u\rangle &= -\langle\boldsymbol{\mu}\cdot\mathbf{F}\rangle \\ &= \bar{E}/n \\ &= \partial(\beta\bar{G}/n)/\partial\beta \\ &= -\mu\mathrm{F}(\coth x - 1/x) \\ &= -\mu\mathrm{F}\mathscr{L}(x), \end{aligned} \tag{59}$$

where the Langevin function (Mayer and Mayer, 1940) is defined by

$$\mathscr{L}(x) \equiv \coth x - 1/x, \tag{60}$$

with

$$x \equiv \beta\mu\mathrm{F}. \tag{61}$$

At the two extremes of small and large x, the Langevin function takes the values

$$\mathscr{L}(x) \rightarrow \begin{cases} (x/3)(1 - x^2/15 + \cdots) & (x<1) \\ 1 \text{ asymptotically} & (x \gg 1). \end{cases} \tag{62}$$

In terms of the polarizability α_μ, the average energy is given by

$$\langle u\rangle = -\alpha_\mu \mathrm{F}^2. \tag{63}$$

From Eq. (59) we thus obtain the polarizability as

$$\alpha_\mu = \langle\boldsymbol{\mu}\cdot\mathbf{F}\rangle/\mathrm{F}^2 = \mu\mathscr{L}(\beta\mu\mathrm{F})/\mathrm{F} = \beta\mu^2\mathscr{L}(x)/x. \tag{64}$$

For low field strengths ($\beta\mu\mathrm{F} \ll 1$), this becomes

$$\alpha_\mu = \beta\mu^2/3. \tag{65}$$

Dipole moments are commonly expressed in terms of the debye unit (D) of 10^{-18} esu cm (or 3.3356×10^{-30} C m). Thus the transfer of one electron charge (4.8×10^{-10} esu or 1.6×10^{-19} C) through a distance of 1 Å (10^{-8} cm or 10^{-10} m) yields a dipole moment of 4.8 D (or 1.6×10^{-29} C m).

3.5 The Distortion Polarizability α_d

The restoring forces that oppose stretching (or compressing) of chemical bonds are generally much stronger than those that oppose bond bending. Accordingly, most of the distortion of the molecular framework by an electric field comes from modifying bond angles rather than bond lengths. Because the formal charge that resides on an atom varies with its environment in the molecule, there is no general theory for the distortion polarizability of molecules akin to that for the electronic polarizability. Although the distortion polarizability is generally relatively small and therefore often neglected for molecules in which the atoms are covalently bonded, certain ionic lattices—notably of the perovskite structure—can exhibit large distortion polarizabilities and correspondingly enormous dielectric permittivities (see DIELECTRIC PROPERTIES OF INSULATORS).

3.6 Dielectric Saturation

A high permittivity can result from a high density of polar groups only if the dipoles are sufficiently mobile and mutually independent to be able to rotate into alignment with the field. That this is not always the case has been shown by the analysis of the dielectric constant of water (Kirkwood, 1939), in which the intermolecular hydrogen bonds maintain an approximate tetrahedral geometry of nearest neighbors. Lack of a fundamental theory that permits reliable estimation of the energies of various conformations, the energy barriers toward reorientation and the local field F requires resort to experimental measurements in each case.

Insofar as the torque on a dipolar group within the dielectric medium is dominated by the local field **F**, dielectric saturation is approached when the dipole orientation energy $\mu \cdot \mathbf{F}$ becomes comparable with the thermal energy kT; i.e., when

$$\mathsf{F} \approx kT/\mu. \tag{66}$$

Thus, the larger the dipole moment, the lower the internal field F at which saturation occurs.

3.7 Ferroelectric and Piezoelectric Materials

An extreme case of dielectric saturation is the phenomenon of ferroelectric behavior exhibited by several classes of capacitor dielectrics, e.g., certain high polymers and ceramics (see DIELECTRIC PROPERTIES OF INSULATORS).

Dielectric materials are generally electrostrictive. This means that under an imposed field the dielectric undergoes a mechanical deformation; in the simplest case, this deformation is proportional to the square of the applied electric field. In nonpolar organic dielectrics, such as polypropylene, kraft paper, polyester, etc., this effect is extremely small. However, highly polar organic polymers and the inorganic barium titanate have well-characterized piezoelectric properties. For obvious reasons piezoelectric behavior is best minimized in capacitors.

3.8 Dielectric Breakdown Strength

Besides a high dielectric permittivity, the other dominant requirement of the dielectric material is a high electrical breakdown strength. Although the decline in permittivity at high fields means that the energy density no longer increases quadratically with field strength, it nevertheless continues to increase monotonically with the applied electric field, so that to achieve high energy densities it is desirable to use the highest field possible. But the applied field is limited by the breakdown strength of the dielectric.

The development of a breakdown "avalanche" starts with the insertion or creation of a free electron in the medium, possibly by cold-cathode emission from a promontory on the negative electrode or by ionization of an atom in the dielectric material produced by the passage of a radioactive disintegration product (α, β, or γ particle) or a cosmic-ray muon. The free electron, accelerated in the applied field, suffers collisions with both the nuclei and other electrons of the atoms and molecules in its path. Because of the great mass disparity, collisions of electrons with nuclei are essentially elastic and serve only to deflect the path of the electron with little loss in its kinetic energy, just as a tennis ball rebounds from a wall collision with little loss in kinetic energy. Also, as long as the electron kinetic energy lies below the energy of the first excited state of the atom (or molecule) with which it collides, the free electron cannot lose energy since the bound electrons are forbidden to absorb energy by the Pauli exclusion principle; that is, the electrons of the target atom have no higher quantum state available at that energy. However, once the kinetic energy of the free electron exceeds the energy of the first excited state, it can excite an atomic electron and lose a corresponding amount of kinetic energy. Unfortunately, this excitation threshold energy is usually not far below the ionization energy of the atom, so that there is a high probability that such a collision will now produce a second free electron. Thus when the field is high enough, the process of electron multiplication continues until the resulting avalanche of electrons causes an arc—that is, dielectric breakdown—between the electrodes. This arc carries a very high current, and acts as a conducting "short circuit" between the capacitor plates.

3.9 Breakdown Mitigation

Two approaches are commonly used to avoid or mitigate avalanche formation:

1. *prevention* (or, at least, deferring to higher fields) of electron multiplication through the agency of a "getter" molecule whose high electron affinity serves to capture and bind the electron in an ion of essentially zero mobility, thus rendering it incapable of further multiplication;
2. *cure* of the breakdown arc by cutting off its source of current through local vaporization and oxidation of a small electrode area surrounding the arc termini. This severs electrical conduction to the remainder of the charged electrode and thus "quenches" the arc. For the metallized electrodes commonly used in capacitor manufacture, only a small fraction of the stored charge is short-circuited by the arc, and the capacitance is reduced only in proportion to the area of the electrode vaporized. For this reason, this process is referred to as "self-healing failure" (de Rosa *et al.*, 1968).

A kind of chemical self-healing occurs on the anodes of electrolytic capacitors (Sec. 4.5), which can reform their dielectric oxide coating when this is temporarily ruptured by cracking or arc formation.

4. TYPES OF CAPACITORS

4.1 The Great Diversity of Capacitor Types

Capacitors range in size from the microscopic elements of integrated circuits (of characteristic picofarad capacitance) to very large units (~farads) used, for example, in pulsed-power supplies for electromagnetic launchers and high-energy laser systems. Their various applications span a similarly wide range: from solid-state electronics, through sensors, computers, communication systems, radio, television, and missile guidance systems, to Marx generators, public power conditioning, etc. The current catalog of a leading electronics supplier devotes 23 pages to discrete capacitor circuit elements produced by a dozen manufacturers, listing several hundred capacitor types per page; a further 40 pages are devoted to electronic power supplies, of which capacitors constitute an integral part.

Rather than attempt to encapsulate the wide range of capacitor features that support this great diversity, the present description will focus on the relatively few generic components, structural geometries, electrical characteristics, and practical engineering considerations.

4.2 Capacitor Structure and Geometry

All capacitors share the common structure of a dielectric medium sandwiched between two electrodes. Apart from the materials used and the enormous range in sizes, the principal differences in capacitors lie in the structures employed to pack the largest capacitance in the smallest volume. To this end, capacitors of small capacitance for low-voltage operation are typically constructed in the form of stacked flat multilayers of alternating dielectric and electrode sheets. Large capacitors such as those used for high-density energy storage and rapid-discharge, pulse-power applications are almost invariably constructed in a cylindrical geometry by winding together (from separate rolls) dielectric film interleaved with metal electrode foil. Cylindrical windings made on sufficiently large-diameter mandrels can be subsequently flattened to reduce volume and allow more efficient packaging.

4.3 The Electrodes

Capacitors with foil electrodes can employ a variety of metals, but for long shelf life and operational lifetimes it is desirable to use metals that resist corrosion. Noble metals—e.g., silver and gold—would satisfy this requirement, but cost considerations favor the much less expensive aluminum. Although aluminum metal is very electropositive, it has the remarkable property of forming in air a very thin transparent oxide coat that is strongly adherent and protects the underlying metal from further oxidation (at least in low humidity). Typical aluminum foils in use range in thickness from 8 to 12 μm. Such foils are readily available commercially, are very stable, and are easy to wind in the manufacturing process. Special care is required, however, to ensure good electrical connection of the capacitor terminals to these large-area aluminum electrodes.

For some applications the metal foil is replaced by a thin metal coating, ~100 Å thick, that is laid down directly on the dielectric surface by vapor deposition or sputtering "metallization." Depending upon the capacitor application, it may be necessary to control the thickness (i.e., resistance) of such metallized electrodes within narrow limits in order, on the one hand, to avoid excessive I^2R heat generation (and energy loss) in rapid discharge, and, on the other, to limit the current and quench the arc when a local breakdown occurs (see Sec. 3.8).

The selection of the electrode system is usually based on voltage and peak current or peak power specifications. High-voltage capacitors almost always have foil electrodes to minimize internal resistance.

4.4 Dielectric Materials

Although capacitors can be made with any type of dielectric medium—vacuum, gas, liquid, or solid—the common premium on low-space requirements usually dictates the use of a solid. Thin flexible films combine large energy densities with convenience in manufacturing (e.g., winding cylindrical capacitors).

A common classification of capacitors is by the type of dielectric employed.

Paper. Kraft paper, made from the cellulose in wood pulp and produced in a very fine, homogeneous tissue of high purity, is still used in many capacitor types, although it is steadily being supplanted by synthetic plastics. Usually several layers of thin paper are used instead of a single thicker sheet to avoid possible overlap of any random defects (ion impurities, pinholes, etc.). The natural moisture content of the cellulose must be removed prior to final packaging of paper capacitors.

Mica. Minerals of the mica group have monoclinic crystal structure and are readily cleaved along the basal plane into thin sheets that are flexible and elastic and have excellent mechanical and electrical properties. The dielectric constant is about 8, with little variation in the radio-frequency range. Mica also exhibits a very low loss. For these reasons mica was one of the earliest materials used as a dielectric, and remains today a mainstay for small electronics capacitors.

Reconstituted mica, a paperlike material made from ground mica platelets, has a dielectric constant of about 6, and can be wound together with metal foil into large cylindrical capacitors using the same manufacturing processes as for paper or plastic film

High-Polymer Plastic Films. Many of the high polymers developed by the chemical industry—usually for textile fibers—have been found suitable as dielectric materials. Because of the mechanical requirements of flexibility these are generally linear polymers, as contrasted with cross-linked two- and three-dimensional structures—which tend to be more brittle. They thus fall into the class of "thermoplastics," which have a softening temperature around 135 °C. Although the polymer chains are linear in a topological sense, they are usually kinked and highly entangled in films that are either extruded or melt-cast. It is therefore customary to subject newly formed film to uniaxial or biaxial stretching prior to metallizing and winding. Stretching generally improves the strength and electrical properties, but may impart a "memory" that causes later shrinkage, especially at temperatures approaching the softening point.

Of all the commercially available dielectric films, polyvinylidene-difluoride and its copolymers have the highest permittivities (see Table 1). This is a consequence of the relatively large difference in electronegativities of the carbon atom (2.5) and the fluorine atom (4.0), which leads to a C–F bond dipole moment of nearly 2 D. An important contributing factor to the dipole-moment density is the small volume occupied by these low–atomic-number elements (6 and 9, respectively).

Ceramics. The early ceramic capacitors were generally made of low-loss, low-permittivity materials such as Steatite. Steatite has a dielectric constant of about 8 with an excellent dissipation factor (<0.001). These capacitors have good thermal and voltage stability and can be operated at 500 volts or more.

Research into other metal-oxide ceramics led to the use of titanium dioxide ($k \sim 80$) for a period, but the formulation of barium titanate mixtures having dielectric constants upwards of 5000 (Tareev, 1975) sparked the widespread use of ceramic capacitors today. Research into metal-oxide semiconductor devices has produced dielectric constants approaching 200 000.

The most common method for producing ceramic capacitors is called the tape casting process wherein the dry ceramic powders are mixed into a liquid organic binder to form a slurry the consistency of cake batter. This slurry is then metered onto a moving belt coated with a polymer film such as polypropylene. The thickness of this "green" ceramic material is controlled by an adjustable gate known as a "doctor blade." The material is then dried to a pliable condition that can be cut into the desired configurations. These cut sheets are then fired in a furnace at about 1300 °C. The firing process is critical in that too low a firing temperature yields a porous material with low capacity and high dissipation factor, while too high adversely affects the capacitor temperature coefficient and also increases the dissipation factor.

After firing, the electrode is patterned onto the ceramic. Several electrode materials are used, but a common one is silver. The ceramic chip is then refired at about half the initial firing temperature to "set" the electrode. These chips can be arranged in series or parallel to obtain higher voltage or capacitance. Leads are then attached, and the assembly is either potted in epoxy or encased in a specialized housing.

Water as Dielectric. Water capacitors are used in large pulse-power systems where rapid discharge and high voltages are involved and particular geometries are desired—usually in the final stages of pulse compression. Typically these capacitors have a coaxial geometry and are best analyzed as pulse-forming lines rather than pure capacitances.

Low-conductivity water is used as the dielectric medium, but the key requirement is a short time during which voltage is applied. For this reason, water capacitors are generally charged by the discharge of a Marx generator containing film-type capacitors. The breakdown field in a coaxial water capacitor has been empirically determined to depend on the area A of the electrodes and the pulse width t according to the equation

$$\mathrm{E}_B(\mathrm{MV/cm}) \approx b/[t(\mu\mathrm{s})]^{1/3}[A(\mathrm{cm}^2)]^{0.06}, \tag{67}$$

where b (≈ 0.23) is a constant that depends on the polarity of the center electrode and the electrode surface condition. Roughening of the electrode surface and applying a prepulse at a relatively low voltage have been found to increase breakdown strength by contributing to the formation of a space charge that makes the buildup of the field at the electrodes more gradual.

Impregnating, Potting, and Canning. Low-voltage dc capacitors are often unimpregnated or "dry," and wrapped with a heavy insulating film capped at each end with epoxy—a design known as "dry wrap and fill." For low-ac-voltage ratings the paper or film, wound in a roll, may be impregnated or partially impregnated, the excess liquid impregnant being drained off, after which the capacitor is potted or canned. Since capacitance depends sensitively upon electrode configuration and spacing, for maximum stability it is desirable to "freeze" these parameters in fixed geometry. For small capacitors this is readily accomplished with standard methods of "potting" in plastics that solidify into rigid structures.

Larger capacitors, particularly those subject to frequent high-field-stress and/or thermal cycling, may develop voids from delamination or cracking. To ameliorate any attendant degradation of capacitance or breakdown strength, most capacitors designed for high-voltage (>500 V) operation are impregnated under vacuum with an insulating dielectric liquid.

The highest voltage ratings are obtained by connecting individual capacitor windings in series within the container and/or by arranging multiple electrodes within a single winding to create series capacitors. Parallel connection of windings is frequently used for large capacitance values as well.

The final operations in capacitor manufacture involve providing the internal connections to the capacitor terminals and sealing in an appropriately configured container ("canning"). For efficiency in packaging, cylindrically wound capacitors are often flattened. Depending on the application and requisite can capacitance, several subunit capacitors can be incorporated in a single can, with either series or parallel connection.

4.5 Electrolytic Capacitors

Electrolytic capacitors are similar in structure to conventional electrostatic capacitors in that they also contain two electrodes separated by a dielectric medium. However, in contrast with capacitors in which the metallic electrodes are deposited ("metallized") onto the dielectric, electrolytic capacitors utilize metal-foil anodes—originally of aluminum, but now increasingly of tantalum—upon which a dielectric oxide film is formed by an electrolysis process. It is this electrolysis process that gives this type of capacitor the generic name "electrolytic": it is not necessary for electrolytic capacitors to contain an electrolyte, although most types do. Prior to electrolysis, the anodes are put through an etching process designed to increase their surface area by several-hundred-fold. This process is of critical importance for the selection of the capacitance–voltage (*CV*) product, described below.

The electrode metals—aluminum or tantalum—are chosen on the basis of the desirable properties of their oxide films, particularly their uniformity, adherence to the metal substrate, and dielectric characteristics. The oxide film thickness is determined by the "forming voltage" used in the electro-oxidation process. To avoid altering the oxide-film properties, the working voltage of the resulting capacitor is generally set between 25% and 90% of the forming voltage. Table 2 lists the characteristics of the aluminum and tantalum oxide films.

The anodized foils are separated by an insulating material to prevent direct mechanical contact between successive layers. This separator is typically porous and acts as a reservoir to hold the electrolyte. The electrolyte is the "real" cathode of the electrolytic capacitor, the cathode foil serving only to make contact to the terminal of the capacitor.

Tantalum has several advantages over aluminum. The higher dielectric constant of Ta_2O_5 (Table 2) imparts a volumetric improvement ratio of about 3 over equivalent aluminum electrolytics. Being much less electropositive, tantalum is relatively inert and does not release hydrogen gas by electrolysis of the electrolyte. Moreover, whereas aluminum electrolytics may require "reforming" after extended disuse, tantalum oxide layers are far more stable.

Table 2. Properties of electrolytic metals and their oxide films.

Metal	Oxidation Potential (*V*)	Oxide	ϵ/ϵ_0	Thickness (Å/V)
Aluminum	1.5	Al_2O_3	8	13.5
Tantalum	0.7	Ta_2O_5	27.6	17

As with aluminum, the thickness of the tantalum oxide layer is increased by the application of higher forming voltages, which translate to higher rated voltages in the finished capacitors. This anodizing process must be optimized, however, since as the oxide layer increases in thickness it tends to bridge and seal off pores in the anode structure, resulting in dramatic losses in capacitance.

Both aluminum and tantalum have the desirable feature of "self-healing" (cf. Sec. 3.9) in that any cracks or separation of the oxide layer from the underlying metal are immediately repaired through reaction with the electrolyte.

Leakage of the liquid electrolyte has been a common problem, especially for aluminum electrolytics in which gas may be formed by reaction of the aluminum metal with the electrolyte. To obviate this problem Bell Telephone engineers pioneered in substituting solid manganese dioxide (MnO_2) for the electrolyte solution. This material has good conductivity and is a strong oxidant, which preserves the self-healing property.

There are two main types of tantalum capacitors marketed today, solid and wet. The solid version utilizes a "solid electrolyte" such as the manganese dioxide described above, whereas the wet tantalum electrolytics employ a liquid electrolyte such as a solution of sulfuric acid, H_2SO_4. Figure 7 schematically illustrates the components of a "wet" powder anode capacitor.

4.6 Chemical Double-Layer "Battery" Capacitors

A new type of electrolytic capacitor is currently being developed by several university and industrial concerns. These are the chemical double-layer capacitors, often referred to as "battery capacitors," based on a double-layer charge-storage principle (Boland, 1985; Yoshida *et al.*, 1986; Rose, 1988; Evans, 1990; Boos and Argade, 1991). The

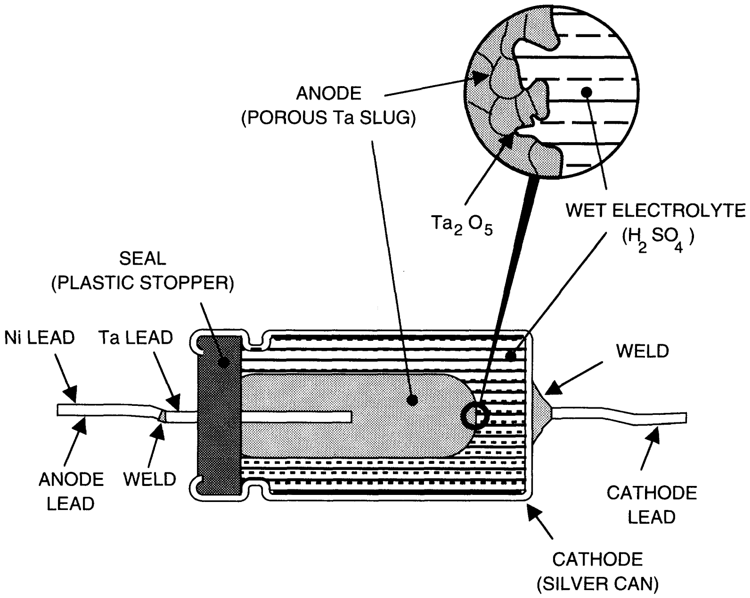

FIG. 7. Components of a "wet" powder anode capacitor.

capacitance of this device derives from the potential difference across the double layer (von Helmholtz, 1879) that is formed by polarization of the electrolyte in the field at the surface of the electrodes. When two of these double layers are brought together with interposed electrolyte, typically sulfuric acid, equal but opposite charges can be stored on the interfaces. Because of the high surface areas of these interfaces, extremely high capacitance values are obtainable, resulting in high volumetric energy densities.

Advanced constructions have been reported in the references given above. Several groups are investigating the use of these "battery" capacitors in pulsed-power applications, such as components for electric vehicles.

5. CAPACITOR APPLICATIONS

Capacitors are used for a broad range of circuit applications—filtering, blocking dc currents, coupling or decoupling components, frequency tuning, timing, energy storage, etc.; the list is virtually endless. This section will touch on a few illustrative uses of capacitors but must be understood to be by no means comprehensive.

5.1 Energy-Storage Capacitors

Energy-storage capacitors are designed primarily for use in high-power electrical applications that require delivery of high-power pulses over specific times. The amount of energy to be stored may range from a few joules to greater than 50 kJ. Typically, the larger energy-storage facilities are assembled in large capacitor banks storing multimegajoules of energy that can be discharged in very short periods of time, giving extremely high bursts of power. Examples of such systems include the pulse-power conditioning capacitor bank that drives the large solid-state lasers used in the NOVA inertial-confinement fusion experiments at the Lawrence Livermore National Laboratory (Haskell *et al.*, 1981), and high-power x-ray generators developed for the U.S. Defense Nuclear Agency and the U.S. Department of Energy.

Energy-storage capacitors must be designed to withstand high voltages; in the case of pulse-shaping or "peaking" circuits, these may be as high as several megavolts. Applications exist requiring each individual capacitor to deliver in excess of 2.5×10^5 A of discharge current over several microseconds. The magnetic forces associated with such large currents must be taken into account in capacitor design.

5.2 dc Filters

dc filter capacitors are used in power supply circuits for reducing the ac ripple voltage of the rectifier. There are many types of circuits for producing dc, ranging from single-phase, half-wave rectifiers to 12-phase, double-wave rectifiers. The ripple voltage levels allowable for typical polymer film capacitors are expressed as a percentage of the dc voltage and decrease as frequency increases. For example, at 60 Hz the allowable ripple voltage level is 25% of the dc level, whereas at 1 kHz the ripple voltage cannot exceed 5% without a significant reduction in life.

dc filter capacitors are also employed in the power supplies of hard tube modulators. To prevent a drooping voltage during a pulse, the capacitor bank should appear as a source of nearly infinite current.

5.3 Timing Circuits

Timing circuits generally utilize the *RC* characteristics of the circuit to time voltage increases or decreases. During the charging process of a capacitor in an *RC* circuit, the buildup of the transient voltage V across the capacitor and the declining circuit current I follow the exponential forms

$$V/V_0 = 1 - e^{-t/\tau}, \tag{68}$$

$$I/I_0 = e^{-t/\tau}, \tag{69}$$

where V_0 is the applied voltage, I_0 ($\equiv V_0/R$) the initial current at time $t=0$, and the characteristic time unit τ is given by

$$\tau = RC. \tag{70}$$

Practically, all capacitors and resistors have losses that affect their time characteristics. Aluminum and tantalum electrolytics have relatively high dc leakage currents that appear electrically as a shunt resistance across the capacitor. This can cause an increase in the *RC* time constant, of which designers must be aware.

5.4 Electromagnetic Interference (EMI) Suppression

Feedthrough and dual-inline-pin (DIP) mount multilayer ceramic (MLC) capacitors are designed to have very low terminal inductances. This permits bypassing to ground of any electromagnetic interference superimposed on the desired signal. In military applications this is important in overcoming adversarial jamming of communications, radars, etc., in sophisticated electronic warfare.

6. WHITHER CAPACITOR TECHNOLOGY?

6.1 Industrial and Military Requirements

Many modern industrial processes—pulsed magnetic forming or welding of metals, explosive shearing, highly penetrating x-ray imaging, high-energy lasing—require delivery of repetitive high power in short pulses. Although present technology does not yet permit achieving electrical energy storage at densities comparable with chemical energy densities, the much shorter time in which an electrical pulse can be delivered makes the *power* density of capacitors highly competitive with other power sources. Moreover, in recent years rapid advances have been made in the technologies of both high–energy-density storage and high power-delivery capabilities of electrical capacitors.

These advances are expected soon to make practical several important applications, heretofore unachievable, ranging from electrical launch of military projectiles and missiles from mobile vehicles (e.g., ships, tanks, self-propelled artillery, antiballistic missile defense) to auxiliary power for rapid acceleration of electrically driven automobiles. Since the recharging of the capacitors can be conducted over the relatively long periods between pulses, this can be carried out at the much lower power levels currently available from ordinary electric generators driven by conventional combustion engines or gas turbines.

6.2 Some Critical Capacitor Technologies

To realize the projected energy and power densities required for capacitors in the foregoing applications, advances are necessary in two key technical areas: increased dielectric permittivity and improved breakdown strength.

For orientation, to achieve in an electrical capacitor an energy density 1% that of TNT would require that

$$\langle \epsilon \rangle \mathrm{E}^2/2 = \epsilon_0 \langle k \rangle \mathrm{E}^2/2 \sim 66 \ \mathrm{MJ/m^3}, \qquad (71)$$

or equivalently,

$$\langle k \rangle \mathrm{E}^2_{\mathrm{kV/mil}} = 0.93 \times 10^4. \qquad (72)$$

This is to be compared with the presently achievable energy density of about 15-fold less.

To reduce this gap, two approaches appear promising:

1. *Increase in permittivity:* In comparison with the relative permittivity of the best commercially available dielectric films (Table 1), the relative permittivity of the various mixed titanates can exceed 10 000 (Tareev, 1975)—but currently only at much reduced breakdown strengths. One challenge, then, is to learn how to develop ceramics, or ceramic–film matrices, that can withstand high electric fields. Again for orientation, an average relative permittivity $\langle k \rangle$ of 10^4 would from Eq. (71) require a field of $\mathrm{E} \approx 1$ kV/mil or 40 MV/m.
2. *Increase in breakdown strength:* Current understanding of the propagation and multiplication of electrons through collisional ionization in solids and gases and the possibility of suppressing ultimate breakdown through electron avalanche formation is in a relatively primitive state. Sulfur hexafluoride is one of the few electron"getters" that have been used successfully for this purpose.

In conclusion, the general principles outlined in this article and illustrated particularly by high–energy-density applications are relevant to capacitors of all types, sizes, and dielectric composition.

GLOSSARY

Capacitor: A device for storing electrostatic energy, consisting of two electrodes (or "plates") separated by a layer of dielectric material. The capacitor is "charged" by transporting electric charge from one electrode to the other, usually under the action of an applied potential difference, thus establishing an electrostatic field within the dielectric (Secs. 1.2 and 1.3).

Ceramic Capacitor: A capacitor whose dielectric is a ceramic material, such as barium titanate (Secs. 1.3 and 4.4).

Dielectric: A nonconducting medium (solid, liquid or gas) that can serve as the province of an electric field (Secs. 1.3, 3.4, and 4.4).

Dielectric Loss: Electrical energy input minus electrical energy recovered from a capacitor, resulting from various combinations of dielectric conduction, leakage, electrical hysteresis, etc. (Secs. 1.1 and 1.6).

Dielectric Permittivity, ϵ: The differential coefficient expressing the rate of change of the displacement field D with the electric field E: $\epsilon = d\mathrm{D}/d\mathrm{E}$. The permittivity of a *linear* dielectric is independent of the field, so that $\mathrm{D} = \epsilon \mathrm{E}$ (Secs. 1.4 and 2.4).

Dielectric Saturation: The phenomenon approached at applied electric fields that are so strong as to cause virtually complete alignment of the permanent dipoles of the dielectric medium, thus greatly reducing the permittivity (Sec. 3.6).

Dipole Moment, μ: For a neutral molecule containing an unsymmetrical charge distribution, the product of the magnitude of the charges separated with the (vector) distance of separation (Secs. 2.2 and 3.4).

Electrolytic (Capacitor): A capacitor whose dielectric medium has been formed directly on one or both electrodes by an electrolytic (e.g., anodizing) process—for instance, as aluminum oxide on an aluminum electrode (Secs. 1.3 and 4.5; Table 2; Fig. 7).

Local (Electric) Field, F: The effective electric field at the site of a molecule (or substituent group), comprising the applied external field together with the superposed fields due to all the other charges and dipole moments of the medium (Secs. 3.1–3.4).

Metallization: The process of forming a thin adherent metallic layer, e.g., by vapor deposition, on a dielectric film to serve as a capacitor electrode (Sec. 4.3).

Polarizability, α: A measure of the ability of a molecule (or substituent group) exposed to an electric field $\mathbf{F}$ to develop a dipole moment μ along the field direction, by displacement of its electrons relative to the nuclear framework and through (partial) alignment of any permanent dipole moments present: $\mu=\alpha\mathbf{F}$ (Sec. 3.1).

Polar Medium: A medium containing permanent molecular (or substituent group) dipole moments (Sec. 3.1).

Relative Permittivity, k: The ratio of the permittivity (ϵ) of a dielectric material to that (ϵ_0) of the vacuum: $k=\epsilon/\epsilon_0$. A *linear* dielectric medium has a constant k value, independent of field strength (Sec. 2.4; Table 1).

Self-Healing (Electrode): A metallized electrode that automatically quenches an arc breakdown by local vaporization of the thin metallic film thus restoring the nonconducting *status quo ante*; also, an anodized electrode of an electrolytic capacitor that automatically reforms the dielectric oxide layer if a crack or breakdown develops (Sec. 3.9).

INTRODUCTION

Electrostatics is concerned with the effects of positive and negative charges at rest. The fundamental charges are the proton and the electron. In general, for every proton, there is also an electron. These charges are equal in magnitude; the proton is positive and the electron is negative. Like charges repel; unlike charges attract.

The basic electrostatic law is Coulomb's law: Two electric charges attract or repel each other with a force that is proportional to the product of the charges and that varies inversely with the square of the distance between them.

While Coulomb's law for the force is simple and compact for a single charge source, it becomes complicated and unwieldy for sources consisting of multiple separated charges and distributions of charge. A large body of theory exists for obtaining the force from these sources; this theory is discussed in Sec. 1. The physical origins of these sources are discussed in Sec. 2. Sources surrounded by materials interact with the material to alter the forces; these interactions are discussed in Sec. 3. Many of us are most familiar with electrostatic phenomena in the atmosphere, discussed in Sec. 4. There are many applications of electrostatics in industry, both in fluids, discussed in Sec. 5, and in vacuum, discussed in Sec. 6. The subject of electrostatic applications in fluids is customarily called "electrostatics." Vacuum and atmospheric applications, while equally significant, are generally considered as topics within the subject area. Strictly speaking, the electrostatic force is fundamental to chemistry and biology as well, as it bonds atoms and molecules together; these topics are discussed in other articles.

The earliest recorded references to the electrostatic force come from the ancient Greeks. In *De magnete*, published in 1600, William Gilbert described many observations of electrostatic phenomena that distinguish electricity from magnetism. A number of electrostatic generators appeared during the next century. Electrical repulsion, conduction, and induction were observed. Benjamin Franklin set the foundations for atmospheric electrostatics in 1752 when he demonstrated the electrical nature of lightening using a kite. He is also credited with the names "positive" and "negative" for the two kinds of charge. In 1785 C. A. Coulomb confirmed the inverse square law of force and measured its magnitude. The basic theory of electrostatics was established by Faraday and Gauss and others in the first half of the 19th century. The word "electrostatic" was introduced about a century ago by Maxwell and Thomson (Roller, 1967).

The Leyden jar, the earliest capacitor, was an early reservoir of charge. In fact, the word "charge" derives from the concept of loading a reservoir, as in loading a cannon. The Leyden

jar was supplanted by the voltaic cell in the early 19th century, and, subsequently, electrostatics languished. Electrostatics was rejuvenated in the first half of the 20th century, beginning with the Cottrell precipitator and culminating with the introduction of xerography by Carlson.

Vacuum electrostatic devices were invented during the first half of the 20th century, and electronic tubes rapidly took on technological importance. Image formation with an electron beam in the 1920s was followed by the development of television and the electron microscope. Since the charge motion in vacuum devices is ballistic, these devices can be fully simulated by computer. With the power to simulate, the performance of vacuum devices has been vastly improved during the last half-century.

Throughout the 20th century, atmospheric electrostatics has benefitted from more extensive and accurate observations coupled with the data-handling capacity of modern computers.

1. THEORY

1.1 Concepts and Definitions

(see also ELECTRODYNAMICS, CLASSICAL)

The unit charge, the coulomb (C), consists of 6.242×10^{18} electrons or protons. In a vacuum a charge of 1 C repels a like charge, at a distance of 1 m, with a force of about 9×10^9 newtons (N), or approximately 1 million tons. In physics and industry the charges encountered are typically vastly smaller than the coulomb.

The charge is the electrical analog of the gravitational mass in mechanics. Just as raising water away from the earth against the gravitational force results in the storage of energy as potential energy, so the separation of two unlike charges, against the Coulomb force, results in the storage of energy as potential energy. Near the surface of the earth, the gravitational potential energy is mgh, where m is the mass, g is the acceleration of gravity, and h is the separation. The analogous stored electrical potential energy is $Q\phi$, where Q is the charge, and ϕ is the unit of electrical potential; the potential is frequently expressed in volts (V), a joule per coulomb. Just as the separation h is the distance between two locations, the electrical potential is the difference in potential between two locations. Thus, it is often called the potential difference.

Since the volt describes energy storage associated with the separation of charge Q from a source charge, just as gh describes the energy storage associated with the separation of mass m from the source mass (the earth), then the volt per meter is the electrical analog of g. This quantity is called the electric field. The field at a point in space is defined by all the source charges and their arrangement about the point. Then the force on a charge at that point is the charge Q multiplied by the field $\mathbf{E}$. The energy change upon moving the charge between two nearby points separated by $\mathbf{h}$ is the scalar product of the force and the vector separation of the points, i.e., $Q\mathbf{E}\cdot\mathbf{h}$, or $Q\phi$. Near the center of a parallel-plate capacitor, the electric field is uniform, just as the gravitational field g is uniform near the surface of the earth.

The capacitance measures the capacity of a system to store electric energy. It relates the stored charge Q to the potential ϕ at which it is stored; there is no familiar mechanical analog for capacitance. The farad (F) is the unit of capacitance, measured in coulombs per volt. The farad is far greater than the amount of capacitance normally encountered, e.g., the capacitance of a parallel-plate capacitor with area 1 m^2 and separation 1 cm is less than 10^{-9} F. From this example, the capacitance is seen to characterize the geometry of the capacitor, and, indeed, in some systems of units, its unit is a length.

A charge in an electric field experiences the Coulomb force. If the charge is free, i.e., the electron or proton can move, or it is attached to a small mass, the charge is accelerated according to Newton's second law and it moves. When the charge moves, the phenomenon falls outside the domain of electrostatics. In customary usage, however, slowly moving charged particles are still considered to be "quasielectrostatic" phenomena. A moving charge is observed as an electric current. In fact, the electric current is used to define the fundamental unit of electricity; this unit is the ampere, a coulomb per second. As the ampere is the fundamental unit, the coulomb is defined as an ampere second, and, thus, the coulomb assumes the awkward size noted above.

While it is widely used, the coulomb is not the only unit of electric charge. The constant in Coulomb's law relating force to charge and distance is dependent on the charge unit and the distance and force units. The units used in this article, the coulomb and the mks system, are called SI, or rationalized mks, units. However, if the Coulomb's-law constant is set equal to unity in the cgs system, the unit of charge is the statcoulomb, equal to 2.081×10^9 electrons or protons. This unit of charge is used in the electrostatic (esu) and Gaussian systems of units. Other systems of units in use include the electromagnetic (emu) and the Heaviside–Lorentz systems. Returning to SI units, the Coulomb's-law constant, 9×10^9 N m^2 C^{-2}, is frequently expressed as $(4\pi\epsilon_0)^{-1}$, where ϵ_0 is called the permittivity of free space; $\epsilon_0 = 1/(36\pi)\times 10^{-9}$ farad/m. [More precisely, the factor 9 is $(2.997\,93)^2$ from light speed.]

1.2 Laws and Equations

Electric charges occur in fundamental units on particles that can be imperceptibly small. The forces are described by Coulomb's law. For larger particles and/or larger charges, the charge is distributed in space; the distribution is characterized quantitatively by the volume charge density $\rho(\mathbf{r})$. The forces and fields associated with extended charge densities require more extensive mathematics, especially when the densities are complicated. The densities may be complicated by the absence of symmetry, because of an unusual distribution in space, by being disjoint, etc. Most of the theory in electrostatics is developed to calculate these electric fields. By contrast, in gravitation, where the force between masses is described by Newton's law, similar to Coulomb's law for the forces between charges, fewer examples of complicated mass densities occur in daily life, and so there is less need for this extensive theory; of course, all the theory developed for electrostatics is transferable to gravitation.

Following Coulomb's work, Gauss showed that the divergence of the electric field is proportional to the charge density; symbolically, in SI units, this statement is

$$\nabla\cdot\mathbf{E} = \rho/\epsilon_0. \tag{1}$$

Upon integration of this equation over volume and applying the divergence theorem from mathematics, also credited to Gauss, Gauss's law emerges. Gauss's law states that the electric flux through a closed surface is proportional to the charge enclosed by the surface. The electric flux through a plane surface in a constant field is the product of the electric field component normal to the surface and the surface area; other surfaces, or planar surfaces in regions of variable field, may be decomposed into differential plane areas, and the electric flux is obtained by integration. Thus, for a charge Q at the center of a spherical imaginary surface of radius R, the field component E normal to the surface is the same by symmetry everywhere over this surface, so that the flux is $4\pi R^2 E$, and Gauss's law yields $4\pi R^2 E = Q/\epsilon_0$, i.e., Coulomb's law. This imaginary surface is frequently called a Gaussian surface. Gauss's law is often used to find the field from symmetric charge densities; e.g., the field E immediately outside a sheet of uniform charge density σ is $\sigma/2\epsilon_0$.

In electrostatics, Faraday's law, one of Maxwell's equations, simplifies to the statement that the curl of $\mathbf{E}$ is zero because the Coulomb force is conservative. Mathematically, this implies the existence of a scalar function $\phi(\mathbf{r})$, such that

$$\mathbf{E} = -\nabla\phi. \tag{2}$$

The function ϕ is the electric potential discussed in Sec. 1.1. When Eq. (2) is inserted in Eq. (1), the differential equation

$$\nabla^2\phi = -\rho/\epsilon_0 \tag{3}$$

is obtained; it is called Poisson's equation, and when ρ is everywhere zero, it is called Laplace's equation. In engineering applications of electrostatics, the electric field is generally needed, because it provides the forces acting on charges; however, the field is a vector function, comprised of up to three components, each of which is a distinct scalar function. To obtain these functions from Eq. (1) is frequently a difficult problem. It is often easier to solve Eq. (3) for the scalar potential function, a single function, and use Eq. (2) to obtain the electric field components.

Equation (3) is not enough to specify ϕ. Also the field obtained from ϕ with Eq. (2) is insensitive to the addition of a constant to ϕ, so the point at which $\phi=0$ is arbitrary; it is often called ground, or ground potential, as the earth is generally the zero level of potential in atmospheric electrostatics. To specify ϕ, boundary conditions are required. Specification of ϕ on a closed surface is a suitable boundary condition, frequently called the Dirichlet problem. Specification of the derivative of ϕ normal to a closed surface is also a suitable boundary condition, called the Neumann problem. The problem is said to be closed or open depending on whether ϕ is to be determined inside or outside, respectively, the boundary. Interior and exterior are often used instead of closed and open, respectively.

Materials in which charge moves freely are called conductors. ϕ is constant throughout a conductor. A region enclosed by a conductor that contains no charge is also at constant ϕ and the field is zero.

1.3 Applications

Electrostatics is governed by the theory outlined above. Its application to specific problems in technology requires skillful use of a variety of mathematical tools. Prior to computers, the principal tool was analytic solution of differential equations. Frequently a problem similar to the specified problem is solved. The solvable problem generally has symmetries that allow Eq. (3) to be reduced from a partial differential equation in three space variables to a set of up to three ordinary differential equations. Often a symmetry is associated with a constant boundary potential on a surface defined by a constant value of a coordinate, e.g., on a spherical surface where the radius is constant in the spherical coordinate system. Thus, unusual coordinate systems are frequently encountered in the analytic solutions of electrostatic problems. Other techniques, such as the method of images and Green's functions, are also used. Solutions to these solvable problems are an important guide in applications of electrostatics (Smythe, 1967).

During the last two decades, numerical computers have vastly extended the domain of electrostatic problems that can be solved. All numerical methods are based on the division of the problem into a large number of small parts. For a closed Dirichlet problem with no free charges, a simple assignment is a rectangular mesh that covers the region interior to the closed surface on which the potential is specified. The potential that fulfills Laplace's equation at a mesh point is the arithmetic mean of the potentials on the neighboring mesh points. Since the potential is specified on the boundary enclosing the mesh, it is apparent that the potential at every mesh point is defined through a set of linear algebraic equations equal in number to the number of mesh points. Sets of thousands or more equations are rapidly solved with modern computers. This method is called the finite-difference method. More difficult electromagnetic problems, mainly problems outside the domain of electrostatics, may require a similar, but more general, method called the finite-element method; of course, the finite-element method, which is widely available, may be applied to all electrostatic problems (DiStasio, 1979; McAllister, 1985; and Kashy, 1990).

The finite-difference method is adequate for most interior problems. Open, or exterior, problems, where the solution extends to infinity, however, are difficult because the computer admits only potentials defined at specified finite locations. Open problems are better done with the division of the boundary surface into a large number of surface elements, frequently called discretization elements. When a surface charge density is assigned to each of these discretization elements, the potential and field everywhere outside the boundary can be calculated with Coulomb's law, so that the difficulty at infinity is avoided. The specified potentials on the boundary surface are used to assign a charge density to each discretization element. This method is frequently called the charge density method (Cendes, 1990). The charge densities can also be recessed behind the boundary surface, resulting in another method called the charge simulation method. When the discretization elements associated with these recessed charge densities are contracted, resulting in isolated charges behind the boundary surface, this method reduces to the well-known method of image charges.

While the mathematical tools in use prior to computers generally required only dexterity with differential equations and algebra, numerical methods require access to computer hardware and, generally, a library of software. While necessary, software to simply solve the problem is frequently not sufficient for a useful solution. Most electrostatic problems require preprocessor software to compose the problem for computer solution and postprocessor software to exhibit the solution.

Composition is required because the computer requires the division of the problem into a large number of small parts, each of which is specified by a set of numbers. As every change of geometry in the problem requires a new set of numbers, preprocessors are needed to generate these numbers. Exhibition beyond listing the potentials and fields at a few points is generally needed to grasp the implications of a solution. Exhibition is done with postprocessors using data visualization techniques, such as contours of the same potential, called equipotential plots, and as electric flux plots. Flux plots contain field lines that show the field direction with arrows and field magnitude by their density.

2. SOURCES

On the largest scale, the universe is believed to be electrically neutral. On the microscopic scale, atoms and molecules are also neutral. Thus charge cannot be generated, only separated. To generate positive and negative charges, electrons must be removed from atoms and molecules, i.e., atoms and molecules must be ionized. Ions and electrons may move about by attachment to other particles or by conduction in certain materials.

Phenomena resulting in ionization include electrical, mechanical, thermal, and chemical processes. Electrical ionization generally occurs near sharp points; hence, the charge transfer it causes is frequently called corona discharge. On mechanical contact between different materials, electrons pass between them, and the electrons are carried away when the materials are separated. Thus, some materials become charged when rubbed with other materials; this is called triboelectricity. As thermal energy is added to atoms and molecules, some of them lose electrons, a process called thermionic emission. Chemically, a battery separates electrons from materials; a metallic conductor is used to direct these electrons to other locations, and eventually back to the battery. Because these electrons rarely escape the conductor, they are not generally considered sources of electrostatic phenomena. There are also other ionization processes, such as ionization by light and radiation. In the remainder of this section, electrical, mechanical, and thermal ionization processes will be discussed.

Corona discharge (see SPARKS, ARCS, AND OTHER ELECTRIC DISCHARGES) results from the ionization of gaseous atoms and molecules in large electrical fields. These fields generally occur near sharp metallic points. Electrical forces on the electrons and nucleus of an atom are in opposite directions, and when the forces are sufficiently large, an electron is removed. In a corona discharge the electric field near a sharply pointed electrode maintained at a high potential relative to its neighborhood ionizes gas atoms which subsequently stream away to charge nearby surfaces. This gas stream can be so intense that it is felt as a wind. When the gas is air, blue light accompanies the ionization, as well as the pungent odor of ozone, audible noise, and electrical static. This light is historically known as St. Elmo's Fire, a spectacular glow from the mast and rigging of large sailing vessels seen upon the approach of an electrical storm. In the dark it is awesome and foreboding. This blue light can also sometimes be seen near high-tension (-voltage) electrical transmission lines. In fact corona discharge limits the power transport on these lines, for it limits the voltage used in them. Corona discharge is also responsible for brush discharge, a discharge characterized by visible streamers. Electrical ionization near sharp metallic points also occurs in vacuum, where electrons emerge directly from the metal. This is called field emission (see FIELD EMISSION AND IONIZATION), a widely used electrical source in electron microscopes.

Triboelectricity is the exchange of charge by different uncharged materials brought into mechanical contact and then separated. It is the earliest manifestation known, dating back to Thales of Miletus (640–546 B.C.), who reported the charging of amber (called elektron in Greek, from which Gilbert introduced the word "electricity" in 1600) upon rubbing with other dry substances. The charged amber attracts other substances and so has similarity to a magnet. Indeed, the separated charges in amber render it an electret, the electrical analog of a magnet. Triboelectricity is the source of many familiar manifestations of electrostatics, such as static cling of garments made from modern synthetic materials, shocks after walking in rugs, the attraction of hair and paper to a plastic comb, etc.

The charge appears to be transferred by friction or rubbing. In fact, it is transferred at the locations of contact between the materials, and charging occurs when the contact is broken and the materials separate. Enhanced charging associated with additional rubbing occurs because more locations come in contact, not from the greater work of rubbing. At the locations of contact, the charge transfer occurs between nearby energy levels at the material surfaces. While some of these energy levels are intrinsic to the material bulk and surface, others are extrinsic to defects and adsorbed impurities. These latter levels restrict reproducibility and quantification of the triboelectric phenomenon.

Thermionic emission (*q.v.*) follows the addition of heat to solids. Some electrons accumulate sufficient thermal energy to escape from the solid. As the solid must be heated to very high temperatures, thermionic emission generally is used to obtain charged particles in enclosed systems, viz., in the absence of oxygen, such as in vacuum tubes.

The charging of an object frequently occurs by induction, historically called influence. Induction is the redistribution of charge in a conductor; charge distributions are discussed in Sec. 3. When it is followed by removal of net charge, the object becomes charged. The electrophorus uses this principle. When small particles separate from a pointed electrode, as in ink-jet printing, they are charged inductively.

3. POLARIZATION

3.1 Fundamentals

As described in the Introduction, electrostatics is concerned with the effects of positive and negative charges; sometimes these charges are locally separated, resulting in dipoles. Polarization is concerned with the effects of dipoles. The fundamental dipole $\mathbf{p}$ is a pair of positive and negative charges of equal magnitude Q separated by a vector $\mathbf{r}$ directed from the negative to the positive charge; thus, $\mathbf{p}=Q\mathbf{r}$. For a larger number of charges, or a distribution $\rho(\mathbf{r})$ of charges, $\mathbf{p}=\Sigma Q_i\mathbf{r}_i$ or $\mathbf{p}=\int\rho(\mathbf{r})\mathbf{r}\, d^3r$, the first, or dipole, moment of the charge distribution. Dipoles have units of charge-distance, and as many molecules are dipolar, the dipole moment 3.33×10^{-30} coulomb meter$=0.393qa_0$, is frequently called the Debye, where q is the fundamental charge and $a_0=0.0529$ nm is the Bohr radius of the hydrogen atom; the magnitude of the Debye is a consequence of its origin in esu units. The name dipole comes from the "two pole" source of magnetic fields, and, implicitly, the dipoles described here are electric dipoles.

The concept of the dipole depends on local separation of charges, i.e., the field is evaluated far from the dipole. As the field of a charge depends inversely on the square of the distance from the charge, so the field of a dipole depends inversely of the cube of the distance from the dipole. As a charge is a scalar quantity, the field around it is isotropic; as a dipole is a vector quantity, the field around it depends on the angle between the dipole and the vector to the field point. A second dipole a distance away may experience this field; the interaction energy depends on the angles formed by the dipole vectors with their separation vector, as well as the separation between the dipole vectors.

A distribution of dipoles generally adopts a configuration to minimize the dipole energy. An electric field $\mathbf{E}$ reconfigures the dipole distribution to produce a polarization field $\mathbf{P}=\chi\epsilon_0\mathbf{E}$, where χ is the electric susceptibility of the dipole distribution, i.e., of the material. This property of the material makes it a dielectric. For a material to be dielectric, χ must be positive. Polarization has units of dipole moment density, i.e., from the definition the units are farads/meter times volts/meter, or coulombs/meter^2, i.e., coulomb meter/meter^3.

Returning to the concept of the single dipole, generally at the atomic or molecular level, the local electric field $\mathbf{E}_l$ can modify its moment. This modified dipole moment is $\mathbf{p}=\alpha\mathbf{E}_l$, where α is the polarizability. The macroscopic susceptibility is related to the microscopic polarizability by the macroscopic relation $\mathbf{P}=\chi\epsilon_0\mathbf{E}$ from the preceding paragraph and the microscopic relation $\mathbf{P}=N\alpha\mathbf{E}_l$, where N is the volume density of dipoles. The ratio of $\mathbf{E}_l$ to $\mathbf{E}$ is a geometric characteristic of the material. As the density of the material decreases, this ratio approaches unity, so $\alpha=\chi\epsilon_0/N$. Dielectric polarization arises from electronic polarization, the distortion of the electron distribution of an atom or molecule; atomic polarization, a change in molecular geometry; orientation polarization, a change in the angles between molecules; and space-charge polarization, the movement of aggregations of charge.

The sum of the polarization **P** and the electric field is frequently defined as the electric displacement vector **D**, i.e., $\mathbf{D}=\epsilon_0\mathbf{E}+\mathbf{P}$. Then $\mathbf{D}=\epsilon\mathbf{E}$, which defines the permeability ϵ of the material (see DIELECTRIC PROPERTIES OF INSULATORS). (Sometimes **D** and **E** are not parallel and ϵ is then a tensor.) The ratio $\epsilon/\epsilon_0=1+\chi$ is the relative dielectric constant of the material. By analogy to the magnetic flux density vector **B** of magnetostatics, the electric displacement is also called the electric flux density. By the same analogy the electric field **E** is the analog of the magnetic field **H**, and the polarization **P** is the analog of the magnetization **M** (see MAGNETS AND MAGNETOSTATICS).

The polarization in materials is generally defined by the relative dielectric constant ϵ/ϵ_0. When this ratio exceeds unity, the electric field in the material is reduced. Mathematically, this reduction arises because the response to a charge distribution ρ is described by **D**; i.e., Maxwell's equation for electrostatics is $\nabla\cdot\mathbf{D}=\rho$ in a dielectric. Physically, the polarization **P** and the source charges ρ are both charge distributions, the polarization, of course, being a dipole distribution. A reduced field in a volume is very useful for storing charges, e.g., in a capacitor, and for shielding charges, i.e., for electrical insulation.

3.2 Applications

A capacitor, previously known as a condenser, is an electrical device used to store charges, generally equal amounts of both positive and negative charge. Capacitors, along with inductors, resistors, and transistors, are components of electronic circuits (see CIRCUIT ELEMENTS). On electrical-appliance circuit boards, they are frequently visible as cylinders or encapsulated packages. As mentioned in Sec. 1.1, the unit of capacitance is the farad (after Michael Faraday); this unit is larger than the capacitance of commonly used capacitors, and so the capacitance will often be indicated in picofarads [pF or (archaic) $\mu\mu$F, both of which are 10^{-12} F] or nanofarads (nF, 10^{-9} F). These capacitors generally consist of alternating layers of metal foil and dielectric film or paper. Alternate layers of the foil contain the positive and negative charge, and the film reduces the field between these charges so the capacitor can be made physically smaller. Other capacitors for circuit boards, and for more general applications, may use liquid or gas for the dielectric material. Integrated circuits contain many capacitors for which the semiconductor is the dielectric material. Capacitors are frequently used to store energy for brief pulses of high power, as in a camera flash device or an automotive ignition condenser (see ELECTROSTATIC CAPACITIVE STORAGE OF ENERGY). For sustained power, chemical batteries can store 10 to 100 times more energy per unit volume than capacitors. Capacitance properly belongs in the domain of electrostatics only when charge is stored; when the capacitor is charged or discharged, as frequently occurs in circuits, phenomena outside electrostatics occur.

Insulators are electrical materials used to maintain the separation of positive and negative charges, i.e., to shield or isolate charges. Usually these charges are moving in wires, and so are perceived as electric currents. Electrical insulation is frequently encountered as a wrapping for electrical wires or as ceramic structures for supporting electric wires and objects. Electrostatically, insulation extends the range of fields for which electrostatic conditions prevail. However, at sufficiently high fields, positive and negative charges no longer remain separated. The resultant disruption of the insulation is called electrical breakdown, and the charge transport is frequently perceived as short luminous glow, such as sparks and lightning, which are discussed in Sec. 4. Insulators emphasize another property of dielectric materials, called the dielectric breakdown strength, i.e., the electric field at which the material breaks down; a typical dielectric breakdown strength is 100 kV/cm.

3.3 Other Polarization Phenomena

In materials the polarization is generally dielectric, i.e., it is produced by an electric field. However, it may also be produced by an applied stress or pressure, called piezoelectricity. Piezoelectricity also includes the converse relation of strain to an electric field. Piezoelectric materials are used to transform, or transduce, electrical and acoustic signals, as in microphones and loudspeakers (see PIEZO-

ELECTRIC DEVICES). Quartz is a widely used piezoelectric material. For small stresses the polarization is linearly proportional to the stress, but the relation is geometrically complicated, as the stress tensor T is frequently expressed as a six-component vector, so, as the polarization is a vector, the polarization is related to the stress by the 18 piezoelectric moduli d, i.e., $P_j=\Sigma_{i=1}^{6} d_{ij}T_i$.

Polarization may also be produced thermally, called pyroelectricity. Pyroelectricity is used in thermometers and radiation detectors, as in a bolometer. Tourmaline is a common pyroelectric material.

Even when the polarization is produced by an electric field, the susceptibility may be negative, in which case the material is paraelectric.

Polarization differs from magnetization in the existence of free electric charges which eventually reconfigure to cancel the polarization; there is, of course, no analogous magnetic charge. There are some materials with polarizations that last for many years, called electrets, used in commercial applications; many of these are organic polymers. In addition, the stable state of some other materials is characterized by a polarization field; these materials are ferroelectric by analogy to ferromagnetism (see FERROELECTRIC DEVICES). These materials, e.g., Rochelle salt, have many of the characteristics of a ferromagnet, e.g., a Curie temperature, domains, hysteresis in the polarization response to an electric field, and a residual polarization. Of course, free charges in the air collect to cancel the residual polarization, so that our common experience with permanent magnets does not have an electric analog.

4. ATMOSPHERIC ELECTROSTATICS

4.1 Global Phenomena

The atmosphere is the layer of air surrounding the earth. The atmosphere and earth together are electrically nearly neutral, but the earth is charged negative while the atmosphere is positive, each with about 500 000 coulombs. The earth is a good conductor, and so this negative charge is distributed nearly uniformly over its surface. While the atmosphere is a poor conductor, the ionosphere that encloses the atmosphere is a good conductor, so that the outer boundary of the atmosphere is at an electric potential that is nearly constant, typically 300 000 V positive relative to the grounded earth. The positive charge is distributed within the atmosphere, and so the earth, atmosphere, and ionosphere form a spherical capacitor consisting of a pair of concentric conductors, i.e., the earth and ionosphere, with the earth carrying the negative charge and the positive charge distributed in the atmosphere between the conductors.

The sources of this charge, that is, its generation at the local, or even atomic, level, are not well known, and there may be several significant sources (see ATMOSPHERIC PHYSICS). The separation of these charges leading to the negative charge on the earth and positive charge in the atmosphere is intimately connected with the weather. The sources of the charge include the interaction of cosmic rays with gas molecules in the atmosphere, radioactive decay of elements in the earth, ejection of charged water droplets in the turbulence of ocean waves, and triboelectrification associated with the contact of wind-blown particles with the earth surface. Cosmic rays are very high-energy charged particles that come from beyond the solar system; their flux onto the earth is independent of time and geography. They are distinct from the solar wind, a flux of charged particles from the sun that is deflected by the ionosphere. A cosmic ray is generally absorbed by the ionization of many atmospheric gas atoms. As the atmospheric density decreases with altitude and cosmic rays impinge from above, this mechanism results in an altitude of maximum charge production, and some measurements are consistent with this maximum.

Radioactive decay of elements in the earth can lead to ionization of gases trapped within the earth that subsequently escape into the atmosphere. It can also generate short-lived radioactive decay gases, such as radon, which enter the atmosphere and decay, thereby generating charged particles in the same manner as cosmic rays. (Recently, concern has been raised about radon entering the atmosphere within homes, where it may be trapped, and decay resulting in damaged human tissue.) While this source might seem to be consistent with maximum charge production near the earth, updraft of the radioactive gases confuses this conclusion.

When a bubble breaks at the ocean surface, small drops emerge that carry positive charge. These drops diffuse into the atmosphere over the ocean and the earth. On the basis of measurements over selected areas of the ocean where the waves are turbulent, evidenced by whitecaps, and on estimates of the ocean area covered by these waves, a significant portion of the positive charge in the atmosphere could originate from these drops.

4.2 Weather

The atmosphere in the global capacitor mentioned above is not a perfect insulator, i.e., it is leaky. The atmosphere has a conductivity, and if no other conductive phenomena were present, most of the positive charge would return to the earth within one hour. A phenomenon generally thought be responsible for moving positive charge away from the earth is stormy weather, e.g., thunderstorms. In fact, the quantity of positive charge in the atmosphere is proportional to the thunderstorm activity on the earth at that moment. It peaks during the hours corresponding to afternoon over the Amazon and central Africa, regions well-known for thunderstorms.

Thunderstorms are associated with lightning (indeed, thunder is the sound associated with lightning). Lightning is electrical breakdown in the atmosphere, and it occurs where the field between the bottom of the thunderstorm and the earth exceeds the breakdown field of the atmosphere. It serves to move substantial charge (1–10 coulombs) rapidly from a local region of the atmosphere to the earth. Lightning is, of course, widely observed, familiar, and dangerous, and it is the subject of a large literature (Wahlin, 1986).

In fair weather, the electric field near the surface of the earth is about 100 V/m directed toward the earth. This field generally decreases with altitude because the density of positive charge in the atmosphere generally decreases with altitude. Thus, it is consistent with a potential of 300 000 V on the ionosphere 100 km above the earth's surface. The charge density on the earth's surface is ϵ_0 times this field, or 1 mcoulomb/km^2, resulting in about 500 000 coulombs when integrated over the earth's surface. Since capacitance is the charge stored divided by the potential, the capacitance of the earth and atmosphere is near 1 F.

This electric field is subject to large variations as the weather or locale changes. This is apparent from the knowledge that much larger fields, 100 kV/cm, are required for breakdown, and breakdown is commonly observed. Not only is large-scale breakdown in the form of lightning a common phenomenon, but smaller breakdowns in the form of shocks and sparks are even more common.

4.3 Sparks and Shocks

Sparks and lightning are the same electrical breakdown phenomenon, but sparks generally describe a lower-voltage breakdown. Electric spark describes the light associated with these smaller breakdowns (see SPARKS, ARCS, AND OTHER ELECTRIC DISCHARGES). The light emission accompanies local heating of the air (indeed, this heating is the cause of the thunder associated with a lightning discharge). Heating can lead to ignition of chemical processes. Sparks are widely used for ignition, as in the spark plugs of gasoline engines, where potentials of 10 kV discharge across a 1-mm gap thousands of times per minute to ignite the fuel mixture. Unwanted sparks and ignition also occur. In some environments, such as petroleum tanks or grain elevators, sparks are a well-known hazard. In these environments, where large amounts of materials are moved through pipes into a reservoir, triboelectric charging between the material and the pipe walls occurs. Sparks occur as this charge moves in the reservoir. If conditions such as the ignition energy and the air-to-material ratio are met, heat from the spark can ignite a massive and deadly explosion.

Electric shock describes the sensation associated with electric current passing through the human body. It is sometimes felt momentarily when the electrostatic charge on the body surface (the human body is a conductor) flows away in the breakdown associated with a spark, as often occurs when one reaches for a door knob after walking across a rug. Of course, shocks are well known, and more dangerous, when the body becomes part of an electrical circuit, and these shocks clearly reveal that the intensity of a shock is related to the current. Thus, the rapidity of the discharge in a spark, as well as the quantity of charge discharged, determines the magnitude of the sensation associated with a spark. The quantity of charge that can accumulate on the body is limited by the breakdown field in air. As this field is 10^6 V/m or more, the maximum charge on a human body surface is a few μcoulombs, assuming the body surface area is about a square meter. As the body can sense currents of a milliampere or less, the discharge time is about a millisecond. Recalling the preceding discussion of sparks igniting explosions, the ignition energy of ether can be only a millijoule, corresponding to the energy $Q\phi$ released from the body in a 1-mm-long spark. Thus, sparks can be a hazard in some hospital environments.

Sparks felt as shocks are only a fraction of the body electrical discharges that occur. Many sparks, too small to feel, have catastrophic consequences for modern electrical equipment, particularly integrated circuits. When a spark is examined in detail, as in the photographic analysis of lightning, it is found to have endpoints which are highly localized, generally to local sharp points of the electrodes between which the charge flows. Thus, in an electrostatic discharge to an integrated circuit, much of the charge may flow to a single element of the circuit. The current may be large enough to melt a conductor on the circuit, resulting in an open circuit. Because the circuit elements are so close together, the charge may cause local breakdown between two nearby conductors, fusing the insulating substrate, and leaving a new conducting path, i.e., a short circuit. A discharge is not even necessary, as large currents can be induced by nearby charged bodies. These short and open circuits may not lead to obvious malfunction of the integrated circuit; instead they may result in spurious behavior that is very difficult to characterize by subsequent testing. These short and open circuits are latent defects that can distort the operation of the integrated circuit. Special care is required to ensure that people are grounded electrically when working with or near exposed integrated circuits (Boxleitner, 1988).

Atmospheric electric potential differences are generally measured with an electrostatic voltmeter. Potential differences across circuit elements are generally measured by diverting a small portion of the current through the voltmeter. However, the currents in the atmosphere are too small to be able to divert a small portion and still have measurable current. Hence, an instrument called an electrostatic voltmeter is used. It utilizes the Coulomb attraction of the plates of a capacitor to measure the potential difference between two electrodes; a part of one of the electrodes is made flexible to obtain the measurement. Thus, only the current to charge the capacitor is needed. An early version of this voltmeter, made by Cavendish, was used by Coulomb to measure the constant ϵ_0.

5. FLUID ELECTROSTATICS

The atmosphere surrounding the earth is a fluid, and it is filled with dust particles. Dust particles are frequently charged, for they adhere to TV screens, collect inside electrical appliances, etc. Lightning is seen in dust storms. Dust drifts in air and responds slowly to external forces, e.g., gravity causes dust to collect on horizontal surfaces in homes. Electrostatic forces can also direct the flow of dust and other particles, and, because electric forces can be far stronger than gravitation, the response can be faster. The electrostatic force on charged particles has been used in the past century in many applications, such as electrostatic precipitation, separation, coating, printing, etc. Particles are generated, if they do not exist already, charged, exposed to a strong field, deposited, and, if appropriate, collected.

Electrostatic precipitation was the earliest application. A precipitator removes particles from a gas, frequently air. It is generally used to clean the air and reduce pollution, although sometimes the precipitated particles have value. It is widely used to collect fly-ash from coal-burning electric plants. In operation the particles are charged with the corona discharge from wires at high voltage. These charged particles are driven by an electric field to the walls of the precipitator where they collect; eventually gravity directs them to a container for removal. The efficiency of collection is an important characteristic of a precipitator. It depends on the type of particles, e.g., large or small, to be collected, as well as on the turbulence of the gas. Electrostatic precipitators were introduced by F. G. Cottrell before 1911 and were rapidly adopted for pollution control. They are also used for dust control in smelters, acid mist control in chemical plants, etc. (Oglesby, 1978).

Electrostatic separation is used to concentrate minerals, purify foods, and sort mixed garbage. The mixture to be separated consists of small particles, and the technique is based on the different affinities of the particles in the mixture for electric charge. Typically, the particles are charged triboelectrically or by corona discharge, passed through an electric field, and collected in a series of bins. Thus, it is analogous to the use of mass and gravity in winnowing. Major applications include iron ore concentration, and separation of zircon from beach sand and of rodent droppings from grain (Inculet, 1984).

Electrostatic coating is used to apply surface coatings on conducting objects. Nearly all objects sold today are coated and much of it is done electrostatically. The coating material, a powder or aerosol, is charged, and an electric field directs it to the object to be coated. The charging is done by corona or induction. The coating is permanently affixed to the object by chemical reaction or fusing. Sometimes the coating particles are oriented by the electric field, as in electrostatic flock coating. The atmospheric field around plants can be used to direct chemical coatings. Major concerns include the transfer efficiency of the coating material and the uniformity of the coating. Sometimes nonuniformities are planned by charging only selected areas of the object to coat in a pattern; these coatings resemble electrostatic printing (Hughes, 1984).

Electrostatic printing includes the xerographic process of photocopying. In xerography a high-resolution, detailed charge pattern, e.g., a page of alphanumerics or graphic art, is coated electrostatically with a dark powder. This charge pattern is created with light on a charged photoconductive layer. Coating is done with a powder of small, charged particles; selectively coating only the detailed pattern is dependent on the dominance of the electrostatic force over other forces present. While a wide variety of photocopying techniques can be made to work in the laboratory, many of them fail in the transition to commercial use. Chester Carlson was successful in leading this transition in the last half-century to make photocopying a part of every office. Electrostatic printing also includes ink-jet printing where a fine beam of tiny charged ink particles is accelerated and directed by electrostatic fields to write as with a fine pen.

To achieve the electrostatic force in these applications, large fields, and, hence, high voltages, are needed. In most applications transformer-rectifier assemblies are sufficient, but for some very high-voltage applications above 100 kV, like particle accelerators, electrostatic generators are needed. Electrostatic generators, such as the Van de Graaff and Wimshurst machines, transport charge from a source to a collector. Electrostatic generators, being relatively safe because of the limited current they can deliver, are widely used in classroom demonstrations. However, this current limitation restricts their use in industry.

The electrostatic force cannot overwhelm other forces for all particles. The gravitational force dominates the motion of large particles—particles larger than a few mm in diameter, as charge is generally confined to their surface while gravity acts on their bulk. Aerodynamic forces dominate the motion of very small particles, as the viscosity of air causes submicron-size particles to move generally with the air flow. The motion of much smaller charged particles in a liquid due to an electric field is called electrophoresis, while the motion of similar uncharged particles due to a nonuniform electric field is called dielectrophoresis.

Not all atmospheric electrostatic phenomena contribute beneficially in technology. Adverse effects are common in the textile and plastic industries where electrostatic forces interfere with the desired motion of the materials. Antistatic agents are used to reduce these forces. Fabrics tend to cling together or balloon out, sometimes leading to such disasters as the failure of a parachute to open, but more commonly disturb the industrial handling of dry textiles and the comfort and appearance of clothing. Textile charging occurs triboelectrically, and it is exacerbated by the speed of the machines. Charging can be reduced with increased conductivity; higher humidity will generally increase conductivity. Hygroscopic materials are often used as antistatic agents, as they collect water from the atmosphere. In fact, natural fibers are less susceptible to electrostatic charges than synthetic fibers because they are more hygroscopic. Electrostatic forces in plastics lead to dust and dirt accumulation, and conducting surface treatments are frequently used to dissipate charge (Horvath, 1982).

6. VACUUM ELECTROSTATICS

Charged particles in air drift in response to the electrostatic force; i.e., their movement is the net displacement after many collisions with air molecules. Charged particles in vacuum respond ballistically to an electrostatic force; i.e., their movement can be predicted with Newton's laws of motion. Drift phenomena were discussed in Sec. 5 and ballistic phenomena will be described in this section. Charged particles, e.g., electrons, in vacuum are frequently formed into beams that are focused, reflected, and deflected in much the same way as are light beams. Thus, the study of these beams is called electron optics (see CHARGED-PARTICLE OPTICS). The lenses, mirrors, and prisms of electron optics are frequently electrostatic fields. The television display tube is a common and well-known example using vacuum electrostatics (Szilagyi, 1988).

While television is the principal consumer application of vacuum electrostatics, as the replacement of electronic vacuum tubes by solid-state devices is virtually universal, there are many laboratory, and industrial applications. These include the electron microscope (see ELECTRON MICROSCOPY), avionics and oscilloscope display tubes (see DISPLAY TECHNOLOGY), particle accelerators (see ACCELERATORS, LINEAR; ACCELERATORS, POTENTIAL DROP; CYCLOTRONS; SYNCHROTRONS), mass spectrometers (see SPECTROMETERS, MASS), electron-beam lithography (see LITHOGRAPHY), x-ray tubes, etc. All these devices rely on a source of charge, frequently thermionic or field emission, a guidance system based on electrostatic or magnetic fields, and detectors to convert the charge to a useful signal. For example, in a television tube the electron beam is emitted and focused electrostatically by the electron gun, deflected magnetically, and converted into a visual image by phosphors. An electron microscope has condenser, objective, and projection lenses, just as in an optical microscope, and many of these lenses are electrostatic. Deflection in an oscilloscope tube is generally done electrostatically because of the high speeds needed.

Electrostatic electron-optical devices, such as lenses, are shaped conducting electrodes in the vacuum enclosure. Voltages are applied to these electrodes by wires through the enclosure wall. For example, when an ion beam passes between two flat plates at different voltages, it is bent, or deflected, by the electric field, just as light is bent by a prism. Also, when different voltages are applied to flat plates with coaxial openings, a beam of electrons passing through the openings is focused. The electric field distribution in the opening acts on the electrons in the same way as the refractive index distribution in a glass lens acts on light.

The electron wavelength is so small that electrostatic optical systems can be described by geometrical optics. The analogs of geometrical-optics theory, such as paraxial-ray theory, aberrations, etc., are used to characterize electrostatic lenses. In addition, the electrons in the beam repel each other electrostatically, leading to a beam divergence that is not found in light optics; this repulsion is called space charge.

The electrostatic theory outlined in Sec. 1 is applicable to electrostatic optical systems, and modern computers permit detailed analyses of complicated systems. Because the electron and ion motion is ballistic in vacuum, complicated motions can also be simulated with computers. Even space-charge effects can be simulated. Thus, the growth of computer technology during the past half-century has resulted in refined precision and improved efficiency in vacuum electrostatic technology. This has occurred in spite of a vacuum mechanical technology (see VACUUM TECHNIQUES AND INSTRUMENTATION) that can be cumbersome and aggravating (Herrmannsfeldt, 1988).

7. OUTLOOK

Atmospheric electrostatics will continue to benefit from the growth of observations in and above the earth's atmosphere. Electronic computers will allow assimilation of this data into models of the atmosphere. Concerns about the environment will accelerate this activity, particularly concerns about the interaction of electromagnetic fields with human life (Brodeur, 1989).

Electrostatic applications in fluids will benefit from computer simulation when concepts from fluid dynamics are applied to simulate charged-particle drift in electrostatic fields. Reductions in size and cost and improvements in efficiency will lead to consumer versions of many of the existing industrial applications.

Applications of vacuum electrostatics will mature, as substitutes for vacuum devices are always attractive. These applications have already drawn tremendous benefit from computer simulations of ballistic electron motion. New applications may emerge from microtechnology in vacuum electronics (Tech, 1990).

Electrostatic theory is very well established and unlikely to change. Computer solution of electrostatic problems is also firmly established and viewed as a tool for the simulation of particle motion.

GLOSSARY

Breakdown (Electric): Electrical rupture of a dielectric.

Capacitance: Capacity of a system to store electric potential energy.

Capacitor (Condenser): A device for storing electric charges.

Charge: (noun) Quantity of electricity. (verb) To add charge to a material.

Charge Density: Distribution of charge in space. It may be volume, surface, or linear.

Corona Discharge: Corona is the faint glow on surfaces of electrical conductors exposed to high fields. Discharge is the accompanying flow of charge.

Coulomb: Unit of charge equal to 6.242 $\times 10^{18}$ electrons or protons.

Coulomb's Law: Basic law of electrostatics: The force exerted between two electric charges is directly proportional to the product of the charges and inversely proportional to the square of the distance between them.

Dielectric: A nonconducting material which can sustain electric fields and has positive electric susceptibility.

Dipole: A pair of equal and opposite charges separated by a small distance.

Discharge: Reduction of potential difference by charge transfer.

Displacement Vector: The sum of the electric field and polarization in a material.

Earnshaw's Theorem: A charge cannot exist in stable equilibrium among a group of fixed charges.

Electret: A block of dielectric material with permanent electrostatic polarization.

Electron: The most elementary charge of negative electricity.

Electron Optics: Branch of electronics that deals with beams of electrons behaving analogously to beams of light.

Electroscope: Instrument for detecting the presence of charge.

Electrophoresis: The movement of suspended particles in a fluid with an electric field.

Electrostatics: The part of the science of electricity for which the distribution of charge is static.

Equipotentials: Surfaces on which the electric potential is constant; also, lines formed by the intersection of such surfaces with specified planes.

Farad: Unit of capacitance needed to store one coulomb with a potential difference of 1 V, i.e., one coulomb per volt.

Ferroelectric: A material with abnormally high electric permeability and appreciable residual polarization and hysteresis.

Field (Electric): A vector quantity characteristic of a point in space equal to the electric force on a small charge at that point, divided by the magnitude of the charge. The unit is force over charge, or potential over distance.

Gauss's Law (or Theorem): The charge enclosed by an imaginary surface in space is equal to the integral of the normal component of the electric field over this surface.

Ground: (noun) Potential of the earth, frequently defined as the zero of potential. (verb) To connect an electric object to the earth.

Ionosphere: The layer of the earth's atmosphere 40 to 400 km above the earth's surface, containing free charged particles.

Laplace's Equation: $\nabla^2\phi=0$ where ϕ is a function defined in space. In electricity ϕ is the electric potential.

Leyden Jar: An early capacitor, developed at the University of Leyden in the 1740s, consisting of a glass jar coated with tin foil within and without and topped with a brass knob connecting to the inner foil. It is charged by applying a source of electricity to this knob.

Paraelectric: A nonconducting material which can sustain electric fields and has negative susceptibility.

INTRODUCTION

Energy is the capacity to do work. The subject of *bioenergetics* deals with the energy changes accompanying the reactions by which living cells (a) mobilize and trap chemical or light energy from their environment and (b) use that energy to drive various vital processes, i.e., to do work. "Work" in a biological sense includes the biosynthesis of specialized organic compounds from simpler precursors, the formation of complex macromolecules from low-molecular-weight building blocks (for repair, growth, and cell multiplication), the "uphill" transport of substances into cells from a dilute environment, as well as physical work performed by flagella, cilia, and muscles. A complete coverage of bioenergetics would include topics that could also be discussed under headings of biophysics, thermodynamics, photochemistry, and cellular biomechanics. This article will focus on cellular energy metabolism at the molecular level. Many key compounds will be referred to by name and standard abbreviation. Readers should consult a biochemistry text for their chemical structures.

1. GENERAL PRINCIPLES

1.1 Varieties of Metabolic Lifestyles

Organisms can be broadly classified as either *phototrophs* (those which use sunlight as their primary energy source) or *chemotrophs* (those which use chemical substances for energy). Chemotrophs can be subdivided into two groups—chemoorganotrophs (which use preformed organic compounds) and chemolithotrophs (which use inorganic substances). Chemotrophs include animals, yeasts, molds, and most species of bacteria.

In broad terms, energy is made available to chemotrophs when electrons from the "en-

digital Encyclopedia of Applied Physics

ergy source" are transferred in a stepwise manner to some final acceptor (Fig. 1). (The energy source originates as "food" taken from the environment.) Thus, energy metabolism in chemotrophs is based on the progress of favorable, enzyme-catalyzed reactions which include one or more oxidation-reduction steps. The overall process results in the oxidation of the "energy source" (also called the *initial electron donor* or *reducing agent*) and the reduction of the final or *terminal electron acceptor* (also called the *oxidizing agent*). Some of the energy released in this overall process is conserved by generating adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and inorganic phosphate (P_i). ATP [Fig. 2(a)] is used directly or indirectly to drive many energy-requiring cellular processes (see Sec. 4). Because cells also need reducing power for many biosynthetic processes, some of the electrons of the energy source are diverted to the nicotinamide-containing coenzymes NAD^+ and $NADP^+$ [Fig. 2(b)]. The overall oxidation-reduction-coupled formation of ATP and NAD(P)H is analogous to the charging of a battery by a water wheel placed in a flowing stream. Most chemoorganotrophs are also *heterotrophs*, meaning that they use preformed organic compounds as their primary source of carbon for biosynthetic processes. Most chemolithotrophs and phototrophs (see below) are *autotrophs*, meaning that CO_2 serves as their major carbon source.

Phototrophs (higher plants, algae, and photosynthetic bacteria) also rely on oxidation-reduction reactions to generate ATP and reduced coenzymes. However, in these organisms, the initial electron source is a pigment system or "photosystem" (chlorophyll, etc.) which, upon absorbing light energy, becomes a much stronger electron donor. ATP is generated as the electrons flow back through a series of intermediary carriers to the original (or to a different) photosystem. When electrons are retained for biosynthetic reductions, another electron source is needed to fill the "positive hole" left in the original pigment system (see Sec. 3). Green plants and algae use water for this purpose (liberating oxygen as a byproduct). Some photosynthetic bacteria use other inorganic substances such as H_2S. Phototrophs use light energy to synthesize organic compounds (carbohydrates,

FIG. 1. Varieties of chemotrophic energy metabolism. Most chemolithotrophs are also autotrophs, i.e., they use CO_2 as their major source of cellular carbon. Most chemoorganotrophs are also heterotrophs, i.e., they use preformed organic compounds as their source of cellular carbon as well as for energy.

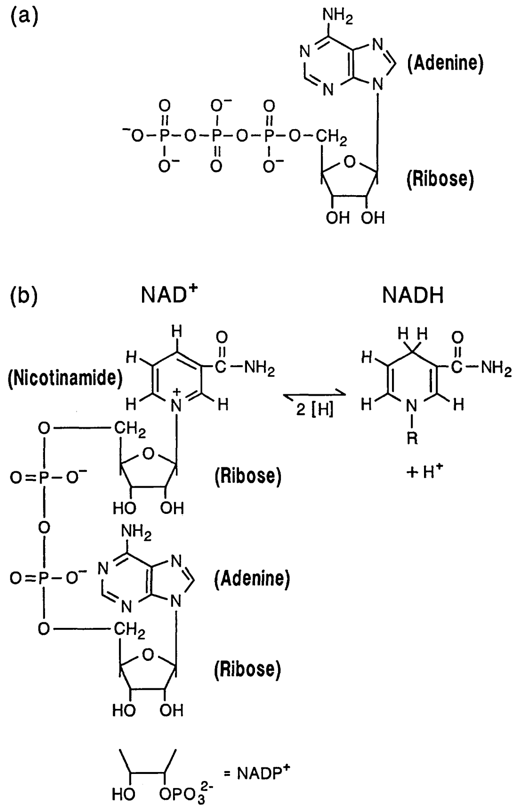

FIG. 2.(a) Adenosine triphosphate (ATP). The compound is shown in its ionized form as it exists at physiological *p*H. ATP is composed of adenine (a purine), ribose (a 5-carbon sugar), and three linearly linked phosphoryl groups. (b) Nicotinamide adenine dinucleotide (NAD^+) and its reduced form, NADH. The coenzyme (derived from the vitamin, niacin) carries two electrons, but only one complete hydrogen. Thus, for each $2e^-$ transferred to NAD^+ (as a hydride ion), an H^+ is also produced. The similar nicotinamide adenine dinucleotide phosphate ($NADP^+$) contains a phosphoryl group esterified to the OH on carbon number 2 of the adenine-linked ribose.

fats, and proteins) from CO_2. In the dark, these organisms act as chemotrophs using their stored organic compounds as energy sources and biosynthetic building blocks.

The following sections describe how biochemists deal with the above types of reactions in quantitative terms.

1.2 The Free-Energy Change (ΔG) of Biochemical Reactions

All physical and chemical processes can be described by a set of basic equations derived from the laws of thermodynamics—laws which describe the conservation and direction of energy flow (see THERMODYNAMICS). In brief, the first law of thermodynamics states that energy can neither be created nor destroyed. In any particular process, one form of energy may be converted into another (including energy into work and vice versa), but the total energy of the system plus its surroundings remains constant. The first law is simply a law of *conservation of energy*. The second law deals with the *increase in universal entropy* that accompanies all processes. One statement of this law is that any real process results in a decreased capacity of the (ever-constant) energy to perform further work. We will see the second law in action when we compare the biochemically relevant "energy yield" of certain metabolic processes with the energy required to reverse the process completely.

The thermodynamic quantity most useful for discussing biochemical reactions is the *Gibbs free energy change* ΔG which indicates the spontaneity of a process.* By convention, a thermodynamic Δ is taken as the difference between the final state and the initial state, defined as "final minus initial." Thus, a negative ΔG means that the components of the system under consideration will contain less energy after a process compared to before the process (i.e., energy will be released as a result of the process). If ΔG is negative, the process as formulated can proceed because it goes "downhill" (see below). ΔG is composed of two other thermodynamic quantities—ΔH (the enthalpy change) and ΔS (the entropy change). ΔH represents the heat liberated or absorbed by a process (a negative ΔH value means that heat is liberated). Caloric values of foods (e.g., 4 kcal g^{-1} for carbohydrates, 9 kcal g^{-1} for fats) are, in fact, the $-\Delta H$ values for the complete oxidation of these substances to CO_2 and H_2O. ΔS can be considered to be a measure of the change in randomness or disorder of reaction components as a result of a process. The relationship between the three thermodynamic quantities is $\Delta G = \Delta H - T\Delta S$. Thus, a reaction with a negative ΔG could be primarily enthalpy driven (ΔH is highly negative; heat is released), or primarily entropy driven (ΔS is highly positive), or driven by a combination of the two factors. For example, the folding of a newly synthesized linear polypeptide chain into a compact functional protein is largely entropy driven. The obvious decrease in entropy of the aminoacyl residues is more than compensated for by the large increase in entropy of water molecules that were originally highly ordered around hydrophobic (nonpolar) amino acid groups (analogous to tiny water droplets on an oily surface). Upon folding of the polypeptide chain, these water molecules return to the relatively unstructured bulk solution when the hydrophobic residues move to the interior of the protein.

---

* In classical thermodynamics, $-\Delta G$ is equivalent to (a) the maximum work that could be performed by the process and also (b) the $T\Delta S$ of the reaction system plus its surroundings.

ΔG can also be expressed in terms more useful for characterizing the progress of a chemical reaction:

$$\Delta G = RT \ln Q - RT \ln K_{eq}$$

or

$$\Delta G = RT \ln(Q/K_{eq}). \tag{1}$$

R is the gas constant (1.987 cal mole^{-1} deg^{-1} or 8.314 J mole^{-1} deg^{-1}) and T is the absolute temperature. Q is the *mass action quotient.* That is, if the reaction is $A+B \rightleftharpoons C+D$, then $Q=[C][D]/[A][B]$ at the moment, or under steady-state conditions such as exist in cells. K_{eq}, the *equilibrium constant,* is the mass-action quotient at equilibrium, i.e., at the lowest energy level of the system. At equilibrium there is no net reaction. Thus, *the sign and the magnitude of* ΔG *describe the displacement of the system from equilibrium and, consequently, the direction and extent of the reaction if it were to proceed.* For example, if $Q < K_{eq}$, (i.e., ΔG is negative), the reaction as written is not yet at equilibrium and can proceed further to the right. The more negative the ΔG, the further the reaction can proceed before attaining its equilibrium position. If $Q = K_{eq}$ (i.e., ΔG is zero), the reaction is at equilibrium and will not proceed in either direction. If $Q > K_{eq}$ (i.e., ΔG is positive), the reaction as written is beyond the equilibrium position and, if it proceeds at all, it will go in the reverse direction (which has a ΔG equal in magnitude, but negative in sign). A reaction having a negative ΔG is said to be "spontaneous," "favorable," or "exergonic" ("energy yielding" or "energy releasing"). Work (in the molecular sense) can be performed by coupling such a reaction to one having a positive ΔG (i.e., to a "nonspontaneous," "unfavorable," "energy-requiring," or "energy-absorbing" reaction).

For most biochemical applications of Eq. (1), the reaction is assumed to occur in dilute aqueous solution of constant water concentration and at a fixed *p*H (usually 7.0). Thus $[H_2O]$ and $[H^+]$ are generally not included in K_{eq} or Q expressions. For example, K_{eq} or Q for the hydrolysis of ATP at physiological *p*H ($ATP + H_2O \rightleftharpoons ADP + P_i + H^+$) is usually given as $[ADP][P_i]/[ATP]$. The numerical value of K_{eq} or Q expressed this way will vary with *p*H and water concentration.

ΔG values are more convenient than K_{eq} and Q for discussing biochemical reactions because the energy quantities are additive. For example, given two sequential reactions, $A+B \rightleftharpoons C+D$ with a ΔG_1 followed by $C+E \rightleftharpoons F+G$ with a ΔG_2, the overall reaction, $A+B+E \rightleftharpoons D+F+G$, will have a ΔG_3 equal to $\Delta G_1 + \Delta G_2$.

1.2.1 The Standard State. In order to catalog and compare different reactions, a reference or *standard state* is used. That standard is $1M$ of all reactants and products (with the exception of water and H^+). Thus, Q at the standard state is unity. The standard state ΔG is notated as $\Delta G^{0\prime}$ (the superscript zero referring to $1M$ reaction components, the prime indicating that $[H^+]$ is different from $1M$, usually $10^{-7}M$). From Eq. (1), we see that if $Q=1$,

$$\Delta G^{0\prime} = -RT \ln K_{eq}. \tag{2}$$

In effect, $\Delta G^{0\prime}$ is another way of stating the K_{eq} of the reaction;* it tells how K_{eq} compares to unity. For example, if $\Delta G^{0\prime}$ is negative, it means that $1M$ of all products is not sufficient to be at equilibrium with $1M$ of all reactants and, consequently, the reaction will proceed to the right. Combining Eq. (2) with Eq. (1) yields another form of Eq. (1):

$$\Delta G = \Delta G^{0\prime} + RT \ln Q; \tag{3}$$

at 25 °C,

---

* The minus log-linear mathematical relationship between $\Delta G^{0\prime}$ and K_{eq} is similar to that between *p*H and $[H^+]$. In both cases, the two conventions give the same information, but in different language.

$$\Delta G = \Delta G^{0\prime} + 1364 \log Q \text{ cal mole}^{-1}$$

$$= \Delta G^{0\prime} + 5706 \log Q \text{ J mole}^{-1}.$$

Discussions of biochemical reactions often use $\Delta G^{0\prime}$ rather than true ΔG values because the intracellular concentrations of reaction components (and hence, the *in vivo* Q) is not always known, but K_{eq} can be experimentally determined *in vitro.* This is not as unreasonable as it may seem. Certainly, intracellular metabolite concentrations are not $1M$ (most fall between $10^{-7}M$ and $10^{-2}M$). But note that for reactions of the type $A \rightleftharpoons P$ or $A+B \rightleftharpoons C+D$ (i.e., equimolecular in both directions), the reaction components need only to be equal in concentration for Q to equal 1. Q can also equal 1 if $[C][D]=[A][B]$ even when no single component is present at $1M$ or at a concentration equal to that of another component.

1.2.2 ΔG of Oxidation-Reduction Reactions. As mentioned earlier, many reactions of energy metabolism are oxidation-reduction reactions. Table 1 lists some compounds of biological interest and their relative tendencies to gain electrons at 25 °C and *p*H 7 under otherwise standard conditions. The numerical value of any E_0' (standard reduction potential as volts per electron) indicates the reduction potential of a half-reaction relative to that of $H^+ + 1e^- \rightarrow \frac{1}{2}H_2$, which is taken as zero under true standard conditions ($1M$ H^+, 1 atm H_2) and −0.414 V at 10^{-7} M H^+, 1 atm H_2. E_0' values may be thought of as electron pressures and, as such, they are independent of the number of electrons in the half-reaction.

Because no substance can gain electrons without another substance losing electrons, a complete oxidation-reduction reaction must be composed of two half-reactions. When any two half-reactions are coupled, e.g., $A_{ox}+2e^- \rightarrow A_{red}$ with an E_0' of −0.19 V and $B_{ox}+2e^- \rightarrow B_{red}$ with an E_0' of −0.32 V, the one with the greater tendency to gain electrons (the one with the more positive reduction potential) goes as written (as a reduction). Consequently, the other half-reaction (the one with the lesser tendency to gain electrons, as shown by the less positive reduction potential) is driven backwards (as an oxidation). Thus, the overall reaction is $A_{ox}+B_{red}$

Table 1. Standard reduction potentials of some biologically important half-reactions.[a]

Half-reaction (written as a reduction)	E_0' at *p*H 7.0 (V)
$\frac{1}{2}O_2+2H^++2e^- \rightarrow H_2O$	0.82
$Fe^{3+}+1e^- \rightarrow Fe^{2+}$	0.77

Cytochrome a_3-$Fe^{3+}+1e^- \rightarrow$ cytochrome-a_3-Fe^{2+}	0.55
Cytochrome-a-$Fe^{3+}+1\ e^- \rightarrow$ cytochrome-a-Fe^{2+}	0.29
Cytochrome-c-$Fe^{3+}+1e^- \rightarrow$ cytochrome-c-Fe^{2+}	0.25
Ubiquinone$+2H^++2e^- \rightarrow$ ubiquinone-H_2	0.10
Fumarate$+2H^++2e^- \rightarrow$ succinate	0.03
Acetaldehyde$+2H^++2e^- \rightarrow$ ethanol	−0.16
Oxalacetate$+2H^++2e^- \rightarrow$ malate	−0.18
$FAD+2H^++2e^- \rightarrow FADH_2$	−0.18[b]
Pyruvate$+2H^++2e^- \rightarrow$ lactate	−0.19
Cystine$+2H^++2e^- \rightarrow 2$ cysteine	−0.22
1,3-diphosphoglycerate$+2H^++2e^- \rightarrow$ glyceraldehyde-3P$+P_i$	−0.29
$NAD(P)^++2H^++2e^- \rightarrow NAD(P)H+H^+$	−0.32
$2H^++2e^- \rightarrow H_2$	−0.41
$CO_2+H^++2e^- \rightarrow$ formate	−0.42
Ferredoxin-$Fe^{3+}+1e^- \rightarrow$ ferredoxin-Fe^{2+}	−0.43
Acetate$+2H^++2e^- \rightarrow$ acetaldehyde	−0.60

---

[a] Standard conditions: Unit activity of all components except H^+, which is maintained at 10^{-7} M. Gases are at 1 atm pressure.

[b] The value given is for free $FAD/FADH_2$. The E_0' of the protein-bound coenzyme varies according to its environment.

$\rightleftharpoons A_{red}+B_{ox}$. The oxidized forms of those substances with highly positive reduction potentials are good oxidizing agents (and are easily reduced). The reduced forms of those substances with highly negative reduction potentials are good reducing agents (and are easily oxidized).

The relative tendency of the overall oxidation-reduction reaction to proceed may be calculated from the difference between the reduction potentials of the component half-reactions:

$$\Delta E_0' = [E_0' \text{ of the half-reaction containing the oxidizing agent}] - [E_0' \text{ of the half-reaction containing the reducing agent}]. \quad (4)$$

If the overall reaction as written is favorable, Eq. (4) yields a positive $\Delta E_0'$. $\Delta E_0'$ provides the same information as $\Delta G^{0\prime}$ except in units of volts. The relationship between $\Delta E_0'$, $\Delta G^{0\prime}$, and K_{eq} is given by

$$\Delta G^{0\prime} = -n\mathscr{F}\Delta E_0', \quad (5)$$

$$\Delta E_0' = (RT/n\mathscr{F})\ln K_{eq}, \quad (6)$$

where n is the number of electrons transferred per molecule (i.e., the number of equivalents per mole) and $\mathscr{F}$ is Faraday's constant (23 063 cal V^{-1} equivalent^{-1} or 96 496 J V^{-1} equivalent^{-1}), a factor that converts volts×equivalent^{-1} to cal×equivalent^{-1} or joules×equivalent^{-1}.

For the reaction $A_{ox} + B_{red} \rightarrow A_{red} + B_{ox}$, the nonstandard-state ΔE is given by

$$\Delta E = \Delta E_0' - (RT/n\mathscr{F}) \ln Q$$

or

$$\Delta E = (RT/n\mathscr{F}) \ln(K_{eq}/Q), \quad (7)$$

where $Q = [A]_{red}[B]_{ox}/[A]_{ox}[B]_{red}$. Thus, at any Q,

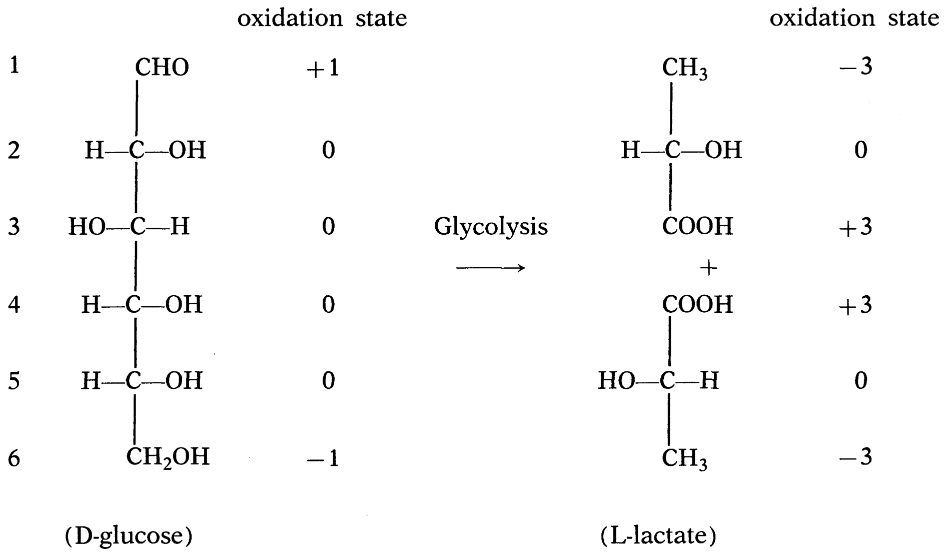
$$\Delta G = -n\mathscr{F}\Delta E. \quad (8)$$

1.2.3 Which Way and How Far, But Not How Fast. While energy considerations allow us to describe the *direction* of a biochemically relevant reaction and the *extent* to which it will proceed, nothing can be inferred from ΔG values about the *rate* of the reaction. Yet, it is the rapid rates of chemical reactions in cells that make life possible. (Clearly, a reaction can be biologically useful only if it can be completed in a time period that is very short compared to the lifetime of a cell.) For example, sucrose is a good biological energy source. The ΔG for sucrose oxidation to CO_2 and H_2O is highly negative. But a teaspoon of sucrose (~10 g) does not burst into flames before our eyes. Indeed, the oxidation rate of dry sucrose (or sucrose in sterile solution) is too slow to measure. On the other hand, a moderately active 75-kg individual can oxidize 10 g of sucrose in about 20 min. (and do so at a relatively low temperature). The agents responsible for rapid reaction rates *in vivo* are *enzymes*—protein catalysts that accelerate the progress of chemical reactions toward equilibrium. The roles of several enzymes in cellular energy metabolism are described in the following sections.

2. COMMON ENERGY METABOLISM PATHWAYS

2.1 Glycolysis—An Anaerobic Pathway

Glycolysis is a ubiquitous pathway among chemoorganotrophs for the utilization of glucose as an "energy source." Other common hexoses, e.g., fructose (derived from sucrose), galactose (derived from lactose), mannose, and the glucosyl residues of the storage polysaccharide, glycogen, feed into the pathway at appropriate points. As shown in Fig. 3, the pathway is "primed" by consuming two moles of ATP per mole of glucose. However, each glucose is split into two moles of triose phosphate, each of which yields 2 moles of ATP. Consequently, the net yield is 2 ATP per glucose. In animal cells and several bacterial species, the end product is lactate. Yeast produces ethanol and CO_2 as end products. Except for the final step(s) (which deal with the disposition of pyruvate), animal, yeast, and several other bacterial versions of glycolysis are identical. Glycolysis (as all other anaerobic fermentations) involves internal oxidation-reduction; i.e., no external oxidizing agent (terminal electron acceptor) is required. In glycolysis leading to lactate, carbon atoms 3 and 4 of glucose are oxidized (a total of 6 e^- are removed), while carbon atoms 1 and 6 are reduced (a total of $6e^-$ are gained). Note (Fig. 3) that 4 of the 6 electrons are transiently carried on NADH. The fate of each carbon atom of glucose upon conversion to 2 lactate is shown below.



The overall conversion is highly exergonic:

$$\text{glucose} \rightleftharpoons 2\ \text{lactate}, \tag{9}$$

$$\Delta G_9^{0\prime} = -47.8\ \text{kcal mole}^{-1}$$

$$= -200\ \text{kJ mole}^{-1}.$$

The energy made available is more than enough to drive the formation of ATP:*

$$\text{ADP} + \text{P}_i \rightleftharpoons \text{ATP} + \text{H}_2\text{O}, \tag{10}$$

$$\Delta G_{10}^{0\prime} = +7.6\ \text{kcal mole}^{-1}$$

$$= +31.8\ \text{kJ mole}^{-1}.$$

In fact, two ATPs are formed for each glucose converted to 2 lactate. The overall process is

$$\text{glucose} + 2\text{ADP} + 2\text{P}_i$$

$$\rightleftharpoons 2\ \text{lactate} + 2\text{ATP} + 2\text{H}_2\text{O}. \tag{11}$$

Under standard conditions, the overall $\Delta G^{0\prime}$ is given by

$$\Delta G_{11}^{0\prime} = \Delta G_9^{0\prime} + 2\Delta G_{10}^{0\prime}$$

$$= -32.6\ \text{kcal}\ (-136.4\ \text{kJ})\ \text{mole}^{-1}.$$

Thus, even with the formation of ATP included, the overall process is highly favorable under standard (as well as under nonstandard, *in vivo*) conditions.

It should be no surprise that sustained energy (i.e., ATP) -requiring processes must be coupled to continuous energy-yielding processes (e.g., glycogen must be continuously metabolized through glycolysis to provide a continuous source of ATP for muscle contraction in an animal fleeing a predator or chasing its lunch). However, it may not be immediately obvious that the reverse is also true: Glycolysis cannot proceed for any useful period of time unless the ATP formed is used. The reason for this obligate coupling is that the intracellular levels of ADP and ATP are (of necessity) fairly low: ~0.3 and 3 μmoles g^{-1}, respectively. An actively contracting muscle may use glucosyl residues of glycogen at a rate of 60 μmoles g^{-1} min^{-1}. Thus, the original ADP pool would last less than 1 sec unless it were continuously regenerated. Similarly, NAD$^+$ (present at about 0.06 μmoles g^{-1}) must be regenerated from the NADH formed at the glyceraldehyde-3-P dehydrogenase-catalyzed step. This is accomplished by the NADH-dependent reduction of pyruvate to lactate. Figure 4 shows how the ADP/ATP and NAD$^+$/NADH cycles must mesh with the overall utilization of glucose in glycolysis.

The enzymes of glycolysis are present in the soluble fraction of cells. In general, the enzymes are considered to be free-floating residents of the cytosol. However, recent stud-

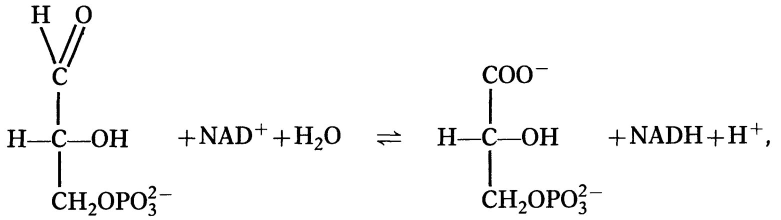
FIG. 3. Glycolysis and gluconeogenesis. Glycolysis (the conversion of glucose to lactate) provides a net gain of two ATP per glucose. Note that gluconeogenesis (the reversal of glycolysis) requires the expenditure of six ATP per glucose.

ies suggest that some enzymes may associate with each other or with structural elements of the cell (e.g., membrane proteins in erythrocytes, contractile proteins in muscle).

2.1.1 Mechanism of ATP Generation in Glycolysis—Substrate-Level Phosphorylation (Chemical Coupling). The formation of ATP in glycolysis proceeds via *substrate-level phosphorylation,* which simply means that the overall process proceeds through discrete chemical intermediates. The reactions of the first ATP formed illustrate how cells couple exergonic and endergonic reactions through a common intermediate. In effect, the cell harnesses the energy made available by the oxidation of glyceraldehyde-3-phosphate (G-3-P) to drive the unfavorable formation of ATP:



$$\mathrm{HC(=O)\text{—}CH(OH)\text{—}CH_2OPO_3^{2-}} + \mathrm{NAD^+} + \mathrm{H_2O} \rightleftharpoons \mathrm{COO^-\text{—}CH(OH)\text{—}CH_2OPO_3^{2-}} + \mathrm{NADH} + \mathrm{H^+}, \quad (12)$$

(G-3-P) [3-phosphoglyceric acid, (3-PGA)]

$$\Delta G^{0\prime}_{12} = -10.6 \text{ kcal mole}^{-1} = -44.4 \text{ kJ mole}^{-1},$$

$$\mathrm{ADP} + \mathrm{P}_i \rightleftharpoons \mathrm{ATP} + \mathrm{H_2O}, \quad (13)$$

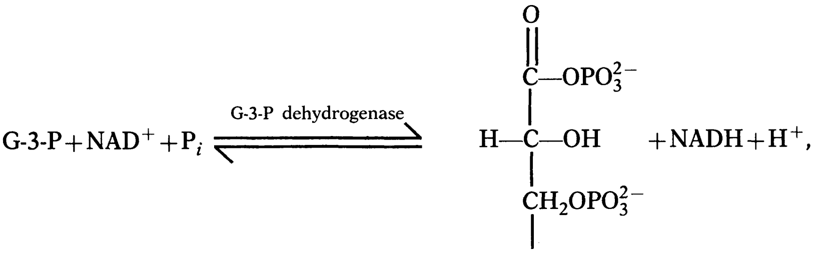
$$\Delta G^{0\prime}_{13} = +7.6 \text{ kcal mole}^{-1} = +31.8 \text{ kJ mole}^{-1}.$$

While the sum of these two reactions is quite favorable,

$$\text{G-3-P} + \mathrm{NAD^+} + \mathrm{ADP} + \mathrm{P}_i \rightleftharpoons \text{3-PGA} + \mathrm{NADH} + \mathrm{H^+} + \mathrm{ATP}, \quad (14)$$

$$\Delta G^{0\prime}_{14} = -3 \text{ kcal mole}^{-1} = -12.5 \text{ kJ mole}^{-1},$$

cells have no mechanism for coupling two independent reactions occurring in the same cellular compartment if the reactions have no common component. Instead, cells catalyze two sequential reactions that accomplish the same result. First, G-3-P is oxidized by NAD$^+$ in a reaction in which inorganic phosphate replaces water. The product then is 1,3-bisphosphoglycerate (1,3-BPG) instead of 3-phosphoglycerate. The $\Delta G^{0\prime}$ of this reaction is not as negative as that of reaction (12) above because energy is conserved by forming the carboxyl-phosphoryl anhydride:



$$\text{G-3-P} + \mathrm{NAD^+} + \mathrm{P}_i \xrightleftharpoons{\text{G-3-P dehydrogenase}} \mathrm{O{=}C(OPO_3^{2-})\text{—}CH(OH)\text{—}CH_2OPO_3^{2-}} + \mathrm{NADH} + \mathrm{H^+}, \quad (15)$$

(1,3-BPG)

$$\Delta G^{0\prime}_{15} = +1.4 \text{ kcal mole}^{-1} = +5.9 \text{ kJ mole}^{-1}.$$

Then, the enzyme phosphoglyceryl kinase catalyzes the transfer of the C-1 phosphoryl group to ADP:

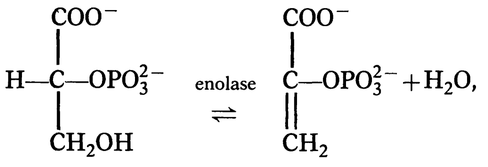
$$\text{1,3-BPG} + \mathrm{ADP} \overset{\text{PG kinase}}{\rightleftharpoons} \text{3-PGA} + \mathrm{ATP}, \quad (16)$$

$$\Delta G^{0\prime}_{16} = -4.4 \text{ kcal mole}^{-1} = -18.4 \text{ kJ mole}^{-1}.$$

The sum of reactions (15) and (16) equals reaction (14).

Although $\Delta G^{0\prime}$ for reaction (15) is positive, the actual *in vivo* ΔG is negative because 1,3-BPG is continuously removed by reaction (16). [Thus, Q for reaction (15) *in vivo* is always $< K_{eq}$ as long as glycolysis is proceeding.]

The formation of the second ATP per triose recovers the two phosphoryl groups used to prime glycolysis. Again, the overall sequence is driven by a favorable oxidation-reduction, although in this case, the electron movements are internal and occur both fore and aft of the ATP-yielding step. First, 2-phosphoglycerate (2-PGA) is dehydrated by the enzyme enolase yielding phosphoenolpyruvate (PEP). Then, the enzyme pyruvate kinase catalyzes a phosphoryl transfer from PEP to ADP yielding ATP and pyruvate. The latter reaction is extremely favorable because of the concurrent tautomerization of the putative product (enol-pyruvate) to the more stable keto form. (In effect, the phosphoryl group of PEP freezes pyruvate into the unstable enol form.) Overall, C-2 of 2-PGA loses two electrons which appear on C-3 of pyruvate:

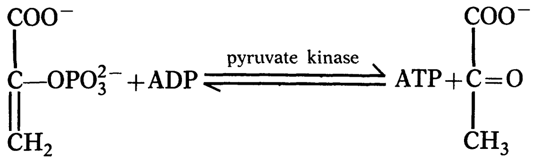


$$\begin{array}{c}\mathrm{COO^-}\\ |\\ \mathrm{H{-}C{-}OPO_3^{2-}}\\ |\\ \mathrm{CH_2OH}\end{array} \overset{\text{enolase}}{\rightleftharpoons} \begin{array}{c}\mathrm{COO^-}\\ |\\ \mathrm{C{-}OPO_3^{2-}}\\ \|\\ \mathrm{CH_2}\end{array} + \mathrm{H_2O}, \qquad (17)$$

(2-PGA) (PEP)

$$\Delta G^{0\prime}_{17} = +0.44 \text{ kcal mole}^{-1}$$

$$= +1.84 \text{ kJ mole}^{-1}$$



$$\begin{array}{c}\mathrm{COO^-}\\ |\\ \mathrm{C{-}OPO_3^{2-}}\\ \|\\ \mathrm{CH_2}\end{array} + \mathrm{ADP} \underset{}{\overset{\text{pyruvate kinase}}{\rightleftharpoons}} \mathrm{ATP} + \begin{array}{c}\mathrm{COO^-}\\ |\\ \mathrm{C{=}O}\\ |\\ \mathrm{CH_3}\end{array} \qquad (18)$$

(PEP) (pyruvate)

$$\Delta G^{0\prime}_{18} = -6.2 \text{ kcal mole}^{-1} = -25.9 \text{ kJ mole}^{-1}.$$

As in all reactions of glycolysis, the actual ΔG of reaction (17) will be at least slightly negative *in vivo* while glycolysis is proceeding.

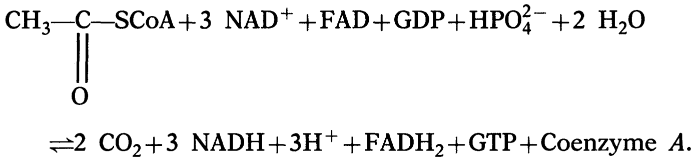
2.1.2 Gluconeogenesis—The Reversal of Glycolysis. Many types of cells can synthesize glucose from noncarbohydrate precursors. The pathway, called gluconeogenesis, is for the most part, a reversal of glycolysis. This bidirectionality is possible because most of the glycolysis reactions are close to equilibrium *in vivo* and consequently, can be easily reversed by small adjustments in the concentrations of reaction components. However, three glycolysis reactions (those catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase) are not reversible in the physiological sense. (Their ΔG values are highly positive in the gluconeogenesis direction—see Sec. 4.1.) As shown in Fig. 3, cells reverse the interconversions at these points by using different reactions with negative ΔG values. (It is noteworthy that the three metabolic traffic circles are the major regulatory points in glycolysis and gluconeogenesis.)

Glycolysis yields ATP. So we would expect glyconeogenesis to require ATP and this is indeed the case. But note that while glycolysis yields 2 ATP per glucose converted to 2 pyruvate, gluconeogenesis requires the equivalent of 6 ATP (4 ATP plus 2 GTP) to drive the synthesis of one glucose from 2 pyruvate. The biochemical economics of the situation is a consequence of the second law of thermodynamics. An examination of all metabolic pathways will reveal that it always costs more ATP (or its equivalent) to synthesize a more complex molecule from simpler precursors than a cell can obtain by breaking the complex molecule down to the simpler precursors.

2.2 Respiration—Aerobic Energy Metabolism

The biological oxidation of a reduced organic compound by oxygen forming CO_2 and H_2O is called *respiration.* Certain bacteria perform a variation on this theme in which a different inorganic substance (e.g., sulfate, nitrate) serves as the terminal electron acceptor. Respiration is a highly exergonic process. For example, the oxidation of glucose by O_2 ($C_6H_{12}O_6+6\ O_2 \rightleftharpoons 6\ CO_2+6\ H_2O$) has a $\Delta G^{0\prime}$ of -686 kcal mole^{-1} or -2870 kJ mole^{-1}. The overall pathway of respiration includes the participation of

1. *glycolysis* (glucose+2 ADP+2P_i+2NAD$^+$ $\rightarrow$2 pyruvate+2 ATP+2 NADH +2H$^+$),
2. an enzyme complex called *pyruvate dehydrogenase* (pyruvate+NAD$^+$+coenzyme *A* $\rightleftharpoons CO_2$+NADH+H$^+$+acetyl-coenzyme *A*), and
3. an eight-step pathway called the *tricarboxylic acid* (TCA) (or citric acid, or Krebs) *cycle.* This last pathway effects the complete oxidation of the remaining two carbon atoms of the acetyl group to CO_2 concomitant with the gathering of eight electrons on nicotinamide and flavin (FAD)-containing coenzymes:



$$CH_3\text{—}\underset{\underset{O}{\|}}{C}\text{—}SCoA+3\ NAD^+ + FAD + GDP + HPO_4^{2-} + 2\ H_2O \rightleftharpoons 2\ CO_2 + 3\ NADH + 3H^+ + FADH_2 + GTP + \text{Coenzyme } A. \qquad (19)$$

Finally,

4. a membrane-embedded *electron transport system* (ETS) channels electrons from NADH and $FADH_2$ to O_2 yielding water. ATP is generated from ADP + P_i by
5. a membrane-associated ATPase (also called *ATP synthase*) (see below).

In eucaryotic cells, processes **2** through **5** all occur within the mitochondria. Acetyl-coenzyme *A* is also an intermediate in the metabolism of fatty acids. Consequently, processes **3** through **5** function in the oxidation of fats as well as carbohydrates.

2.2.1 The Electron Transport System and the Chemiosmotic Mechanism of Oxidative Phosphorylation. Although one mole of GTP (an ATP equivalent) is produced per mole of pyruvate in the TCA cycle, the majority of the ATP is formed by a process called *oxidative phosphorylation* which taps the energy produced when NADH and $FADH_2$ are oxidized by O_2. The yield is 3 ATP for each NADH plus 2 ATP for each $FADH_2$ produced intramitochondrially. NADH produced in the cytosol by glycolysis is used to reduce dihydroxyacetone phosphate to glycerol phosphate. The latter compound enters the mitochondria where it is oxidized by FAD. Thus, the total yield is 36 ATP for each glucose oxidized to 6 CO_2 and 6 H_2O.

The components of the electron transport system (which are associated with the inner mitochondrial membrane) include two types of substances which carry only electrons and two which carry one or two complete hydrogen atoms (H=electron plus proton). Most cytochromes (heme-containing proteins) and the non-heme, iron-sulfur-containing proteins belong to the first type. The second type include flavoproteins (proteins containing the coenzyme flavin mononucleotide or flavin-adenine dinucleotide), and a quinone (ubiquinone, also called coenzyme Q). Electrons are transferred from NADH or $FADH_2$ to O_2 by a series of favorable sequential oxidation-reduction reactions (Fig. 5).

Unlike the formation of ATP in glycolysis, or GTP in the TCA cycle, the formation of ATP in oxidative phosphorylation does not proceed through discrete chemical intermediates. Instead, the oxidation of NADH or $FADH_2$ generates a charge and a *p*H gradient across the proton-impermeable inner mitochondrial membrane, i.e., the "energy-rich" intermediate is physical in nature rather than chemical.

FIG. 4. ATP and coenzyme cycling. Because of the limited supply of ADP and NAD^+ in a cell, they must be continually regenerated in order to permit a prolonged period of glycolysis.

The features of this "chemiosmotic" model (in its simplest form) are as follows.

The electron carriers of the electron-transport system alternate in order between those which carry complete hydrogen atoms and those which carry only electrons. Furthermore, the carriers are arranged asymmetrically within the membrane such that when electrons are transferred from a complete hydrogen carrier to an electron-only carrier, the protons are released on the exterior side of the membrane. When electrons are transferred from an electron-only carrier to one that carries a complete hydrogen, the needed protons are obtained from the interior side of the membrane (i.e., from the mitochondrial matrix). The final carrier, cytochrome a_3 (also called cytochrome oxidase), promotes both the transfer of electrons to O_2 and the release of protons on the exterior side of the membrane. As a result of these sequential reactions, protons are pumped out of the mitochondrial matrix into the cytosol. (The outer mitochondrial membrane is "leaky" and thus, the intermembrane space is at equilibrium with the cytosol.) Essentially, the favorable free-energy change of NADH or $FADH_2$ oxidation is used to generate an *ion electrochemical potential* ($\Delta\Psi$) and an H^+ *concentration gradient* (ΔpH) across the inner membrane. Thus, compared to the cytosol, the mitochondrial matrix becomes negatively charged and has a higher *p*H. The return of protons to the matrix (i.e., the reaction $H^+_{out} \rightleftharpoons H^+_{in}$) is an exergonic process. In general, ΔG for the movement of a charged substance from "side 1 " of a membrane to "side 2" is given by

$$\Delta G = Z\mathcal{F}\Delta\Psi_{2/1} + RT\ln([C]_2/[C]_1), \qquad (20)$$

where Z is the net charge on the substance, $\mathcal{F}$ is Faraday's constant, $\Delta\Psi_{2/1}$ is the electrochemical (or membrane) potential expressed as

side 2 compared to side 1, $[C]_2/[C]_1$ is the actual concentration ratio (side 2/side 1), i.e., Q for the reaction as written. For the movement of protons ($Z=+1$) from side 1=cytosol =outside to side 2=matrix=inside, Eq. (20) can be written as

$$\Delta G_{\text{out}\to\text{in}}=\mathscr{F}\Delta\Psi_{\text{in/out}} +2.3RT\log([\text{H}^+]_{\text{in}}/[\text{H}^+]_{\text{out}}) \tag{21}$$

or, noting that $p\text{H}=-\log[\text{H}^+]=\log(1/[\text{H}^+])$,

$$\Delta G_{\text{out}\to\text{in}}=\mathscr{F}\Delta\Psi_{\text{in/out}}-2.3RT\ \Delta p\text{H}, \tag{22}$$

where $\Delta p\text{H}=p\text{H}_{\text{in}}-p\text{H}_{\text{out}}$.

The voltage equivalent of the ΔG for proton influx, called the *protonmotive force*, $\Delta\tilde{\mu}_{\text{H}^+}$, is obtained by dividing Eq. (22) by $\mathscr{F}$:

$$\begin{aligned}\Delta\tilde{\mu}_{\text{H}^+}&=\Delta\Psi_{\text{in/out}}-(2.3RT/\mathscr{F})\Delta p\text{H}_{(\text{in-out})}\\ &=\Delta\Psi_{\text{in/out}}-0.059\ \Delta p\text{H}_{(\text{in-out})}\\ &\qquad\text{at } 25\ ^\circ\text{C}.\end{aligned} \tag{23}$$

As defined above, $\Delta\tilde{\mu}_{\text{H}^+}$ will have a negative sign under the conditions described. Readers should be aware that some sources express the $\Delta\tilde{\mu}_{\text{H}^+}$ driving force in positive terms. This is analogous to speaking of ATP ($\Delta G^{0\prime}$ of hydrolysis$=-7.6$ kcal mole^{-1} or -31.8 kJ mole^{-1}) as having a standard *phosphoryl group transfer potential* of $+7.6$ kcal mole^{-1} or $+31.8$ kJ mole^{-1}.

The formation of ATP is accomplished by a multisubunit, membrane-embedded proton-translocating enzyme called ATPase or ATP synthase. This enzyme couples the endergonic ATP synthesis half-reaction ($\Delta G^{0\prime}=+7600$ cal mole^{-1}) to the simultaneous exergonic proton influx half-reaction. For example, if the ΔpH across the inner membrane is 1.2 units (interior more alkaline) and the $\Delta\Psi$ is -0.13 V (interior negative), the ΔG for proton influx will be -4635 cal mole^{-1} or $-19\,393$ J mole^{-1} [Eq. (22)]. If at the same time, the intramitochondrial [ADP]/[ATP] ratio is maintained at 6 while $[\text{P}_i]=0.01M$, the ΔG for ATP synthesis will be $+9267$ cal mole^{-1} or $+38\,773$ J mole^{-1} [Eq. (3)]. Clearly, the influx of one H$^+$ cannot provide sufficient driving force to produce ATP. However, the coupled influx of 2H$^+$ will just be sufficient to tilt the overall reaction in the ATP formation direction:

$$\text{ADP}+\text{P}_i\rightleftharpoons\text{ATP}+\text{H}_2\text{O}, \tag{24}$$

$$\begin{aligned}\Delta G_{24}&=+9267\text{ cal per mole,}\\ &=+38\,773\text{ J per mole,}\end{aligned}$$

$$2\text{H}^+_{\text{out}}\rightleftharpoons 2H^+_{\text{in}}, \tag{25}$$

$$\begin{aligned}\Delta G_{25}&=-9270\text{ cal per 2 moles,}\\ &=-38\,786\text{ J per 2 moles,}\end{aligned}$$

Sum:

$$\text{ADP}+\text{P}_i+2\text{H}^+_{\text{out}}\rightleftharpoons\text{ATP}+\text{H}_2\text{O}+2\text{H}^+_{\text{in}}, \tag{26}$$

$$\Delta G_{26}=\text{slightly negative.}$$

In healthy cells, reaction (26) will continue indefinitely as the H$^+$ is pumped back out of the mitochondria by the continued operation of the ETS, and ATP leaves the mitochondria while ADP and P$_i$ enter.

3. PHOTOSYNTHESIS

Photosynthesis is the process whereby higher plants, algae, and certain bacteria use light energy to drive the synthesis of reduced organic compounds (e.g., glucose) from CO_2 and an electron source (H_2O in plants; other inorganic substances such as H_2S or H_2 in bacteria). Photosynthesis and respiration are the two major limbs of the solar-powered carbon cycle of nature (Fig. 6). Indeed, heterotrophic life on earth is completely dependent on photosynthesis because chemoorganotrophic food chains can not be forever circular. (The chemical elements of biomolecules—carbon, hydrogen, oxygen, nitrogen, phosphorous, and sulfur—are completely recyclable, but the second law of thermodynamics dictates that energy is not.) A complete description of the photosynthetic process is beyond the scope of this article, but can be summarized as follows:

1. The "light" reaction (generation of ATP and NADPH):

$$\begin{aligned}&12\ \text{H}_2\text{O}+18\ \text{ADP}+18\text{P}_i+12\ \text{NADP}^+\\ &\xrightarrow{60h\nu} 18\ \text{ATP}+12\ \text{NADPH}+12\ \text{H}^+\\ &\qquad+6\ \text{O}_2+18\ \text{H}_2\text{O}.\end{aligned}$$

(Water appears on both sides of the reaction because labeling experiments have estab-

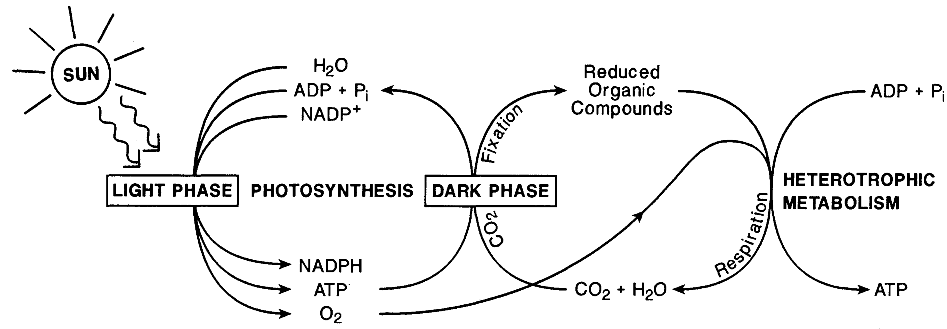

FIG. 6. The major limbs of the carbon cycle. At any time, living organisms contain about 830×10^{15} g of carbon (90% of which is present in plants), while the atmosphere contains about 670×10^{15} g of carbon as CO_2. About 10% of the total carbon is recycled per year.

lished that all 12 atoms of the oxygen produced are derived from water.)

2. The "dark" reaction (CO_2 reduction to glucose):

$$\begin{aligned}&6\ CO_2+18\ ATP+12\ NADPH+12\ H^+\\&\quad+12\ H_2O\\&\rightarrow C_6H_{12}O_6+18\ ADP+18\ P_i\\&\quad+12\ NADP^+.\end{aligned}$$

If one NADPH is considered to be energetically equivalent to 3 ATP, the overall synthesis of glucose from 6 CO_2 plus 6 H_2O is seen to cost 54 ATP. (Recall that aerobic cells obtain only 36 ATP for each glucose completely oxidized to 6 CO_2 plus 6 H_2O).

Figure 7 shows (in abbreviated form) how the capture of light energy by plants leads to the generation of ATP and NADPH. Two photons are captured by photosystem I (a chlorophyll and electron-carrier–containing center within the thylakoid membrane structures of the chloroplast). The absorption of light energy elevates two electrons to a highly negative reduction potential. (One can also envision that light excites a pigment component of photosystem I so that it becomes a much stronger reducing agent.) The two electrons are transferred to $NADP^+$ through a series of electron carriers (phylloquinone and iron-sulfur proteins, including ferredoxin) producing NADPH. A similar excitation occurs when photosystem II absorbs two photons. This time, the two electrons are transferred (via pheophytin, quinones, cytochromes, and plastocyanin) to the oxidized photosystem I, restoring that system to its original state. During the electron transport process, protons are pumped into the thylakoid lumen. (The direction of H^+ movement is the opposite to that which occurs in mitochondria.) The resulting $\Delta\tilde{\mu}_{H^+}$ is used to generate one ATP, as described earlier. Finally, two electrons from H_2O make up the electron deficiency in photosystem II yielding oxygen as a product. The overall noncyclic process (so called because the electrons that leave photosystem I do not return to that system) generates 1 NADPH + 1 ATP (and liberates $\frac{1}{2}$ O_2) per 2 photons. Twelve repeats yield sufficient NADPH for the "dark" reaction, but only 12 of the 18 ATP that are required. The remaining 6 ATP are produced by six traversals of a cyclic process in which two electrons excited from photosystem I are transferred back to the same photosystem, generating a $\Delta\tilde{\mu}_{H^+}$ which yields 1 ATP per 2 photons. The overall process requires the input of 60 einsteins (moles) of photons (36 into photosystem I plus 24 into photosystem II) in order to produce the 18 moles of ATP and 12 moles of NADPH required for the reduction of 6 moles of CO_2 to one mole of glucose. The energy of an einstein of photons is given by $E=Nh\nu=Nhc/\lambda$, where N is Avogadro's number, h is Planck's constant, ν is the light frequency, c is the speed of light, and λ is the wavelength of the light. If the wavelength of the captured light is given in cm, the energy in an einstein of photons can be calculated as

$$E=2.86/\lambda_{\text{cm}}\ \text{cal einstein}^{-1}$$

or

$$E=11.95/\lambda_{\text{cm}}\ \text{J einstein}^{-1}. \qquad (27)$$

Thus, about 2900 kcal of visible light energy (average $\lambda=600$ nm) are required to form one mole of glucose. Recall that the oxidation

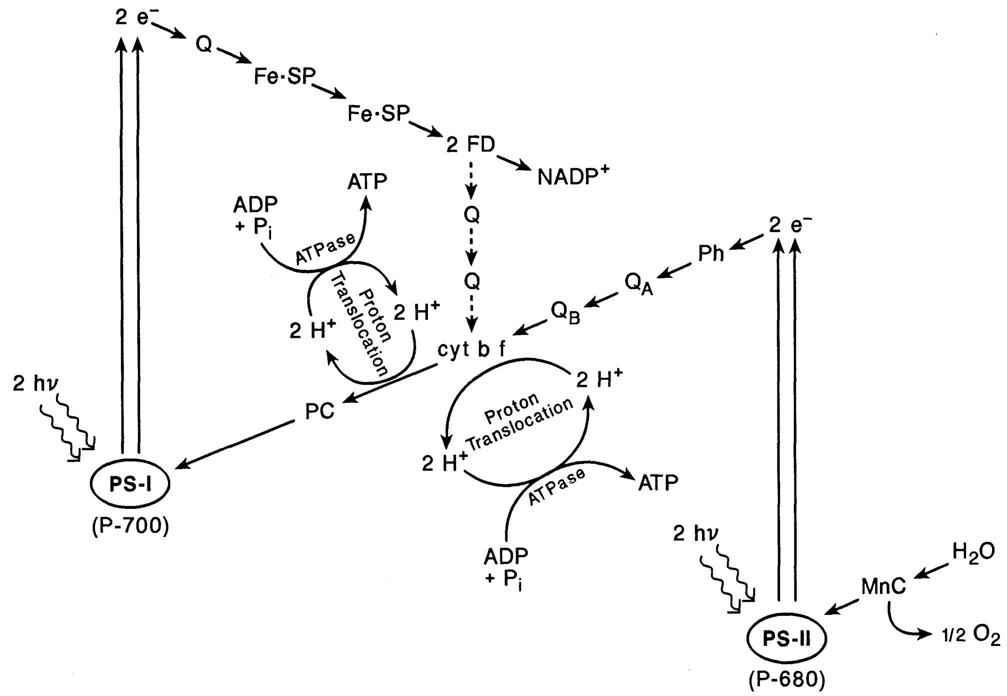

FIG. 7. The path of electrons during noncyclic (solid line) and cyclic (broken line) photophosphorylation in plants. Photosystem I (PS-I) has an absorption maximum (λ_{max}) of 700 nm (7×10^{-5} cm) and thus is sometimes indicated as P700. Photosystem II (PS-II, P680) has a λ_{max} of 680 nm. Q, Q_A, Q_B are quinones; FeSP represents non-heme, iron-sulfur proteins; Ph is pheophytin, a chlorophyll molecule in which the central Mg^{2+} is replaced by $2H^+$; PC is plastocyanin, a copper-containing protein; cytbf is a complex of two cytochromes; MnC is a manganese-containing reaction center involved in transferring electrons from H_2O to the "positive hole" of photosystem II. The photosynthetic apparatus harnesses the (literally) free energy of sunlight ultimately making all manner of energy-requiring biological processes possible, including the formation of complex, highly organized (low entropy) macromolecular and cellular structures from simple, low molecular weight (high entropy) inorganic and organic precursors.

of glucose via aerobic respiration yields only 686 kcal $mole^{-1}$. But this "inefficiency" of the carbon cycle is of no consequence because the primary biological energy source, sunlight, is (for all practical considerations) unlimited and inexhaustible.

4. HOW DO CELLS DRIVE ENERGY-REQUIRING REACTIONS?

4.1 Limitations of Coupled Reactions

In order to appreciate the role of ATP, let us examine a simple cellular task—the formation of glucose-6-phosphate (G-6-P) which is necessary to initiate glycolysis. Theoretically, G-6-P can be formed from glucose and P_i by the G-6-P phosphatase-catalyzed reaction

$$\text{glucose}+P_i \overset{\text{G-6-Ptase}}{\rightleftharpoons} \text{G-6-P}+H_2O, \qquad (28)$$

$$\Delta G^{0\prime}_{28}=+3.3\ \text{kcal}\ (+13.8\ \text{kJ})\ \text{mole}^{-1},$$

$$K_{eq}=3.81\times10^{-3}M^{-1}.$$

At the usual intracellular levels of glucose (5 mM) and P_i (10 mM), the maximum (equilibrium) level of G-6-P would be 0.19 μM. It would be necessary to maintain the [G-6-P] somewhat below 0.19 μM in order to keep the reaction proceeding to the right. But there is a practical limitation to this approach: The enzymes that use G-6-P require about 30-μM G-6-P in order to work at their half-maximum rates. At the normal cellular levels of these enzymes, G-6-P could not be metabolized at a biologically useful rate. So, while the continual formation of G-6-P via the above reaction can (in theory) be made thermodynamically feasible, it is not kinetically feasible.

Another way to drive a reaction is to increase the concentrations of reactants. In theory, an equilibrium G-6-P concentration of 30 μM could be attained if the concentrations of glucose and P_i were maintained at about 0.09 *M* each. But once again, the limitations of living cells make this an impractical option. Most cells will not accumulate solutes to internal levels much greater than $10^{-2}M$. There are many reasons for this upper limit. One is that cells must expend energy to concentrate solutes to levels higher than that in the external environment. The energy cost increases with increasing internal concentration. Another reason is that high concentrations of charged compounds, such as inorganic phosphate, inhibit the activities of many enzymes. Perhaps the simplest explanation is that cells must maintain thousands of different organic compounds (including proteins) in solution. The solvent capacity of a cell is not sufficient to maintain a large number of different compounds at high concentrations. Thus, some highly endergonic reactions can be neither pulled nor pushed by simply manipulating internal concentrations. How then do cells drive these reactions? The answer lies in the special properties of a group of compounds biochemists call *energy-rich compounds.*

4.2 "Energy-Rich" Compounds

To the biochemist, the term *energy-rich compound* generally refers to a compound that has a rather highly negative $\Delta G^{0\prime}$ of hydrolysis. One class of such compounds are the *nucleoside triphosphates,* of which ATP is the most abundant in cells. ATP plays a central role in cellular energy metabolism, linking the oxidative (or photosynthetic) pathways that supply chemical (or light) energy to the biosynthetic pathways that require energy to proceed. Consider the problem of forming G-6-P. On paper, the hydrolysis of ATP yields sufficient "energy" to drive the synthesis of G-6-P from glucose + P_i:

$$\text{glucose} + P_i \xrightleftharpoons{\text{G-6-Ptase}} \text{G-6-P} + H_2O \qquad (29)$$

$$\Delta G^{0\prime}_{29} = 3.3 \text{ kcal } (+13.8 \text{ kJ}) \text{ mole}^{-1},$$

$$\text{ATP} + H_2O \xrightleftharpoons{\text{ATPase}} \text{ADP} + P_i, \qquad (30)$$

$$\Delta G^{0\prime}_{30} = -7.6 \text{ kcal } (-31.8 \text{ kJ}) \text{ mole}^{-1}.$$

However, reactions (29) and (30) cannot be coupled in the usual sense because there is no common intermediate. So, if glucose, P_i, and ATP are mixed together in the presence of ATPase and glucose-6-phosphatase, both reactions would proceed independently toward their respective equilibrium positions. The concentration of G-6-P at equilibrium would be almost the same as in the absence of ATP and ATPase. (The uncoupled situation is analogous to burning a gallon of gasoline on the driveway. A lot of energy will be released, but your car will not move.)

If we add reactions (29) and (30) we obtain

$$\text{ATP} + \text{glucose} \xrightleftharpoons{\text{hexokinase}} \text{G-6-P} + \text{ADP}, \qquad (31)$$

$$\Delta G^{0\prime}_{31} = -4.3 \text{ kcal } (-18 \text{ kJ}) \text{ mole}^{-1},$$

$$K_{eq} = 1421.$$

Reaction (31) is more than just the sum of two uncoupled reactions. It is, in fact, the actual reaction used by cells to produce G-6-P from glucose. However, reaction (31) is not catalyzed by glucose-6-phosphatase plus ATPase, but rather by a completely different enzyme called hexokinase. Hexokinase accomplishes the "coupling" of reactions (29) and (30) by combining them into a single reaction.

The hexokinase-catalyzed reaction exemplifies a key biological role of energy-rich compounds. Although energy-rich compounds have highly negative free energies of hydrolysis, their use seldom involves simple hydrolysis. Instead, they are used as *group transfer agents* that donate parts of their structure to acceptors other than water (when the appropriate enzyme is present). In the hexokinase reaction, ATP serves as a phosphoryl-group ($-PO_3^{2-}$) donor. The advantage of ATP over inorganic phosphate as the precursor of the phosphate ester group is obvious: The hexokinase-catalyzed phosphate transfer reaction proceeds far to the right. At the steady-state levels of ATP and glucose in a cell, G-6-P can accumulate to a level that permits the subsequent G-6-P–utilizing enzymes to operate at biologically useful rates. Clearly, a very low steady-state concentration of ATP can accomplish the same result as a much higher concentration of inorganic phosphate. We might say, then, that the use of ATP as a phosphorylating agent is nature's way of conserving the limited solvent capacity of a cell.

ATP serves not only as a phosphoryl donor, but also as a pyrophosphoryl donor, as an adenylyl (AMP) donor, and as an adenosine donor. Other nucleoside triphosphates (NTP) play similar roles. The group transfer may be an end in itself (e.g., G-6-P, nucleic acid synthesis), or may be a prelude to further reactions. Indeed, most biosynthetic reactions are driven by group transfer from an NTP producing an "activated" intermediate containing an easily displaced leaving group. For example, consider the synthesis of sucrose from glucose. The $\Delta G^{0\prime}$ for the reaction 2 glucose $\rightleftharpoons$ sucrose+H_2O is about +7 kcal mole^{-1}. However, *in vivo*, a plant cell might proceed by the sequence of coupled reactions shown below (UTP stands for uridine triphosphate):

	$\Delta G^{0\prime}$ (kcal×mole^{-1})	
$2\ \text{glucose} + 2\ \text{ATP} \overset{\text{hexokinase}}{\rightleftharpoons} 2\ \text{G-6-P} + 2\ \text{ADP},$	-4.3×2	(32)
$\text{G-6-P} \overset{\text{phosphoglucose isomerase}}{\rightleftharpoons} \text{fructose-6-P (F-6-P)},$	$+0.5$	(33)
$\text{G-6-P} \overset{\text{phosphoglucomutase}}{\rightleftharpoons} \text{G-1-P},$	$+1.7$	(34)
$\text{G-1-P} + \text{UTP} \overset{\text{UDPG synthetase}}{\rightleftharpoons} \text{uridine diphosphate glucose (UDPG)} + PP_i,$	$+0.7$	(35)
$\text{UDPG} + \text{F-6-P} \overset{\text{sucrose-P synthase}}{\rightleftharpoons} \text{sucrose-P} + \text{UDP},$	-0.7	(36)
$PP_i + H_2O \overset{\text{inorganic pyrophosphatase}}{\rightleftharpoons} 2\ P_i,$	-5.0	(37)
$\text{sucrose-P} + H_2O \overset{\text{sucrose phosphatase}}{\rightleftharpoons} \text{sucrose} + P_i,$	-3.8	(38)
Sum: $2\ \text{glucose} + 2\ \text{ATP} + \text{UTP} + 2\ H_2O \rightleftharpoons \text{sucrose} + 2\ \text{ADP} + \text{UDP} + 3\ P_i.$	-15.2	(39)

Essentially, the formation of one mole of sucrose from 2 moles of glucose is driven by the free energy of hydrolysis of 3 moles of nucleoside triphosphate (NTP). The expenditure of 3 NTP converts what would be an unfavorable (endergonic) reaction into a highly favorable (exergonic) reaction sequence that proceeds far to the right. (But notice that an actual NTP hydrolysis reaction does not occur anywhere in the sequence.)

Although the above reactions were characterized by their $\Delta G^{0\prime}$ values (some of which were slightly positive), it is crucial to recognize that if sucrose is continuously formed from 2 glucose, then the actual ΔG of every reaction in the sequence must be negative. (If the overall flow of a stream is from high to low ground, there can be no regions along the course with a net uphill flow.)

Sucrose has the same overall oxidation state as glucose. Consequently, only ATP and UTP are required for the biosynthetic process. If we examine the formation of a more reduced product from glucose (e.g., fatty acids), we would find that reducing power in the form of NADPH is required along with ATP.

4.3 Active Transport

The accumulation of solutes across a membrane and against a concentration gradient is a major energy-requiring activity of cells. Many such *active transport* processes are driven by a transmembrane electrochemical potential, $\Delta\tilde{\mu}$, usually of H^+ or Na^+. This $\Delta\tilde{\mu}$ is generated either by an electron transport system within that membrane, or by a membrane-embedded ATPase that couples the "outward" translocation of H^+ (or Na^+) to ATP hydrolysis. Uptake of the solute (e.g., a neutral amino acid) is accomplished by a specific membrane transport system (sometimes called a "permease") which cataylzes the *cotransport* (*"symport"*) of the amino acid and H^+ or Na^+. In effect, the downhill flow of H^+ or Na^+ drives the simultaneous uphill flow of amino acid. The amino acid can be accumulated to an internal/external concentration ratio such that the positive ΔG for further uptake,

$$\Delta G = RT \ln \frac{[\text{amino acid}]_{\text{in}}}{[\text{amino acid}]_{\text{out}}}, \tag{40}$$

numerically equals the negative ΔG provided by the H^+ or Na^+ electrochemical potential [Eq. (20)], i.e., the sum of the two half-reactions has a zero ΔG. The protons taken up by symport are reextruded, thereby maintaining the $\Delta\tilde{\mu}$ across the plasma membrane.

4.4 Other Types of Energy-Rich Compounds

In addition to nucleoside triphosphates, cells contain several other types of compounds that have highly negative ΔG's of hydrolysis—or, in a functional sense, have high group-transfer potentials. These include several classes of anhydrides such as inorganic pyrophosphate, acyl phosphates (e.g., acetyl phosphate, 1,3-bisphosphoglycerate), acyl adenylates (particularly amino acyl adenylates), and phosphosulfates (e.g., adenosine-5′-phosphosulfate). Other types include thioesters (e.g., acetyl-coenzyme *A*), enol phosphates (PEP may be the sole example), guanidinium phosphates (e.g., creatine phosphate), and sugar nucleotides (e.g., UDPG). A complete description of each type, their metabolic roles, and the chemical basis of their high group-transfer potential is beyond the scope of this article. In general, one or more of the following factors contribute to the instability of all energy-rich compounds: electrostatic repulsion between like-charged atoms, spontaneous ionization or tautomerization of a primary reaction product, and resonance stabilization of the products of the reaction. All energy-rich compounds share an essential feature: They are *thermodynamically unstable*, but *kinetically stable*. That is, they can persist in solution for prolonged periods without decomposing but react readily in the presence of a specific group-transfer enzyme.

GLOSSARY

Active Transport: "Uphill" transport and accumulation of a solute within a cell (or cellular compartment) against a concentration gradient. Active transport is an energy-requiring process.

Alcohol Fermentation: Yeast glycolysis; the anaerobic conversion of one mole of glucose to two moles of ethanol plus two moles of CO_2.

Aldolase (FBP aldolase; aldolase A): Enzyme that cleaves the 6-carbon fructose-1,6-bisphosphate into two triose phosphates (dihydroxyacetone phosphate and glyceraldehyde-3-phosphate).

ATP: Adenosine-5′-triphosphate (adenine-ribose-P-P-P), the most common "energy-rich" compound in cells. ATP is generally used as a source of transferable phosphoryl, pyrophosphoryl, adenylyl, and adenosyl groups which "activate" the acceptor.

ATPase (ATP synthase): An enzyme that catalyzes the reversible reaction $ATP + H_2O \rightleftharpoons ADP + P_i$.

Autotroph: Organism that uses CO_2 as its sole source of carbon.

Calorie: Unit of energy, work, and heat. One calorie (with a small c) is equivalent to the heat needed to raise the temperature of 1 g of water by 1 °C. One Calorie ("large calorie," with a capital C) is 1000 calories (1 kcal). The caloric values of foods are given in terms of Calories. 1 cal = 4.184 J.

Chemical Coupling: See substrate-level phosphorylation.

Chemiosmotic Mechanism: Process whereby the endergonic synthesis of ATP from ADP and P_i by a membrane-spanning enzyme (ATPase or ATPsynthase) is driven by the coupled (simultaneous) exergonic influx of protons catalyzed by the same enzyme.

Chlorophyll: Green, magnesium-containing protein-bound porphyrin that serves as the primary light-absorbing pigment of higher plants, algae, and some bacteria.

Chloroplast: Organelle within photosynthetic organisms that contains the light-capturing pigments and the enzymes of photosynthesis as well as many other enzymes.

Coenzyme: Low-molecular-weight (compared to proteins) organic compound that serves as a group-specific carrier. Most coenzymes are derived from water-soluble vitamins.

Coenzyme A: Sulfur-containing coenzyme, derived from the vitamin pantothenic acid, that carries acyl groups in thioester linkage.

Coenzyme Q: Membrane-bound quinone that serves as a $1e^-$ or $2e^-$ carrier in the mammalian electron transport system.

Coupled Reactions (Apparent): Reactions (true or hypothetical) whose sum equals an actual reaction.

Coupled Reactions (True): Sequential reactions with a common component, e.g., $A \rightleftharpoons B$, $B \rightleftharpoons C$.

Cyclic Photophosphorylation: ATP synthesis by photosynthetic organisms driven by electrons returning via associated carriers to the same photosystem from which they were excited by light.

Cytochrome: Protein containing a heme (iron porphyrin) center that acts as an electron transfer agent.

Dehydrogenase: Common name for the class of enzymes that catalyze coenzyme-dependent oxidation-reduction reactions.

Einstein: One mole (Avogadro's number) of photons.

Electron Transport System: Electron carriers, generally membrane-bound, that transfer electrons sequentially from an initial donor (e.g., NADH, $FADH_2$) to the terminal acceptor.

Energy-Rich Compound: Biochemical jargon for a compound having a highly negative ΔG of hydrolysis.

Enolase: Common name of the enzyme that catalyzes the interconversion of 2-phosphoglycerate and phosphoenolpyruvate.

Enthalpy Change (ΔH): Heat change accompanying a reaction. ΔH is negative if heat is evolved; positive if heat is absorbed.

Entropy Change (ΔS): Change in the degree of randomness (disorder) as a result of a reaction. The ΔS of the reaction components (the "system") may increase, decrease, or remain constant, but the total ΔS of the system plus its surroundings always increases as a result of any real reaction.

Enzyme: Protein catalyst that accelerates the rate at which a reaction approaches equilibrium. Living cells contain more than 1000 different enzymes, each highly specific for a particular reaction.

E_0': Symbol for the standard reduction potential of a half-reaction at $p\mathrm{H} = 7$.

Equilibrium: Lowest energy level of a system; energy level at which the process or reaction does not proceed in a net forward or reverse direction. If the equilibrium is a dynamic one (as all chemical equilibria are), the forward and reverse reaction rates are equal.

Equilibrium Constant (K_{eq}): Mass action quotient of reaction components at equilibrium. For the common reaction type $A + B \rightleftharpoons C + D$, $K_{eq} = [C][D]/[A][B]$.

Flavoprotein: Protein containing the tightly bound, 2H-carrying coenzyme flavin mononucleotide (FMN) or flavin adenine dinucleotide (FAD).

Free-Energy Change: See Gibbs free-energy change.

Gibbs Free-Energy Change (ΔG): Maximum work that can be performed by a process; a measure of the displacement of a system from equilibrium.

Gluconeogenesis: Synthesis of glucose from noncarbohydrate organic precursors such as lactate, TCA cycle intermediates, and amino acids.

Glycolysis: Anaerobic conversion of glucose to lactate or ethanol plus CO_2.

Group-Transfer Potential: Free energy of hydrolysis of an energy-rich compound expressed as a positive value.

Heterotroph: Organism that uses preformed organic compounds as its source of carbon.

Iron-Sulfur Protein: Electron-transfer protein containing one or more iron atoms bound to acid-labile sulfur atoms or cysteine residues of the protein polypeptide (or both).

Isomerase: Common name (in carbohydrate metabolism) for an enzyme that catalyzes the interconversion of keto and aldo structural isomers.

Kinase: Common name for an enzyme that catalyzes a phosphoryl transfer reaction between a nucleosidetriphosphate and an acceptor. Specificity is given by a prefix (e.g., hexokinase, ribokinase).

Lithotroph: Organism that uses inorganic compounds as its source of energy.

Mass-Action Quotient: Ratio of concentration driving forces of opposing reactions (i.e., for the reaction $nA+mB \rightleftharpoons rC+sD$, the mass action quotient Q is $[C]^r[D]^s/[A]^n[B]^m$).

Metabolism: Sum total of all the enzyme-catalyzed chemical reactions that occur in cells.

Mitochondrion: Double-membraned organelle within eucaryotic cells that contains pyruvate dehydrogenase, the enzymes of the TCA cycle, the electron transport system, enzymes of fatty acid oxidation, and many other enzymes.

Mutase: Common name (in carbohydrate metabolism) for an enzyme that catalyzes the intramolecular transfer of a phosphoryl group from one carbon atom to another.

NAD^+: Nicotinamide adenine dinucleotide (nicotinamide-ribose-P-P-ribose-adenine), a coenzyme that transiently carries a pair of electrons. [See Fig. 2(b)].

$NADP^+$: Electron-carrying coenzyme similar in structure to NAD^+. [See Fig. 2(b)].

Noncyclic Photophosphorylation: ATP synthesis by photosynthetic organisms driven by electrons from photosystem II as they flow to photosystem I via associated carriers.

Oxidation: The loss of electrons.

Oxidative Phosphorylation: ATP formation from ADP + P_i concomitant with electron transfer from a reduced coenzyme (NADH, $FADH_2$) to O_2 via a membrane bound electron transport system.

Oxidizing Agent: Compound that accepts electrons donated by another substance (e.g., NAD^+ is an oxidizing agent in many dehydrogenase-dependent redox reactions).

***p*H:** Logarithmic convention for indicating the H^+ (hydrogen ion; proton) concentration ($p\mathrm{H} = -\log[\mathrm{H}^+]$).

Photophosphorylation: Light-driven formation of ATP.

Photosynthesis: Light-driven overall formation of reduced organic compounds from CO_2.

Photosystem: Light-absorbing center of photosynthetic organisms; contains various pigments (including chlorophyll).

Phototroph: Organism that uses light as the primary source of energy.

Protonmotive Force ($\Delta\tilde{\mu}_{H^+}$): Driving force (potential energy) for the movement of protons (H^+) down a concentration and electrochemical gradient.

Pyruvate Dehydrogenase: Complex of three distinct enzymes that catalyze the overall oxidative decarboxylation of pyruvate forming acetyl-*S*-coenzyme *A*, CO_2, and NADH.

Redox Reaction: Overall oxidation-reduction reaction in which one substance (the oxidizing agent) gains electrons (and thus, is reduced) while another substance (the reducing agent) loses electrons (and thus, is oxidized).

Reducing Agent: Compound that donates electrons to another substance (e.g., NADH is a reducing agent in many dehydrogenase-dependent redox reactions.

Reduction: The gaining of electrons.

Respiration: Overall biological oxidation (by oxygen) of reduced organic compounds to CO_2 and H_2O.

Spontaneous Reaction: A reaction that will proceed in the direction written (if it proceeds at all) because the reaction components are not at equilibrium (i.e., a reaction with a negative ΔG). The word "spontaneous" implies nothing about the reaction rate.

Standard Free-Energy Change ($\Delta G^{0\prime}$): ΔG of a reaction when all components are $1M$.

Standard Reduction Potential (E_0'): Tendency of a half-reaction to proceed as a reduction under standard conditions at $p\mathrm{H}=7$ (expressed in terms of volts) relative to that of the $2H^+ + 2e^- \rightarrow H_2$ half-reaction which is -0.41 V.

Standard State: Reference state of $1M$ of all reactants and products used for tabulating and comparing energy changes accompanying a reaction.

Steady State: Condition in which the rate of formation of a substance equals the rate at which the substance is removed, resulting in a constant level of that substance over time. That steady-state level may or may not equal the equilibrium level. The intermediates of most metabolic pathways are in a steady state *in vivo.*

Substrate-Level Phosphorylation: Formation of ATP via discrete phosphorylated chemical intermediates (also called chemical coupling).

Symport: Simultaneous transport of two substances across a membrane, one of which moves down a concentration and/or electrochemical gradient driving the accumulation of the other "uphill."

Terminal Electron Acceptor: Final electron acceptor (oxidizing agent) in an electron transport chain.

Ubiquinone: Another name for Coenzyme Q.

INTRODUCTION

Energy conversion is a vast subject, involving the transformation of energy among all its myriad forms. Virtually all processes that involve change are made possible by energy conversion. From a global perspective, available energy originates primarily with the sun and energy-rich mineral substances (e.g., uranium) and is transformed into useful forms by plants, animals, and human activity. Organisms utilize whatever forms of energy are available for survival, gaining the capacity for activity and change by transforming energy from one form into another.

Some important but diverse examples of energy-conversion processes in biology are photosynthesis in plants and muscle contraction in animals. In chemistry examples include electrolysis of water, chemical reactions that absorb or produce heat, and chemical reactions that produce electricity. In nuclear physics, examples are fission and fusion reactions and radioactive decay. In solid-state physics some important examples are light absorption by materials to produce electricity or heat, and light emission in various processes. In mechanical and electrical engineering important examples include internal combustion and steam engines, mechanical machinery (e.g., gear trains), turbines, electric generators and motors, refrigeration technology, etc. These examples illustrate the broad spectrum of energy-conversion processes.

From the perspective of the disciplines of applied physics (as opposed, for example, to biology), the phenomena of electromagnetism form a central part of energy-conversion technology. For this reason and to limit the number of topics that must be discussed, the

primary emphasis of this article is placed on processes in which electricity is produced and on processes in which electricity is converted to electromagnetic radiation. Chemical processes such as combustion and nuclear processes such as fission and fusion will be regarded simply as providing heat sources for subsequent conversion to electricity. For a treatment of nuclear power the reader is referred to NUCLEAR ENERGY, FISSION, and NUCLEAR ENERGY, FUSION. For a treatment of energy conversion with emphasis on mechanical technology such as engines, see Russell *et al.* (1989). After a discussion of the forms of energy in Sec. 1, and the general properties of energy converters in Sec. 2, conventional large-scale systems are discussed in Sec. 3. Subsequently in Sec. 4 alternative approaches to electricity generation are treated, followed in Sec. 5 by presentation of several techniques for efficient conversion of electricity to electromagnetic radiation. A complementary article, STORAGE OF ENERGY, covers large-scale energy storage systems.

1. FORMS OF ENERGY

Forms of energy may be classified as kinetic or potential. Kinetic energy may be classified into macroscopic forms (e.g., rotation of a flywheel) and microscopic forms (e.g., a particle beam, or motion of atoms in a gas). Potential energy may be classified in terms of the fundamental forces involved. The "strong" nuclear force mediates interactions between nuclei, nucleons, quarks, etc., while the "weak" nuclear force is responsible for radioactive decays. The electromagnetic force controls the motions of charged particles in situations in which nuclear reactions are unimportant. This is the case for ordinary matter, as it is simply composed of assemblages of electrons and nuclei. The gravitational force, shared by all matter, is likewise a fundamental force.

From a technological point of view, electromagnetic forces are particularly important, since they govern all processes that are not nuclear or gravitational. Electromagnetic forms of energy may be further subdivided into macroscopic forms, such as in the electric field of a capacitor or the magnetic field of a solenoid, and microscopic forms. Microscopic electromagnetic energy is contained in the particular arrangement of electrons and nuclei in a given material; it may be further subdivided into thermal and nonthermal. The thermal portion of the energy in a system is that associated with the fact that the absolute temperature is not zero. It can further be associated with the disorder (entropy) of the system, but not merely with motions of particles in the system, as sometimes supposed. For example, the zero-point motion required by quantum mechanics occurs even at absolute zero. The kinetic energy associated with this motion is unavailable, but not unimportant: the zero-point motion of electrons is responsible for the rigidity of solid matter.

Changes in microscopic electromagnetic energy, occurring during energy conversion, may be classified into chemical and physical changes. Chemical changes require the breaking or formation of electronic bonds between atoms, as occurs in combustion or at the electrode of a battery. Physical changes are those in which no chemical reaction occurs; for example, ionization of a simple plasma or a phase transition such as vaporization of a liquid. The distinction between chemical and physical changes is not always sharp. For example, the absorption of light by a semiconductor can be described as either a chemical or physical change. From a chemical point of view an incoming photon displaces an electron bonding two atoms. Both the broken bond and the liberated electron are then free to move in the crystal lattice. From a physical point of view, the incoming photon excites an electron from the valence band to the conduction band, leaving a hole behind in the valence band. Thus, photon absorption by semiconductors is an example of a class of "interdisciplinary" processes for which the perspectives of both chemical and physical points of view are both quite important.

2. GENERAL PROPERTIES OF ENERGY CONVERTERS

2.1 Energy Efficiency as a Figure of Merit

For any energy-conversion process the obvious and conventional figure of merit is the efficiency, the ratio of useful output energy to input energy. High-efficiency processes are important, not just because they are more effective, but also because they reduce the amount of waste heat that must be dissipated. In many cases, the maximum theoretical value is unity. However, when input thermal energy is involved, for heat engines, the maximal (Carnot) efficiency is less than unity. Likewise, for heat pumps (see Sec. 2.3) the question of maximal efficiency is more complex. For these reasons it is often useful to define the "second- law efficiency," which is the ratio of the efficiency to the maximum value permitted by the second law of thermodynamics.

In specialized applications, the best figure of merit may not be energy efficiency, but rather some related quantity. For example, in illumination engineering one uses luminous efficacy, measured in lumens of light output per watt of input. The lumen is a specialized unit of the quantity of light that accounts for the fact that the human eye is more sensitive to some wavelengths than others.

2.2 Simple Nonthermal Energy Converters

Simple nonthermal energy converters are those in which energy is transformed without using or producing (i.e., dissipating) heat. This is an idealized case since some heat generation can always be expected, but it can be closely approached by some real systems. A lever arm is one example. An efficient electric motor is another example. Because of time-reversal invariance of virtually all the basic laws of physics, nonthermal processes are reversible. Dissipative mechanisms that generate heat (and entropy) are associated with a specific direction in time and thus cause irreversibility. In the limit of zero heat dissipation the lever used to produce a large force over a small displacement can be used in reverse to produce a small force over a large displacement. Likewise, the efficient electric motor can be used in reverse to generate electricity.

The lever example will serve to illustrate the properties of simple nonthermal energy converters more explicitly. The same type of analysis can be applied directly to simple mechanical systems such as ropes and pulleys, gear trains, etc., and by extension to various other devices such as motors. The relation between input and output displacement is

$$d_{\text{out}} = C d_{\text{in}} ,$$

where C is a constant determined by the geometry of the lever. Let the input and output forces be F_{in} and F_{out}, respectively. The work done by the lever is just $d_{\text{out}} F_{\text{out}}$. The relationship between input and output forces can be determined from the geometry of the lever, but it can be equally well be obtained from energy conservation ($d_{\text{out}} F_{\text{out}} = d_{\text{in}} F_{\text{in}}$):

$$F_{\text{out}} = C^{-1} F_{\text{in}} .$$

Any simple converter that has a linear relation between input and output displacements and in which energy is neither lost nor stored must have the same relation between input and output forces. The time-reversed motion of the simple converter merely involves the change in sign of the displacements, while the forces remain the same as those for forward motion. Energy is then transferred from output to input.

Friction can now be considered to see how dissipative processes affect converter performance. Frictional forces oppose the motion of the converter and therefore reduce the output force below the value $C^{-1} F_{\text{in}}$, accompanied by the irreversible generation of heat. Time-reversal invariance is now broken, as the frictional forces change sign when the direction of motion is changed, and heat is, of course, generated irrespective of the direction of operation.

2.3 Thermal Energy Converters

Thermal energy converters accept input energy Q in the form of heat at a high temperature T_2 while producing work W and rejecting the waste heat $Q-W$ at a lower temperature T_1. Since the input entropy Q/T_2 must be greater than or equal to the output entropy $(Q-W)/T_1$, it follows immediately that the maximum efficiency is given by the Carnot value:

$$\eta_C = W/Q = 1 - T_1/T_2. \tag{1}$$

Also of interest is the fact that the same considerations can also be used to describe the maximum (reversible) performance of a refrigerator (i.e., a heat pump). In this case each energy flow is time-reversed: $Q-W$ is negative and represents heat removal at the low temperature T_1, W represents input work, and Q represents heat rejected at the high temperature T_2. The technical figure of merit, called the coefficient of performance or COP, is thus given by

$$\mathrm{COP}=(Q-W)/W=T_1/(T_2-T_1),$$

where the first equality defines COP, and the second equality gives the maximal Carnot value. For further discussion of these issues, see HEAT ENGINES AND REFRIGERATORS and THERMODYNAMICS, EQUILIBRIUM.

The approach of efficiency and COP to the ideal maximum ("second-law") values in reversible machines is associated with indefinitely large heat-transfer areas and slow changes of time-dependent variables, so that the irreversible entropy increase can approach zero. However, economic considerations dictate that any conversion device must have limited size and process energy at a finite rate, so that it is clear that economic machines will not necessarily exhibit high second-law efficiencies.

2.4 Irreversible Converters and Onsager's Theorem

Various transport processes have the potential for use in energy-conversion devices due to the interaction of one process with another. An important example is the Peltier effect observed with thermocouples in which the transport of electricity causes the transport of heat. A reciprocal process is that the transport of heat in the same system causes the transport of electricity (Seebeck effect). Lord Kelvin (1854) postulated and Onsager (1931) proved that the coefficients describing these reciprocal phenomena must be equal. From Onsager's proof it is clear that the existence of reciprocity relations is quite general; they apply to systems undergoing irreversible transport that are not too far from thermal equilibrium. Suppose F_1 and F_2 are generalized forces (such as temperature or concentration gradients) that produce the fluxes J_1 and J_2 (e.g., heat and particle flow). The forces and fluxes can be chosen such that the rate of increase in entropy, per unit volume, is simply $J_1F_1+J_2F_2$. The linear relation between generalized forces and fluxes defines the kinetic coefficients L_{ij}:

$$J_1=L_{11}F_1+L_{12}F_2,$$

$$J_2=L_{21}F_1+L_{22}F_2.$$

Here, the nondiagonal elements of L describe how the processes labeled 1 and 2 interact with one another; Onsager's theorem gives the result that $L_{12}=L_{21}$. In the specific example of the Peltier and Seebeck effects at the junction of dissimilar materials, the result assumes the form

$$\pi=VT,$$

where π is the Peltier coefficient (heat flow per unit current), V is the thermoelectric power (open-circuit voltage per unit temperature difference), and T is the absolute temperature.

3. CONVENTIONAL LARGE-SCALE ELECTRIC GENERATION SYSTEMS

3.1 Sources of Electric Energy: Mainly Combustion

Large-scale commercial power plants process enormous quantities of energy. High efficiency is vital in order to reduce the large cost of the input energy. The existing technology of such plants represents the competition to be improved or supplanted by any new large-scale energy-processing techniques that are developed. Figure 1 shows the electric energy production, broken down by energy source, for the United States. The overall U.S. energy picture also includes large contributions from gas and oil for industrial, commercial, and residential heating, and oil use for transportation (not shown in the figure). Total U.S. energy use represents about 23% of world energy use of 3.2×10^{20} J/y (United Nations, 1992). As may be seen in Fig. 1, combustion of coal provides the dominant share of electricity output. Combustion of oil was important in the 1970s but declined during the 1980s. Natural gas is of importance because it is available, burns cleanly, and can be allowed to pass through combustion turbines. Nuclear power is a very important component in the energy mix, still increasing in energy output despite the present absence of orders for new plants. Hydroelectric power is the only major source that is converted directly into electricity without first being converted into heat.

With the exception of hydroelectric power, all mainstream electrical energy production is by means of heat engines. Either steam or combustion gases are expanded through turbines, and the shaft horsepower is converted to electricity. Many alternative energy-conversion schemes also use heat-engine technology, such as solar thermal conversion, geothermal energy, fusion power, etc. In the next two sections, the major components of this technology, turbines and generators, will be discussed further.

3.2 Turbines

Turbines are devices for converting the kinetic energy of a moving fluid to the mechanical energy of a rotating shaft, using nozzles and/or vanes. They replaced the reciprocating engines of the 19th century, because of decreased wear on moving parts and reduction in vibration.

Steam turbines are ubiquitous in large power systems, and can handle power up to above 1 GW, which is the full output of a large power plant. The rotation rate is generally 1800 or 3600 rpm in the United States, and 1500 or 3000 rpm in the rest of the world, synchronized to the desired 60- or 50-Hz electrical output frequency. Typical input conditions for a modest-sized (15-MW) unit (Hall *et al.*, 1987) are 755 K and 59 bar (900 °F, 850 lb in^{-2}). Temperatures above 811 K (1000 °F) are not usually used because the combination of high temperature, high pressure, and corrosive environment reduces reliability. If heat is rejected at 300 K, the corresponding Carnot efficiency is 0.60. The actual efficiency is approximately 0.29, which is the product of the ideal turbine (Rankine) cycle efficiency (0.37) and the turbine–generator efficiency (0.79). With a larger (30-MW) turbine and a higher input temperature of 811 K (1000 °F), the efficiency can be raised to 0.33.

The terminology "combined cycle" is generally used to describe the use of a gas turbine as a topping cycle, followed by a steam turbine. Topping cycles are those which utilize very high-temperature heat, which is then passed to a "bottoming" cycle. The combustion products pass directly through the turbine, which limits fuel to natural gas or clean-burning petroleum liquids. Turbine input temperatures can be rather high (1300 K), with output temperatures (800 K) suitable as input for a steam turbine. Efficiency in plant sizes of 100–600 MW is about 0.42 (Hall *et al.*, 1987), which is very high for conversion of thermal energy to electricity.

3.3 Generators

Generation of electricity from shaft rotational power is most easily (and efficiently) performed with an alternating-current generator. The simplest arrangement possible is a static magnetic field in which a loop of conducting wire is rotated. In accordance with Faraday's law, a voltage is induced in the rotating loop, proportional to the time derivative of the magnetic flux threading the wire loop. If the loop is connected to a load resistor, current will flow and energy will be

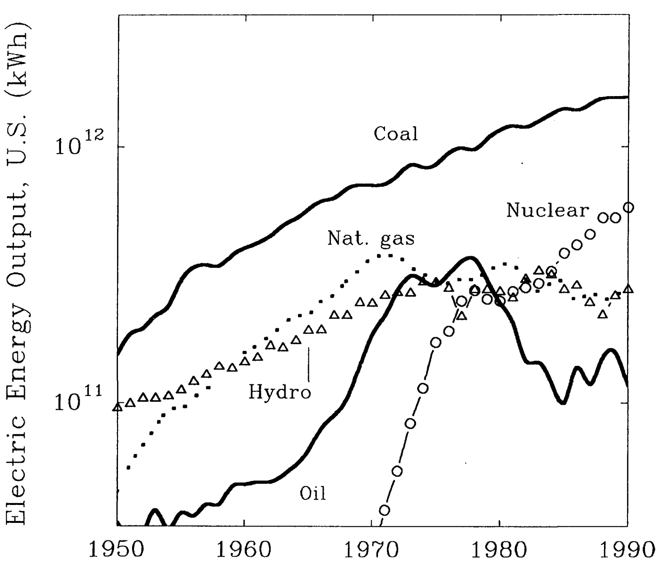

FIG. 1. Electric energy production in the United States for the period 1950–1990. Data are from the *Annual Energy Review 1990* of the U.S. Energy Information Administration (1991).

delivered to the load. If the wire resistance and bearing friction are small, such a generator has a high efficiency; it only suffers from the engineering difficulty of low output power per unit volume. The example of the wire loop can also be used to illustrate the reciprocity of simple, nonthermal, reversible energy converters. If an alternating current of suitable frequency is applied to the wire loop, it will rotate, acting as a motor. The motive force is the Lorentz force due to the magnetic field's action on the moving charges in the current-carrying wire.

For real generators (and motors), the output power per unit volume and per unit mass is nearly as important as the efficiency. For this reason, it is important to have high torque and high rate of shaft rotation. The high torque is achieved by maximizing the magnetic fields of both field and armature coils, using soft iron to enhance greatly the resulting magnetic induction. The magnetization of iron saturates at an induction of about 2 T, and so this is roughly the field that can be achieved in the gap between the iron in the armature and that of the rotor. Still higher fields are desirable and may be feasible in the future by the use of superconducting coils without iron.

Losses in a typical 10 000-kV A generator, operated at 80% power factor (8-MW output), include (Appleyard and Rosenberg, 1987) I^2R losses in the field and armature windings, losses due to magnetic hysteresis in the iron, and losses due to induced eddy currents caused by the varying magnetic field. Eddy-current losses in the iron are reduced by adding 3% silicon to increase resistivity and by the use of laminations. All of the losses can be effectively minimized, resulting in the remarkable overall generator efficiency of 0.968.

3.4 Environmental Aspects of Large-Scale Energy Conversion

The operation of large-scale energy-conversion systems has various environmental impacts. Some of these impacts are similar to any other large-scale activity such as construction of roads or buildings. More important, however, are the impacts of acquiring the energy resource and disposing of the by-products. Thus, for example, fossil-fuel plants emit oxides and sulfates that lead to acid-rain formation. These emissions must be controlled at the plant to levels that will minimize ecological damage downwind. Another problem with the combustion of carbonaceous fuels is the greenhouse warming of the earth due to CO_2 production. CO_2 hinders the earth's natural cooling process in which thermal infrared radiation is emitted into space. It is well established that the concentration of carbon dioxide in the atmosphere has been increasing substantially over the last several decades, and combustion is clearly a major source. In the future, therefore, it may be desirable to limit CO_2 production from combustion to assist in limiting global warming.

Nuclear plants have special problems related to the highly radioactive by-products that are produced. Thus it is necessary to guard against accidents that may release large amounts of radioactivity into the atmosphere, as in fact occurred at Chernobyl, U.S.S.R., in 1986 (Hohenemser, 1988). Also, some of the long-lived radioactive wastes produced by nuclear plants must be isolated from the environment for hundreds of years.

All energy-conversion systems release heat to the environment. This "thermal pollution" must be managed to avoid undue perturbation of the environment. For example, if river water is used for cooling, aquatic life is affected by the resulting temperature rise.

Certain energy-generation systems are often regarded as being particularly benign. These include hydropower, windpower, solar power, and perhaps geothermal systems. However, each system certainly does have specific environmental impacts. Perhaps the ultimate "clean" technology is energy conservation, since increases in the efficiency of energy use can actually reduce the environmental impacts of energy use.

4. ALTERNATIVE APPROACHES FOR ENERGY CONVERSION TO ELECTRICITY

Several important alternative schemes for producing electricity involve heat as an intermediate step, such as geothermal energy and solar thermal energy. These techniques will not be further discussed here, since the conversion of heat to electricity can be performed by the "conventional" techniques outlined in Sec. 3. Likewise, the use of turbines to convert the kinetic energy of a moving fluid to electricity, in hydroelectric conversion and for wind energy, will not be discussed. The reader is referred to the separate articles GEOTHERMAL ENERGY, SOLAR ENERGY, and WIND ENERGY and to the article on hydroelectric power by Wachter (1987).

4.1 Photovoltaic Conversion

Photovoltaic energy converters are heat engines in which thermal radiation from a high-temperature source is converted into electricity, using the electron-hole plasma excited in a semiconductor as the engine's working fluid. When photons with energies greater than the semiconductor's band gap are absorbed, electron-hole pairs are produced. The minority carriers thus produced (holes in *n*-type material, electrons in *p*-type material) carry most of the energy of the input photon. Each minority carrier diffuses until it falls down the built-in potential barrier at the *p-n* junction, becoming a majority carrier on the other side. In a well-designed photovoltaic cell, the short-circuit current corresponds to nearly one electron circulating in the external circuit for each absorbed photon (quantum efficiency of unity). The open-circuit voltage is comparable to the energy gap of the semiconductor (typically $\frac{1}{2}$ of this value) and increases slowly (logarithmically) with increasing input photon flux. This increase of output voltage with increasing photon flux is due to the higher thermodynamic quality of the input energy; it corresponds to higher effective radiation source temperature or, what amounts to the same thing, less entropy per unit energy in the input radiation. (The relatively smaller entropy input means that the energy efficiency is less constrained by the second law of thermodynamics. For an *ideal* photovoltaic converter, the open-circuit voltage is actually *determined* by the second law of thermodynamics.)

The "incidental" losses in photovoltaic cells, such as those due to series resistance, optical reflection, parasitic photon absorption, etc., can be reduced to levels of just a few percent, but there are two inherent losses that are particularly important. Photons with energies below the band gap cannot produce electron-hole pairs, and the corresponding energy is lost. Photons that have energies well above the band gap energy produce energetic electron-hole pairs in which the excess energy appears in the form of kinetic energy. This excess energy is thermalized by inelastic scattering with lattice vibrations (phonons) on the short time scale of roughly 10^{-13} s and becomes unavailable for conversion. The inherent losses in photovoltaic conversion clearly depend on the spectral distribution of the input radiation; a broad spectrum leads to large inherent losses, and a narrow spectrum can permit efficient operation. Thus the best conversion efficiencies may be expected in photovoltaic conversion of laser light. For example, in an experiment by D'Amato *et al.* (1992), a GaAs cell converted 826-nm (1.5-eV) radiation to electricity with an efficiency equal to 0.59.

For solar radiation input, we may regard the input spectrum as that of a blackbody with absolute temperature $T = 5800$ K:

$$b(E) = (2E^3/h^3c^2)[\exp(E/kT) - 1]^{-1}, \qquad (2)$$

where b is the radiant energy flow per unit solid angle, area, and photon energy at the surface of the sun. E is the photon energy, c is the speed of light, h is Planck's constant, and k is Boltzmann's constant. [Actually, Eq. (2) is an approximation because the solar spectrum is somewhat colder in the ultraviolet region and is modified by the earth's atmosphere; it totals about 1 kW m^{-2} at the earth's surface.] From Eq. (2), the average photon energy can be obtained:

$$\langle E \rangle = 2.701kT.$$

For $T = 5800$ K, we have $\langle E \rangle = 1.35$ eV, in the near-infrared region (920 nm). A systematic analysis of ideal photovoltaic conversion (Sze, 1981) shows that the best band gap is about 1.1 eV for highly concentrated solar radiation (efficiency, 0.37) and about 1.3 eV for unconcentrated radiation (efficiency, 0.31). Important solar-cell materials and their band gaps are Si (1.12 eV), InP (1.35 eV), GaAs (1.42 eV), CdTe (1.56 eV), and $CuInSe_2$ (1.02 eV). Materials with larger and smaller energy gaps are considered for schemes in which the solar spectrum is split into several components in order to raise efficiency.

As of this writing, the highest conversion efficiencies for silicon cells are approximately 0.27 with concentrated sunlight and 0.23 with unconcentrated light (1 sun). For GaAs cells, 0.29 has been achieved with concentrated light. Amorphous Si cells, which are less expensive to manufacture, have achieved efficiencies of 0.12. With a combined GaAs-GaSb tandem cell, in which the GaSb cell converts long-wavelength radiation passing through the GaAs cell, it appears possible to achieve efficiencies for concentrated radiation of over 0.35 (Fraas *et al.,* 1989). The total market for photovoltaic cells in 1988 was about 35 MW (Carlson, 1990), the cells being primarily for calculators and small off-grid power systems. For further information, see PHOTOVOLTAIC DEVICES.

4.2 Photoelectrochemical Conversion

The term photoelectrochemical conversion is applied to several processes in which the absorption of light causes the transport of electrical charge in an electrochemical cell. Photoelectrochemical cells (PECs) are similar to photovoltaic cells in that they utilize a semiconductor junction; however, the usual semiconductor *p-n* junction is replaced by a semiconductor-electrolyte junction. One example of a PEC is *n*-type CdSe (energy gap, 1.7 eV), in an aqueous solution of potassium ferricyanide–ferrocyanide (Licht and Peramunage, 1990). The efficiency of this device was 0.164 in sunlight. The stability of the output photocurrent was greatly enhanced (to at least hundreds of hours) by adjustment of electrolyte *p*H and cyanide concentration.

Semiconducting materials for photoelectrochemical conversion tend to exhibit corrosion, which limits cell lifetimes. Narrower band-gap materials such as Ge (0.6 eV) and even Si (1.1 eV) are particularly difficult to use; wider gap materials such as GaAs (1.4 eV) and the cadmium chalcogenides appear more promising.

An alternative approach to photoelectrochemical conversion uses dye molecules in solution to absorb the incident light, rather than a semiconductor. The excited dye molecule then injects an electron into the semiconducting electrode. In this scheme, it would appear that the function of the semiconductor is to serve as a transparent electrical conductor which, being fabricated from small particles, has a large surface area for adsorption of the active dye molecules. O'Regan and Gratzel (1991) have described a system using a charge-transfer dye (a brownish-red trimeric ruthenium complex), an iodide-triiodide redox electrolyte, and an *n*-type TiO_2 electrode composed of nanophase (10 nm) particles. The conversion efficiency was 0.079, stable over a period of 2 months.

4.3 Thermoelectric Conversion

Thermoelectric conversion is one of the oldest techniques for producing electricity. It has applications in systems in which it is important to produce electricity without moving parts. Examples include high-reliability space applications and gas-fired appliances for auxiliary electric output. One constructs a loop, called a couple, from two dissimilar materials. If one junction is heated and the other cooled, electricity flows in the loop. Useful electrical output may be obtained by cutting one side of the loop and inserting the load resistor across the gap. The open-circuit (Seebeck) voltage is given by the product of the thermoelectric power V of the couple and the input temperature difference. Two types of irreversible losses are important. First, the current circulating in the loop produces Joule I^2R heating. Also, ordinary heat conduction from the hot source to the cold sink dissipates input heat without contributing directly to the output electricity. Because of high thermal conductivities, metals exhibit low output power. On the other hand, the extraction of useful amounts of electrical power requires that the materials be electrical conductors.

In practice, narrow-band-gap semiconductors are the most useful materials. A single material can be used to form a couple if one leg is doped *p* type and the other *n* type. PbTe (energy gap, 0.32 eV) is an important material; typical dopants are Na for *p* type, PbI_2 for *n* type. Deviations in the Pb:Te ratio also affect conductivity type. Bi_2Te_3 (0.13 eV) and the alloy $(Bi_{1-x}Sb_x)_2Te_3$ are also used. The same materials are used for the reverse application, that is, to produce refrigeration (heat-pumping) effects when current is passed through the thermoelectric couple in the reverse direction. For conversion of high-temperature heat (say above 500°C, 773 K), silicon–germanium alloys are preferred (e.g., $Si_{0.8}Ge_{0.2}$), on account of good mechanical properties at elevated temperatures and somewhat larger band-gap energies (0.6–1.1 eV), which are desirable at high temperatures. Silicon and germanium have the same valence and crystal structure, but different atomic masses, a desirable situation that leads to lower (phonon-mediated) thermal conductivity than is measured for either element in pure form.

One of the most important applications for thermoelectric generators has been to provide a stable electrical power supply that lasts for years in space missions. The heat source is a radioisotope generator or a nuclear reactor. Efficiencies for operational systems working between 1073 and 344 K with outputs of a few watts are on the order of 0.08 (Dick *et al.*, 1985). Higher efficiency is difficult to obtain because of the irreversible heat conduction. However, there appears to be some promise for further improvements with advanced materials such as Ru_2Si_3 (Ohta *et al.*, 1991). For further information, see THERMOELECTRIC DEVICES.

4.4 Thermophotovoltaic Conversion

In this conversion scheme a heat source, which can be any high-temperature source such as combustion, nuclear, or solar, is used to heat a radiator into incandescence. This high-temperature radiation is transmitted to a photovoltaic cell, where it is converted to electricity. This technique is not yet used in applications, but it has thermodynamic advantages over thermoelectric conversion, due to the lack of a conduction path between the hot source and cold sink. For the best performance, the heat radiator should be a selective emitter that emits its thermal radiation only in a narrow wavelength band that is matched to the peak in the spectral conversion-efficiency curve of a suitable photovoltaic cell. It is also desirable that the temperature of the hot side be roughly matched to the band gap of the photovoltaic cell. Thus if one could use 5800-K radiation (as for solar photovoltaics), a band gap of 1–1.5 eV would be best. For 1500-K radiation, which is a more practical radiator temperature for extended material lifetimes, band gaps as low as 0.3 eV can be considered.

Summarizing and extending earlier work on thermophotovoltaic conversion, Nelson (1986) described systems with gas-fired mantles of Yb_2O_3 and Er_2O_3, which are selective emitters matched to Si and Ge photovoltaic cells, respectively. Another interesting development by Fraas *et al.* (1989) has been the GaSb photovoltaic cell (energy gap, 0.72 eV). Estimates by Morgan *et al.* (1989) of attainable conversion efficiency with the GaSb cell, without a selective emitter, are 0.14 for hot and cold temperatures of 1373 and 350 K.

4.5 Ferroelectricity, Pyroelectricity, and Piezoelectricity

Some crystalline materials of low symmetry, in the form of single crystals, have a permanent electric dipole moment. This dipole moment is due to the fact that, within each unit cell, the negative charge is displaced with respect to the positive charge. These materials are called ferroelectric. They also exhibit a temperature dependence of the electric dipole moment, a phenomenon referred to as pyroelectricity. Other crystalline materials can acquire a dipole moment proportional to an applied mechanical stress. These materials (which include the ferroelectrics) are termed piezoelectric. Examples of ferroelectric materials are KH_2PO_4, $BaTiO_3$, $LiNbO_3$, and GeTe. An example of a material that is piezoelectric but not ferroelectric is crystalline quartz. Other important piezoelectric materials are lead zirconate–lead titanate alloys, and the polymer polyvinylidene fluoride (PVF_2). See also FERROELECTRIC DEVICES.

It is possible to construct heat engines in which the pyroelectric material is the dielectric of a capacitor, which is alternately heated and cooled. For the simplest cycle, a load resistor is simply connected in parallel with the capacitor. At present, high output impedance and low efficiency remain problems. The efficiency is roughly 0.01 (12% of the Carnot efficiency in a limited temperature range), but further improvements appear possible (Olsen *et al.*, 1985). Energy densities as large as 0.9 MJ m^{-3} have been achieved using ferroelectric polymers as the dielectric (Olsen and Bruno, 1986).

Piezoelectric devices are used as transducers, such as microphones and acoustic buzzers, and for translation stages for small mechanical motions, such as those required in scanning tunneling microscopes. See PIEZOELECTRIC DEVICES. However, they have potential for electric generation as well. They convert mechanical motion (strain) to a high-voltage, low-current output. Conversion efficiencies can be high, of the order of 0.5, but output power per unit volume is small. Thus piezoelectric generators are limited to specialized applications; they certainly cannot compete with standard electrical generators fabricated with copper and iron.

4.6 Thermionic Conversion

Thermionic devices utilize input heat to eject electrons from an emitter (see THERMIONIC EMISSIONS). These electrons cross an evacuated or plasma-filled space and impinge on a collector electrode. While crossing the vacuum gap, the electrons lose some of their thermal kinetic energy and cause the buildup of electrostatic potential energy, which can be withdrawn by allowing the electrons to circulate in an external circuit.

When a vacuum is used between emitter and collector, the space charge due to the emitted electrons inhibits the emission of additional electrons. This problem can be minimized by the use of a very narrow gap (a few micrometers) or by the introduction of a plasma into a larger gap (a few hundred micrometers). The introduction of a plasma between the electrodes greatly complicates the analysis but improves the performance. Cesium vapor is often used for the plasma, a material that also coats the electrodes and facilitates electron emission by reason of its low work function. It appears that barium oxide is used as the electron emitter in the 6-kW Soviet TOPAZ system (Rasor, 1991). Sources of thermodynamic losses include collisions in the plasma, exchange of thermal radiation between emitter and collector, and heat loss from the emitter due to thermal conduction along the electrical lead.

Output power and efficiency are strongly increasing functions of the hot-side temperature. For the present technology, emitter temperatures should exceed 1600 K. Rasor (1991) quotes typical parameters for a thermionic diode converter as source temperature, 1800 K; sink temperature, about 800 K; output power, 71 W; and efficiency, 0.12.

4.7 Sodium Heat Engine (SHE)

This approach to electricity generation is also sometimes given the name alkali-metal thermoelectric converter (AMTEC). The technique uses a novel material called β''-alumina as a special solid electrolyte (fast ion conductor). It is composed of Al_2O_3 and a small percentage of sodium and potassium oxides. It is otherwise electrically insulating but permits Na^+ ions to diffuse rapidly through it.

In the SHE cycle (Weber, 1974), high-temperature (900–1300-K) liquid sodium is pressed against a β''-alumina plate with a porous metal electrode on the backside. Sodium atoms become ionized at the front surface of the plate and pass through it as Na^+ ions. This action causes an electric field to develop across the alumina plate, which is used to force the electrons to flow from the liquid sodium through the load, recombining with the sodium ions at the porous metal electrode. In order to maintain a large concentration gradient across the alumina electrolyte, the sodium is permitted to evaporate from the backside, being condensed at the heat rejection temperature of 400–800 K. After condensation, the sodium fluid is pumped back to the hot side of the device by means of a novel electromagnetic pump that has no moving parts. This pump utilizes a portion of the output electricity, passing a current through the liquid metal in the presence of a magnetic field from a permanent magnet. The Lorentz force thus created causes the small needed liquid flow.

Efficiencies as high as 0.19 have been obtained (Hunt *et al.*, 1981), working between 1073 and 473 K, and efficiencies of 0.25 are projected for 1-kW devices (McBride *et al.*, 1989).

4.8 Fuel Cells

Fuel cells are electrochemical devices in which a chemical fuel, which is usually H_2 but which may also contain CO, CH_4, etc., is oxidized to produce electric output. Thus they are similar to batteries in that they use chemical reactions to produce electricity (see ELECTROCHEMISTRY and STORAGE OF ENERGY), but they differ from batteries in that they are continuously supplied with fuel rather than relying on a finite internal supply. They are not heat engines, as all processes can take place at a uniform temperature. However, the chemical reactions taking place may cause the net evolution or absorption of heat.

The important phosphoric acid fuel cell will serve as an example. (The following information is summarized from a handbook on fuel cells by Kinoshita *et al.*, 1988). It uses concentrated phosphoric acid at about 200°C as the electrolyte. The electrolyte permits the desired mobility of ionic species between the anode (negative terminal) and the cathode (positive terminal). The operating temperature is elevated to provide adequate ionic conductivity. A Pt catalyst is used on both anode and cathode. A matrix of SiC is used to contain the electrolyte. The reaction at the anode is

$$H_2 \rightarrow 2H^+ + 2e^-,$$

and the cathode reaction is

$$\tfrac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O.$$

Thus the net effect of the chemical reactions is that the hydrogen is oxidized to water, and two electrons circulate through the external circuit for each water molecule formed. The electrical circuit is completed by the diffusion of the protons (H^+ ions) through the electrolyte.

Phosphoric acid fuel cells appear near commercialization for large-scale power generation, after decades of research to reduce cost and extend operational lifetime. Cost estimates are only a factor of about 3 above that of conventional fossil-fuel-fired power plants for 11-MW units. An efficiency of 0.41 is expected.

Other important fuel cells, identified by their electrolytes and their operating temperatures, are the polymer electrolyte (80 °C), alkaline (100 °C), molten carbonate (650 °C), and solid oxide (yttria-stabilized zirconia, 1000 °C) cells. The polymer and alkaline types have been used for power generation in space. For example, a 7-kW alkaline fuel cell with KOH electrolyte has been used in the U.S. Space Shuttle.

4.9 Magnetohydrodynamics

In magnetohydrodynamic (MHD) systems a conducting fluid is forced to flow through a duct in the presence of a transverse magnetic field (see MAGNETOHYDRODYNAMICS). An electric current flows that is orthogonal to both fluid motion and magnetic field direction, due to the Lorentz force ($q\mathbf{v}\times\mathbf{B}$, the product of charge, velocity, and magnetic field) acting on the mobile charges in the conducting fluid. The effect was first demonstrated by Michael Faraday, using mercury. Various other fluids have been used, including seawater. (The reverse MHD effect is under consideration as a technique for ship propulsion.) However, most engineering investigations have focused on ionized gases as the working fluid.

The MHD generator is seen as a potential replacement for the turbogenerator. For example, heat from combustion of fossil fuel can be used to produce very high-temperature gas, which is expanded through the MHD duct, producing dc output current. Very high temperatures are required to maintain the gas partially ionized and, hence, electrically conducting. These high temperatures lead to materials lifetime problems. The plasma can be seeded with readily ionized material such as alkali metals to increase the conductivity available at a useful input temperature. Rosa (1987) describes an example of a topping cycle that operates between 2800 and 1400 K, as an addition to a fossil plant. Efficiencies in the range of 0.5–0.6 are projected for such a plant. Another MHD application is the generation of very high electric outputs for periods of a few minutes, using a rocket engine to provide the needed input plasma.

5. EFFICIENT CONVERSION OF ELECTRICITY TO ELECTROMAGNETIC RADIATION

An important class of energy-conversion processes are those in which electricity is used to generate electromagnetic radiation. A few particularly efficient processes are briefly enumerated here, ordered from low to high frequency.

5.1 Radio-Frequency and Microwave Radiation

Radio-frequency and microwave radiation is produced by connecting a source of alternating current to an antenna. Antenna efficiencies are high, and so the conversion of dc or low-frequency electrical power to high-frequency power is the key to efficient production of radiation. Modern semiconductor electronics generally makes it possible to convert electrical energy freely and efficiently from one frequency to another (see POWER ELECTRONICS). For example, even to convert from one dc voltage to another, it is convenient to use ac electrical power as an intermediate step. Such switching converters may use MOSFETs (metal oxide semiconductor field-effect transistors) to chop the input voltage at 100 kHz, an inductor to transform the voltage, and a filter to smooth the output voltage. Efficiencies above 0.9 are readily achievable. For high-power switching (thousands of amperes, thousands of volts), thyristors are available. These *p-n-p-n* devices can switch in a few microseconds. MOS transistors can switch efficiently at higher frequencies (to a few hundred megahertz), but there comes a point at which for high-power applications, vacuum tubes such as magnetrons and klystrons become more efficient than solid-state devices. This crossover is due, at least in part, to the fact that high-speed semiconductor devices are generally small, which conflicts with the need to dissipate heat at elevated power levels. Milnes (1980) gives an example of an *n*-channel Si MOSFET that can produce 16 W of power at 700 MHz with an efficiency of 0.26. Another example is work by Popovic *et al.* (1991), who used an array of GaAs FETs to produce 21 W of continuous power at 5 GHz with an efficiency of 0.2.

Magnetrons are microwave-frequency vacuum tubes that utilize the cyclotron motion of electrons in the field of a permanent magnet to convert dc electrical power to microwave frequencies. Electrons emitted from the negative cathode are subjected to a magnetic field orthogonal to their motion, which causes them to move in helical orbits. This motion is used to couple electromagnetic energy into a resonant microwave cavity. Pulsed magnetrons are used in radar applications as sources of high peak power (see RADAR TECHNOLOGY). Fixed-frequency magnetrons are used for heating applications in the familiar microwave oven and for various industrial processes. Farney (1982) cites an example of 25-kW output at 915 MHz, with an efficiency above 0.7. Weaver (1989) cites similar values for the maximum available continuous power available from commercial tubes at 1 GHz, declining to about 300 W at 30 GHz.

5.2 Infrared Radiation

In the infrared portion of the electromagnetic spectrum, thermal sources, such as blackbody cavities, become useful. The spectrum of radiation is given by Eq. (2). The efficiency of thermal emission can be high (unity), but there is a general difficulty in limiting this broad-band emission to a desired specific wavelength range.

One notable source of infrared radiation is the CO_2 laser (see LASERS, GAS). Among gas lasers, its efficiency is unusually high; high output powers are available as well. The radiative transition involves changes in the vibrational (and rotational) modes of the CO_2 molecule, unlike the electronic transitions used at shorter wavelengths. The most efficient transition is at 9.6 μm wavelength (31 THz), where the energy efficiency approaches 0.27 (Verdeyen, 1981). Hundreds of kilowatts of continuous output have been produced by large devices. And, as is the case with many lasers, *very* high instantaneous power outputs ($>10^{12}$ W) are achievable in very short pulses.

Another remarkable class of high-efficiency infrared laser is the semiconductor diode laser (see LASERS, SEMICONDUCTOR). Considerable progress has been made to extend operation into the visible portion of the spectrum, but high-efficiency devices operate primarily in the near-infrared region (near 1 μm). The mid-infrared region (near 10 μm) is also accessible but requires cryogenic operating conditions. Diode lasers are most often fabricated from the semiconductor GaAs, alloyed with AlAs for shorter wavelengths (larger band gap) or with InAs for longer wavelengths. Reported electrical-to-optical energy-conversion efficiencies now exceed 0.50 (Endriz *et al.*, 1992: 60 W output, 200-μs pulses, 50 Hz, 25 °C). These remarkable efficiencies indicate that each of the steps involved in producing light from a GaAs laser is highly efficient: low parasitic losses in getting the electrical energy in (series resistance), efficient production of minority carriers by *p-n* junction injection, efficient recombination of minority carriers with majority carriers to produce infrared light, and efficient coupling of the infrared energy out of the device aperture.

One important application of semiconductor laser diodes is for pumping of solid-state lasers. In one recent solid-state laser-pumping experiment a GaAs laser-diode bar emitted continuous 10-W output of 810-nm light through a 10-mm by 1-μm aperture (Shannon and Wallace, 1991). This light was used to pump a solid-state Nd:YAG laser (yttrium aluminum garnet crystal doped with Nd), which emits at the slightly longer wavelength of 1.06 μm. The output of the Nd:YAG laser was 1.9 W (optical-to-optical efficiency, 0.19).

5.3 Visible Light Emission

Visible electromagnetic radiation (i.e., light) is particularly important because it corresponds with the human visual range. The sensitivity of the human eye ranges from 400 to 700 nm, and peaks at 555 nm in the green. The use of light for illumination consumes roughly 25% of electricity production, and so the efficiency of lighting is economically very important. The quantity of visual light is measured in lumens (lm), a unit devised to account for the variation of the eye's sensitivity with wavelength. By definition, the *luminous efficacy* of light of 555 nm wavelength is 683 lm/W.

The simplest lighting device is the incandescent bulb. The tungsten filament is heated electrically to about 3000 K. Higher temperatures are not permitted by filament lifetime considerations. The spectral emission peaks in the near-infrared region and thus the efficiency for visible light emission is low. The luminous efficacy is roughly 15–20 lm/W and depends on filament temperature.

Fortunately, gas-discharge lamps have been designed that have much higher efficacy. The ubiquitous conventional fluorescent lamp, together with the ballast used to stabilize the discharge current, has a luminous efficacy of roughly 100 lm/W (Dakin, 1991). It employs an Ar and Hg plasma discharge in which the electron temperature rises well above that of the ions to about 11 000 K. Typical concentrations of species in the plasma are (Dakin, 1991), in units of cm^{-3}, Ar, 10^{17}; Hg, 2×10^{14}; free electrons, 2×10^{11}. The mercury in the plasma produces 254-nm radiation in the ultraviolet part of the spectrum. This radiant energy is absorbed by a phosphor coating on the inside of the glass tube that encloses the plasma, causing fluorescence in the visible spectrum. Different phosphors are used to achieve the color rendering desired in a particular lamp. The function of the Ar buffer gas is to prevent diffusion of the energetic electrons to the cool glass enclosure.

Low-pressure sodium lamps contain mixtures of Na and Ne and operate in a regime similar to fluorescent lamps (Dakin, 1991). The partial pressure of Na is about 1 Pa (10^{-5} atm). In this case the dominant emission is from the sodium transitions at 589 nm, in the yellow portion of the visible spectrum. There is no need for a fluorescent phosphor with its attendant losses, and so the luminous efficacy is very high, nearly 200 lm/W. However, the nearly monochromatic emission has the consequence that color perception of illuminated scenes is not possible.

One other important class of lamps is called "high-intensity discharge" lamps. These utilize high-temperature, high-pressure (near 10^5 Pa) electrical discharges in which the ions, atoms, and electrons are nearly in thermal equilibrium at temperatures of 4000–6000 K (Waymouth, 1991). At these temperatures the peak of the blackbody spectrum is in the visible range, which aids in the avoidance of copious infrared emission. Constituents for the plasma are chosen for strong optical emission in the visible part of the spectrum and include Hg, various metal halides, and sodium, usually in combination. The spectral content of the light varies with elemental composition of the plasma; efficacies range up to 100 lm/W.

INTRODUCTION

The physical basis of sound and the properties of sound waves in solids, liquids, and gases are set forth elsewhere in this Encyclopedia (see ACOUSTICS, LINEAR; ACOUSTICS, NONLINEAR; ACOUSTIC PROPERTIES OF LIQUIDS; SOLIDS, ACOUSTIC PROPERTIES OF; ATMOSPHERIC ACOUSTICS; ACOUSTICAL INSTRUMENTATION). Included there are the theory of and mathematical physics for propagation and the methods and instruments for measurement.

This article describes the areas in the physical sciences and engineering to which acoustical methods have been applied. In the physical sciences these include measurements of elastic constants, piezoelectric and piezomagnetic constants, electric permittivity and magnetic permeability constants, and internal friction for solids. In liquids and gases, acoustical methods measure bulk modulus of elasticity, internal relaxation and friction, and surface tension. Areas in engineering include the control of the sounds of music and speech in rooms and auditoria (see ACOUSTICS, ARCHITECTURAL), the control of excessive noise in the environment (see NOISE, ACOUSTICAL), the detection of flaws in engineering materials, and the monitoring of progress toward collapse when such materials are periodically stressed. Military applications have included the location of enemy artillery by acoustical ranging. In underseas warfare, the location and tracking of enemy submarines are accomplished by means of sonar techniques. The locations of surface vessels and submarines under way are also determined by means of detecting the ship noise radiated and propagated through the water (see ACOUSTICS, UNDERWATER).

The audiometer is an electroacoustical instrument used by otologists and by audiologists (see ACOUSTICS, PHYSIOLOGICAL). It measures the amount of hearing loss experienced by persons with hearing varying from normal to moderately impaired to profoundly deaf. The instrument has been developed in parallel with prosthetic electroacoustical devices; e.g.,

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

hearing aids, which amplify speech, music, and incidental sounds of the environment for the benefit of persons with impaired hearing. Other bioacoustical applications are mainly for diagnosis, by means of ultrasound, of such human ailments as tumors, kidney stones, and cardiovascular irregularities, and for treatment of gallstones and kidney stones by lithotripsy (see BIOLOGICAL EFFECTS OF SOUND AND ULTRASOUND).

The application of acoustical methods in modern applied physics and technology is legion. This article includes a relatively small number of such methods. However, they have been applied also to other areas of acoustics: physiology and psychology of speech and hearing; music and musical instruments (*q.v.*); the acoustics of buildings; and the control of noise in the environment. Most of the latter applications have been to the development of acoustic instruments and to standard methods for measuring sound in the atmosphere.

In closing this introduction we note that the first theoretical research into the effect of a moving atmosphere on the propagation of sound waves was carried out by W. Voigt in the latter part of the 19th century. A few years later H. A. Lorentz applied this acoustical (theoretical) analysis to electromagnetic waves, and thereby arrived at what is called today the "Lorentz transformation." The work of Lord Rayleigh (1894), who some say covered everything one would ever want to know about acoustics, is worthy of note here.

1. TRANSDUCERS AND ELECTROACOUSTICS

Virtually all applications require at some stage the controlled production of vibration and/or radiation of sound waves. This is most often achieved by applying energy as electrical wave forms to an electroacoustical transducer. The article ACOUSTICAL INSTRUMENTATION has a general description of the various transducers used in acoustics.

Conversely, measurement of vibrations and radiated sound waves is done in the great majority of cases by means of calibrated transducers—microphones, hydrophones, seismometers, accelerometers, etc. The study of transducers has given rise to the science of electroacoustics, whose main objectives are the study of the conversion of wave forms of electrical energy into vibration and sound waves and, conversely, the study of the conversion of wave forms of sound energy into electrical wave forms in electronic circuits. Analysis of the electrical signal output of transducers, by means of sophisticated computerized electronic circuits, is included in the science of electroacoustics.

This is not to say, however, that the radiation of sound into various media is engineered in all cases by means of electroacoustic transducers. Powerful explosive sources, which may be called chemoacoustic transducers, are still used to study the propagation of sound to large distances in the atmosphere, in the ocean, and into the earth. The parameters of such sources are not normally as well controlled as in electroacoustics.

Most transducers are reversible; the physical mechanism that allows a transducer to receive sound as a microphone may also permit it to send sound as a loudspeaker. In water, the corresponding transducers are called a hydrophone and a projector. Furthermore, many reversible transducers have the same generalized transfer impedance for the two directions of energy flow, and these are called reciprocal transducers. When a transducer is known to be reciprocal, one can calculate its performance in transmitting from measurements in receiving, and vice versa. Similarly, one may test a reversible transducer to determine if it is reciprocal. A familiar analogous example in electrical engineering is the electric motor. It is an electromechanical transducer that converts electric currents into mechanical forces. When it is used reversibly as an electric generator (dynamo), it converts mechanical forces into electric currents.

Electrical phenomena are accompanied by two physically distinct fields—the electric (electrostatic) fields of electric charges and the magnetic fields of moving charges. Reversible acoustic transducers fall into two classes—one in which the physical action depends entirely on electric fields, the other in which it depends on magnetic fields.

The moving-coil loudspeaker is a generally useful transducer for radiation of sound into the atmosphere (Rice and Kellogg, 1925). The transducer is reversible, and it can be designed as a microphone. The basic form is a helical coil of conducting wire elastically restrained to move in its axial direction. The coil is in a fixed radial magnetic field, on which the entire transducer action depends. See Fig. 1.

Piezoelectric (solid) materials are useful for sound radiation into solids and liquids (Cady, 1964; Mason, 1950; Mason, 1981; National Defense Research Committee, 1946c; see also PIEZOELECTRIC DEVICES). The action is electrostatic, and the transducers are reversible. The action is due to electric dipoles distributed throughout the solid material. The dipole moment changes under applied mechanical stress. Quartz and tourmaline are naturally occurring piezoelectric crystalline minerals. Small single crystals can be used as seeds for artificially growing larger single crystals. Synthetic piezoelectrics can be produced by application of electrostatic fields to several types of plastic or polymer materials and ceramic materials. Such materials are called ferroelectric, and some of them are called electrets when polarized. Polyvinylidene fluoride (PVDF) is an example of a polymer material (Sessler, 1981), while barium titanate and lead zirconate–titanate are examples of the ceramics (Berlincourt, 1981, 1992).

Piezomagnetic (solid, basically magnetostrictive) materials may be considered to be analogous to the piezoelectric materials, except that the action is electromagnetic (National Defense Research Committee, 1946d; see also MAGNETOSTRICTIVE AND MAGNETOMECHANICAL DEVICES). There are no known purely piezomagnetic minerals, even single crystals (Cady, 1964). However, synthetic piezomagnetics can be produced by the application of electromagnetic fields to several types of magnetostrictive metals and metal-oxide ceramics. Such materials are ferromagnetic, and their initial discovery clearly preceded anything ferroelectric. Nickel and the cobalt–iron alloy 2-V Permendur are examples of the metals that found considerable application in the past, while rare-earth–iron alloys such as Terfenol D, a terbium–dysprosium–iron ternary alloy (Clark, 1988), have become important because of their extremely large strain response (a few parts per thousand) to magnetic field excitation.

FIG. 1. Construction of a moving-coil loudspeaker.

An important transducer for making accurate measurements on sound waves in air is the condenser microphone (Wente, 1917; Cook, 1941; Hilliard, 1950). The basic action is electrostatic. A detailed description of the microphone is given in Sec. 1.1. In the article TRANSDUCERS several other types of transducers are described. See also ACOUSTICAL INSTRUMENTATION.

1.1 Condenser Microphones (Capacitive Transducers)

We consider here in detail only the condenser microphone (Fig. 2). It is particularly important for making accurate measurements of sound waves in air. Conversely, as a result of its reciprocal action, it can be used to produce accurately known sound waves when a known voltage is applied to its electrical terminals. Some technical aspects of the condenser microphone are described in the article ACOUSTICAL INSTRUMENTATION.

The condenser microphone consists basically of a flexible diaphragm placed very close to a rigid metallic back plate, the two forming the plates of an electrical condenser. It responds to the *sound pressure* associated with the molecular motions in a sound wave in air, as does the ear of man. It is used with a nonfluctuating polarizing voltage, large in comparison with the smaller voltages produced by the acoustical action. The response of the microphone is the fundamental quantity required for its use as an accurate acoustical measuring instrument: at any particular fre-

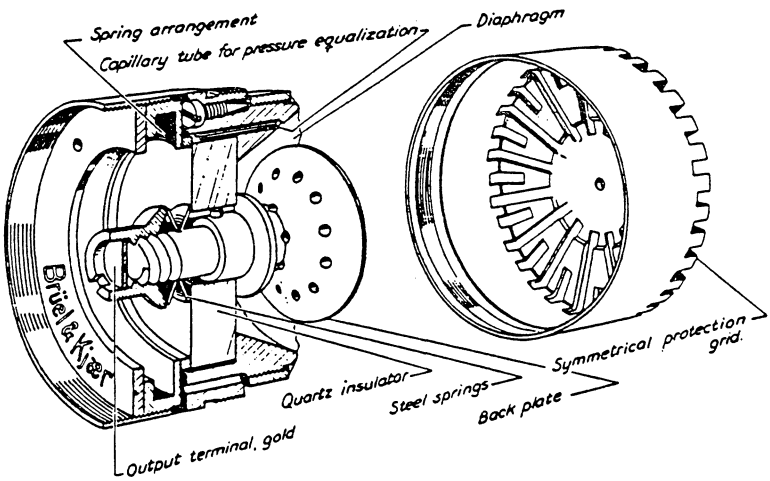

FIG. 2. Exploded view of conventional condenser microphone.

quency of sinusoidal oscillation, it is the complex-number ratio of the microphone's sinusoidal electrical output to the (sinusoidal) pressure acting on the diaphragm.

Practical requirements on standard condenser microphones are freedom from nonlinear distortion, uniformity of response of both amplitude and phase as functions of frequency, stability of response (including freedom from hysteresis) with temperature and humidity changes, and physical size small enough to minimize the amount of scattered sound power.

The condenser microphone appears to meet these requirements more satisfactorily than any other type of microphone. A knowledge of its construction is not sufficient to yield with requisite accuracy an absolute value of its response, which is best determined by means of the reciprocity method. Nevertheless, simple lumped parameters, which describe very well the microphone's response and electrical admittance as a function of frequency, can be determined empirically from the reciprocity calibration.

1.2 Calibration and Reciprocity

It is often important to have an accurate measure of the response, or output, of an acoustical instrument to a known stimulus or input. For convenience, let us assume that the acoustical instrument of interest is the condenser microphone, discussed above. The voltage or current response to a sound pressure or sound particle-velocity stimulus, determined quantitatively, represents a calibration of the instrument (Cook, 1940; Beranek, 1988; Bobber, 1970; National Defense Research Committee, 1946a, 1946b). Although there are many details to be concerned with, such as whether the input is a pure-tone sinusoid, a transient impulse, or a band-limited random noise, and whether the instrument is operating in a free field or in a different specified environment, we shall consider here only the simple case of pure tones in a free field. The general symbol for response of a transducer in a sound field (ANSI/ASME, 1984) is M_{yx}, where y is related to the output and x to the input. Thus the open-circuit voltage response to pressure in a sound field would employ the quantity symbol M_{Up}, and have the unit, based on the International System (SI), of volt per pascal, for which the unit symbol is V/Pa.

If one has a microphone with a known receiving sensitivity as a function of frequency, its output as a function of frequency may first be measured in a sound field created by a loudspeaker. Then another microphone, for which a calibration is desired, may be substituted for the reference microphone and the loudspeaker driven by the same electrical signal as a function of frequency. By comparing the outputs of the two microphones, one may deduce the receiving sensitivity of the second microphone. This procedure is called a secondary calibration, since it is dependent on knowledge of the calibration of a standard reference instrument. Most engineering and almost all manufacturing procedures employ this approach to perform necessary tasks speedily and at low cost.

When it is necessary to calibrate a primary standard, without any previous assumed knowledge of its response, there is a more detailed procedure available called a reciprocity calibration. To perform a reciprocity calibration it is necessary to have three transducers, one of which is a loudspeaker, one a microphone, and the third a reversible and reciprocal unit capable of serving as a loudspeaker and as a microphone. The concept of reciprocity (Rayleigh, 1894) was developed by several investigators, including Cook (1940 and 1941), and the basic mathematics can be found in Beranek (1988). The magnitude of the absolute receiving response of the reversible transducer in a free field is given by

$$|M_{Up}| = \{[E^{m}_{\mathrm{oc}}/i][e_{\mathrm{oc}}/e^{m}_{\mathrm{oc}}][2d\lambda/\rho c]\}^{1/2}, \quad (1)$$

where the first ratio in brackets is the open-circuit voltage at the microphone when the reversible transducer is driven with a constant current, the second ratio is the open-circuit voltage of the reversible transducer divided by the open-circuit voltage of the microphone when each is driven by the loudspeaker under identical conditions, and the third ratio is the magnitude of the reciprocity factor, $|J|$, for a small transducer:

$$|J| = 2d\lambda/\rho c. \quad (2)$$

In Eq. (2), d is the spacing between the loudspeaker and the reversible transducer (operating as a microphone) or the microphone, and also the spacing between the reversible transducer (operating as a loudspeaker) and the microphone; λ is the wavelength of the sound wave; ρ is the density of the medium, in this case air; and c is the speed of sound.

The calibration of the microphone, $|M^{m}_{Up}|$, is simply

$$|M^{m}_{Up}| = |M_{Up}|(e^{m}_{\mathrm{oc}}/e_{\mathrm{oc}}). \quad (3)$$

By the principle of reciprocity, the transmitting current response, $|M_{pI}|$, of the reversible transducer is given by

$$|M_{pI}| = |M_{Up}|/|J|. \quad (4)$$

The same technique is applicable with hydrophones and projectors in water and also in other liquids and gases.

2. MEASUREMENT OF PHYSICAL PROPERTIES

Acoustical phenomena and the propagation of sound are studied by measuring physical quantities in the medium of sound propagation (Beranek, 1986; Pierce, 1989). Measured quantities are the sound pressure at a point, the particle velocity, the optical density, deflection at a surface or interface, and many others. The passage of a sound wave is manifest as a continuous time series of limited duration. The wave form of the time series represents the variation in amplitude of the acoustical quantity. Problems such as losses by dispersion (scattering of a wave by turbulence or temperature gradients, for example) are treated in Sec. 2.1. The basic function of a receiving transducer (microphone, hydrophone, or seismometer) is to produce an electrical quantity with a wave form that is a copy of the wave form of its corresponding acoustical quantity. In gases and liquids the acoustical quantity usually observed by a receiving transducer (microphone, hydrophone) is the fluctuating sound pressure at a point within the medium. For solids the quantity observed may be the fluctuating particle velocity (vibration) at a point on the surface; seismic vibrations in the earth are measured in terms of surface motion by means of geophones and seismometers placed on its surface.

The electrical wave form of the transducer is received by an electrical network that performs the entire task of signal processing and display/readout. In many automated or computerized operations the display/readout is replaced by a feedback circuit to control the desired operation. For purposes of circuit analysis the transducer is represented in the network by an electroacoustical equivalent circuit (Mason, 1950) and the establishment of analogies between acoustical and electrical quantities (see Fig. 3). Some typical wave forms are continuous sinusoidal with harmonic overtones, sharp pulses separated by times long in comparison with the pulse width

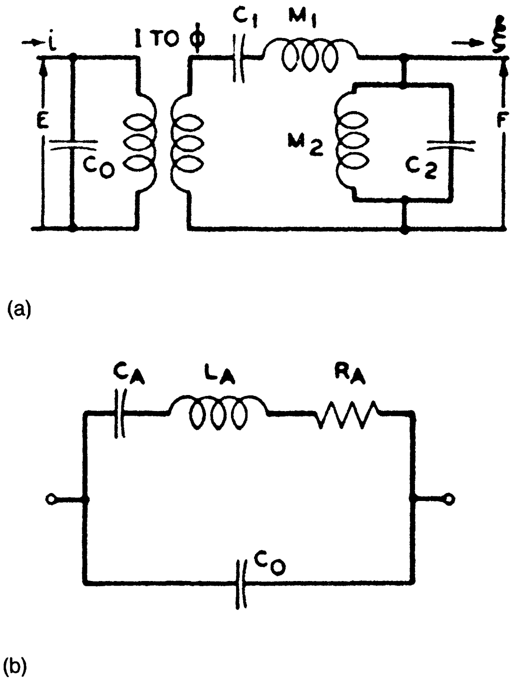

FIG. 3. Equivalent electromechanical and electrical circuits for a piezoelectric crystal (Mason, 1950).

(sometimes called low duty cycle), filtered random noise, amplitude- and/or frequency-modulated wave forms, etc. Important functions of the network are amplification, phase shifting or time delaying of sinusoids, calculation of the mean square amplitude over various time intervals, measurement of elapsed time between two pulses, and correlation of the wave form of the received pulse with a known or estimated replica of the transmitted pulse.

Some acoustical investigations and applications require measurement with two or more microphones. Then additional useful network functions are, for instance, multiplication of two voltages and averaging over a time interval (cross-correlation coefficient); and multiplication of two voltages, the Fourier components of one being phase-shifted by $\pi/2$ radians relative to the other (calculation of intensity in a sound field).

2.1 Sound in Solids, Liquids, and Gases

The passage of sound waves through a material is basically the transit of elastic waves obeying Hooke's law. In solids, liquids, and gases, the waves are composed of very small oscillations of pressure (stress), displacement (density), and temperature. The oscillations of audible sound waves in the atmosphere are typically of the order of 10^{-3} to 10^{-6} times the amounts of the ambient pressure, density, and temperature that enter into the atmosphere's equation of state.

In liquids and solids, surface waves also can be generated. Acoustical methods applied to such phenomena yield measurements of additional physical quantities. For example, the surface tension of liquids is readily measurable by means of surface waves. In piezoelectric crystals, ceramics, and polymers and in piezomagnetic metals and ceramics, electroacoustical methods of measurement are normally chosen to yield accurate values of piezoelectric and piezomagnetic moduli, respectively, which are very difficult to obtain by means of static mechanical and electrical stimuli.

We can see from the following considerations the advantages of using an acoustical method to determine the elastic constants and moduli of metals used commonly in engineering and physics. Many years ago the determination required the use of large static loads on large specimens in order to measure accurately enough the very small deflections produced by the application of the load. The development of electroacoustics has made it possible to measure the velocity of sound in solids. The phase velocity of sound waves (produced by suitable transmitting transducers) is measured by receiving transducers which pick up the sound. The measurements yield results on relatively small samples, of considerably greater accuracy than those obtainable from static measurements of the elastic moduli.

Simple measurements of sound velocity are also possible in crystalline materials, plastics, liquids, and gases. Where the sound velocity is independent of the direction of the sound waves in the material, as in gases and in most liquids, it is commonly called sound speed. The basic methods of measurement are very similar in all media. A sound wave is described by small oscillations of the medium, sinusoidal in time, and satisfying a linearized differential equation for propagation through the bulk volume of the medium. The sound can be idealized as plane waves having longitudinal oscillations, parallel to the direction of propagation. The physical quantity that is readily measurable (in liquids and gases) is the sound pressure, p, whose representation is

$$p=p_0e^{-\alpha x}e^{j(\omega t-\omega x/c)}=p_0e^{j(\omega t-kx)}, \tag{5}$$

where $k=\omega/c-j\alpha$ is the propagation constant. The wave is not dispersive. The phase velocity c is independent of the generalized frequency ω. The attenuation of the pressure amplitude takes place exponentially with distance along the propagation path and is denoted by α.

The differential propagation equations for isotropic homogeneous media show that

$$c^2=\gamma Y/\rho, \tag{6}$$

where γ is the ratio of the specific heat of the material at constant ambient pressure to the specific heat at constant volume; Y is the isothermal modulus of elasticity for the propagation mode; ρ is the density of the material. The acoustical measurements on longitudinal waves at practically all frequencies, in any solid or liquid material, yield adiabatic moduli of elasticity, γY. The basic physical mechanism is an oscillatory increase of temperature, as can be seen from the equation of state, when a material is compressed by passage of a sound wave and its density is increased.

If shear waves are the mode of propagation, then there is no density variation, hence no temperature variation, and so γ is replaced by 1. The acoustical measurement yields directly the shear modulus of elasticity.

The phase velocity in gases is in fact a function of frequency, as well as of temperature and ambient pressure as indicated above. In a monatomic gas (helium, argon, etc) sound propagation is essentially a transport-of-momentum process. There is variation of the sound speed—dispersion—and increasing absorption of sound energy at high frequencies. These latter effects arise from the internal viscosity and thermal conductivity of the gas and are collectively called classical phenomena. Thus at low frequencies the gaseous propagation takes place adiabatically, and at very high frequencies the oscillations occur almost isothermally.

In a polyatomic gas a principal mechanism during the passage of a sound wave is the time τ required for the internal rotational and vibrational degrees of freedom of the individual molecules to acquire energy from intermolecular collisions. At oscillation periods greater than τ, the sound speed is less than that at short oscillation periods (less than τ), This variation in sound speed is called "intrinsic dispersion." The entire phenomenon is usually called a "relaxation" effect. In the neighborhood of a relaxation frequency the sound absorption is increased to an amount two or three orders of magnitude greater than the absorption due to viscosity and thermal conduction. For carbon dioxide at 20 °C and at 1.0 atm pressure, the relaxation frequency is at 20 kHz; see Fig. 4. The time τ is determined from the acoustical relaxation frequency.

The attenuation factor α is, in liquids, due mainly to viscous losses arising from shearing motions in longitudinal waves. The propagation equations then show that α is directly proportional to ω^2. Therefore c and α/ω^2 characterize a liquid at any given temperature and pressure.

In most liquids, however, there is an additional attenuation. In natural waters this arises from the presence of dissolved salts, principally $MgSO_4$ in sea water. The excess absorption is due to relaxation mechanisms. The product $\alpha\lambda$ has maxima at various acoustical frequencies dependent upon the relaxation times of the transient chemical effects accompanying the transit of a sound wave. Acoustical measurements of absorption can therefore yield the relaxation times of the molecular interactions taking place in the liquid with

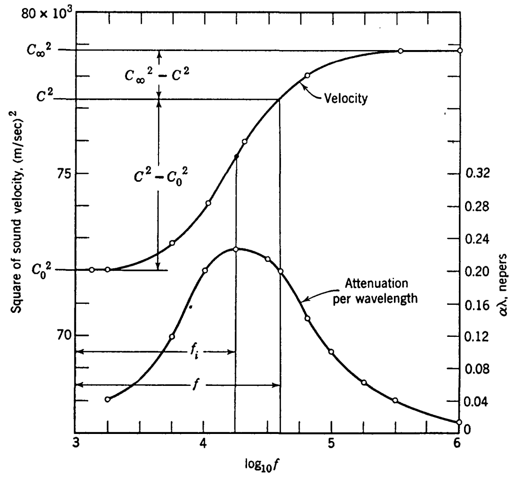

FIG. 4. Velocity dispersion and concomitant absorption in carbon dioxide (R. W. Leonard in Hueter and Bolt, 1955).

dissolved salts. In other liquids, the cause of the absorption may be a molecular-structure rearrangement and relaxation.

In solids the attenuation mechanisms are not yet all known. A conspicuous possible mechanism in polycrystalline materials is the scattering of sound energy (out of the main wave) by grains of the material. Acoustical measurements of α then yield in effect the cross-sectional area (for scattering of sound) by the polycrystalline grains.

2.1.1 Sound Speed in Natural Waters. The local speed of sound, c, must be known in detail for various maritime and military operations in many natural waters. In the ocean the variation of c with depth is particularly important. The gravity force gives rise to a stratified structure in which the variation of c with vertical depth is much greater than that in horizontal directions. Laboratory measurements over many years have resulted in an empirical formula that yields c as a function of the temperature T, depth d, and salinity S. These three quantities can be conveniently measured at sea, and the empirical formula for c (Wilson, 1960a, 1960b, 1962) that is simplified here,

$$c=1449.3+4.572T-0.0445T^2+0.0165d$$
$$+1.398(S-35), \qquad (7)$$

will then yield an "indirect" value for it. The ranges in which the above formula is applicable are $T=-3$ to $+30$ °C, $d=0$ to 10 000 m, and $S=33$ to 37 parts per thousand.

Measurements made in the ocean show that c has a minimum value at depths of about 1000 m in equatorial and temperature latitudes. The minima give rise to acoustical "SOFAR" (SOund Fixing And Ranging) channels in the oceans, centered at about 1000 m depth, in which sound is propagated in horizontal directions to large distances with only small loss. There are also sound channels that can develop at or near the surface as a consequence of seasonal changes in temperature.

The need for "direct" measurements of the variations of c with depth has led to the development of a velocimeter (Greenspan and Tschiegg, 1963). This instrument uses an electric "sing-around" principle. A short pulse is radiated by a piezoelectric crystal source; it travels a few centimeters through the water to a crystal hydrophone and is immediately reshaped as a fresh pulse by the electroacoustical circuitry. The repetition frequency of the pulse transit is a function only of the sound speed c. A calibration of the instrument is necessary; the velocimeter is immersed in water in a tank in which both T and d (or the hydrostatic pressure) can be varied. The upshot is that either by the direct velocimeter, or by the indirect empirical formula, sound speed c can be measured in natural water with an uncertainty no greater than ±0.02%.

2.2 Piezoelectric Constants

Piezoelectric crystals have unusually convenient physical properties. The crystal itself can be used as a transducer. A dynamical determination by acoustical methods can be made of piezoelectric, elastic, and dielectric constants. After the discovery of the piezoelectric effect in crystalline quartz by the Curie brothers, Jacques and Pierre (Curie and Curie, 1880), they made early measurements of the effect in several other crystals by static methods that they reported in their initial paper. The basic physical action in a piezoelectric crystal is the production of electric charges on the external surfaces of the crystal, when internal stresses are applied; transient mechanical loads were applied by the Curies, and the electric charges produced were measured by ballistic galvanometers and electrometers. The following year they reported the discovery of the inverse effect (Curie and Curie, 1881): electrostatic fields applied to a piezoelectric material generate stresses and/or strains. As indicated in the article TRANSDUCERS, the action is electrostatic and reversible.

The first applications of piezoelectricity were to an electrometer with increased sensitivity (c. 1896) and to an ultrasonic quartz–steel sandwich transducer (now called a *Tonpilz,* which means "sound mushroom") for use in detecting German submarines during World War I (c. 1915).

Beginning about 1920, electric circuits were used to create sinusoidal (in time) mechanical forces and motions in crystals at audio (i.e., sonic) frequencies. The electric charges and currents produced as a result of the piezoelectric effect were measured at the same audio frequencies by means of electronic circuits. Measurements on piezoelectric resonators were made particularly at and near the acoustical natural frequencies of vibration.

Such measurements were rapidly extended through ultrasonic frequencies and into the radio-frequency range. The frequency of oscillation of electric circuits may be accurately controlled and stabilized by the "high-Q" (small internal friction losses compared to stored piezoelectric energy) acoustical oscillations of crystals such as quartz (Cady, 1922; Nicolson, 1917). They are also the basis for narrowband filters designed for electronic circuits. The piezoelectric effect serves as the coupling between acoustical oscillations of the crystal and the electronic circuitry.

The basic constitutive equations for piezoelectricity (ANSI/IEEE, 1987) are given in tensor notation as

$$T_{ij}=c^{E}_{ijkl}S_{kl}-e_{kij}E_k\,, \tag{8}$$

$$D_i=e_{ikl}S_{kl}+\epsilon^{S}_{ik}E_k\,, \tag{9}$$

and in compressed matrix notation as

$$T_p=c^{E}_{pq}S_q-e_{kp}E_k\,, \tag{10}$$

$$D_i=e_{iq}S_q+\epsilon^{S}_{ik}E_k\,, \tag{11}$$

where $S_{ij}=S_p$ when $i=j$, $p=1, 2, 3$, and $2S_{ij}=S_p$ when $i\neq j$, $p=4, 5, 6$, and the summation convention for all repeated indices is understood. Other forms of the constitutive equation pairs, with the subscripts omitted, may be written as

$$S=s^{E}T+d_tE, \quad D=dT+\epsilon^{T}E, \tag{12}$$

$$S=s^{D}T+g_tD, \quad E=-gT+\beta^{T}D, \tag{13}$$

$$T=c^{D}S-h_tD, \quad E=-hS+\beta^{S}D. \tag{14}$$

In the above equations, T is the stress in pascals, S is the strain and is dimensionless, D is the electric displacement in coulombs per square meter, and E is the electric field in volts per meter; c is the elastic stiffness in pascals, s is the elastic compliance in reciprocal pascals, ϵ is the permittivity in farads per meter, and β is the impermittivity in meters per farad; the piezoelectric constants are d in meters per volt (= coulombs per newton), e in coulombs per square meter [= newtons per (meter volt)], g in meter volts per newton (= square meters per coulomb), and h in volts per meter (= newtons per coulomb). The subscript t indicates a transposed matrix and the superscripts denote variables that are held constant in the determination of the associated parameter.

Piezoelectric crystals are now used extensively throughout the communications industries: as transducers, as frequency-control elements, and as filters in electronic circuits. Ferroelectric ceramics and polymers have taken over some of these applications in recent years—for example, transducers for underwater sound applications (sonar), accelerometers, and microphones.

2.2.1 α- and β-Quartz and Tourmaline. The following summary describes application of an acoustical method to determine the piezoelectric constants of quartz as a function of temperature.

α-quartz is the stable crystalline form at temperatures below 573 °C. It has symmetry designated 32 in the international notation and D_3 in the Schoenflies notation. When heated above 573 °C, the crystal structure changes suddenly to symmetry 622 and D_6, respectively. This form, stable above 573 °C, is called β-quartz.

α-quartz has two nonzero piezoelectric constants (tensor components), d_{11} and d_{14}. d_{11} is the electric polarization per unit normal stress on a plane perpendicular to the electric axis. d_{14} is the electric polarization per unit shearing stress on a plane perpendicular to the optic axis. For more precise definitions of piezoelectric constants see ANSI/IEEE (1987), and for a summary of the measurements of the d constants for α-quartz see Cady (1964).

For β-quartz, its crystal symmetry requires that $d_{11}=0$. However, d_{14} is not zero. Up to the time in 1950 when the acoustical method being described here was applied, no quantitive measurements of d_{14} for α-quartz at high temperatures nor for β-quartz at temperatures above 573 °C had been reported in the technical literature.

Another technique of measurement was a determination of the equivalent electroacoustical circuits (Fig. 3) (Van Dyke, 1928) of long, relatively thin bars (Fig. 5) driven electrically. The voltages and currents were sinusoidal at frequencies near resonance for the fundamental longitudinal modes of the bars. The equivalent circuits were determined from measurements using an electrical Q meter (Figs. 6 and 7). The only other physical quantities needed were the physical dimensions and orientation angles of the bars and the density of quartz. The resonance frequencies of the bars were in the range from 35 to 60 kHz. The piezoelectric constants for α-quartz are given in Fig. 8. Since quartz belongs to one of the 11 crystal classes (point groups) having no center of inversion or plane of symmetry, two different types of the same species may exist. Each type is the mirror image of the other; neither type can be made to look exactly like the other by a simple rotation. If one type appears right-handed with right-handed rectangular axes, the other will appear left-handed. The left-handed type is regarded as the crystallographic inversion of the right-handed type, rather than its mirror image.

Polar crystals, such as tourmaline, have a polar axis along which an electric polarization develops when the crystal is subjected to hydrostatic pressure. This can also be produced by a sound pressure at audio frequencies. Tourmaline is in the trigonal–ditrigonal polar class, which is No. 19 of the 32 crystal classes and has the symmetry $3m$ or C_{3v}. A determination of the piezoelectric d constant under hydrostatic pressure d_h, where

$$d_h = 2d_{31} + d_{33}, \tag{15}$$

was made on a black California tourmaline crystal. The hydrostatic pressure was applied by means of sound pressures at several frequencies. The source of sound was a condenser microphone operating as a loudspeaker to produce an accurately known sound pressure. The charge on the crystal produced by the sound pressure was measured electronically. The result for the measurement of d_h was 2.23×10^{-12} C/N. The crystal motions took place adiabatically. The accompanying thermal oscillations could produce pyroelectric charges in polar tourmaline. However, it appears that such charges would have a negligible effect on the piezoelectric measurement, and the above result is the same as that which would be obtained statically. Applying measurements of d_{31} and d_{33} measured by Voigt (1910) (also given in Mason, 1950) in Eq. (15) agrees with the above value of d_h within 10%.

2.2.2 Polarized Ferroelectrics, Barium Titanate, Lead Zirconate–Titanate, and Polymers. Ferroelectric crystals and polycrystalline materials are analogous to ferromagnetic materials in that they have polarization-field and strain-field curves in the form of hysteresis loops. The principal prop-

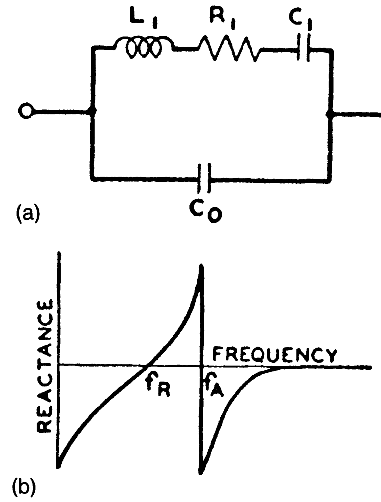

FIG. 7. Equivalent electrical circuit of a piezoelectric crystal and a plot of its reactance vs frequency (Mason, 1950).

erties of these materials tend to vary considerably with temperature. The earliest known ferroelectric crystal is Rochelle salt ($NaKC_4H_4O_6 \cdot 4H_2O$), which is ferroelectric in the temperature range from −18 to +24 °C (the two Curie temperatures). While all piezoelectric crystals, in addition to the first-order (linear) piezoelectric effect, also have a second-order electrostrictive effect in which a strain occurs proportional to the square of the applied electric displacement, it is small except in ferroelectric materials. About 1942 it was discovered that barium titanate, which occurs as a polycrystalline ceramic as well as a single crystal, is ferroelectric at temperatures up to 120 °C, its Curie temperature (Fig. 9). Mason (1950) made the excellent prediction: "The amount of motion generated in barium titanate ceramic is larger than that in magnetostrictive materials, and it appears that barium titanate may be an important electromechan-

ical transducing element." That did, in fact, prove to be true for several years until the discovery in the 1960s that ternary ceramic alloys, the lead zirconate–titanates, generated even larger strains (Berlincourt, 1981). Small amounts of additive substances are employed to modify the properties of ceramics by vendors, who often give their specific formulations trade names. All of the ceramic materials are normally polarized by applying a high electric field, usually at a temperature near the Curie temperature, and allowing the ceramic pieces to cool slowly to room temperature before removing the applied field. After the removal of the field, a ceramic piece is left in a remanent state of polarization and it is effectively piezoelectric with a linear strain-to-field ratio as long as the applied field is not excessive. For practical engineering application, it is not common to apply a dc polarizing voltage or to drive an element beyond its linear range.

Piezoelectrically polarized polymer materials, such as polyvinylidene fluoride (PVDF or PVF_2) discovered by Kawai (1969), are very flexible and may be polarized either electrically or by mechanically stretching in a direction normal to the polarization direction, or both (Sessler, 1981). When polarized electrically only, the two normal directions are effectively identical and $d_{31}=d_{32}$. However, when all or part of the poling is the result of mechanical stretching, these constants are unequal (Wilson, 1985). Since much greater polarization can be obtained by the latter method with a resultant much higher output voltage to applied mechanical strain capability, it is usually the polarization method of choice. For some applications this can lead to undesirable nonuniformity in response in the two primary directions normal to the polarization, that is, the stretch direction and the direction normal to it. By mounting a pair of polymer elements with their stretch directions orthogonal, Ricketts (1992) has shown that at least the two lowest modes of a plate may be neutralized to provide an effectively uniform response that is useful to increase receiving frequency capability.

Among recent developments are flexible ceramic materials, in which nonactive flexible materials are combined into composite ceramics for purposes such as to increase the hydrostatic piezoelectric constant by decreasing d_{31} and, sometimes, increasing d_{33}. Piezoelectric rubber compounds with conductive rubber electrodes are examples of commercially available flexible ceramic materials.

2.3 Piezomagnetic Constants

The discovery of the phenomenon of magnetostriction is attributed to James Prescott Joule in 1842, but it was not until 1865 that the inverse effect was discovered by Villary. Magnetostrictive materials are analogous to the ferroelectric electrostrictive materials discussed above. Because the earlier known materials were all ferromagnetic metals, they were generally more rugged than the piezoelectric crystals. As better fabrication techniques were developed, the advantage of ruggedness has all but disappeared. By polarizing such materials to make them effectively linear, one obtains the analog of the polarized piezoelectric materials; these are called piezomagnetic (Cady, 1964). They differ in that nonmagnetic phenomena were characterized by only 32 crystallographic classes, whereas magnetic phenomena are characterized by 90 crystallographic classes (Birss, 1964). The additional 58 crystal classes represent conditions for which changes in directions of magnetic moments are a significant symmetry feature. Many of these additional classes may be simulated with piezoelectrics when moving charges are involved; however, that is beyond the scope of this article.

For most practical applications of piezomagnetic materials, the dimensional considerations are much simplified, sometimes involving only one dimension when the direction of polarization and the principal direction of mechanical strain are identical. Shortly following the publication of the first IEEE standard on piezoelectricity in 1949, the latest revision being ANSI/IEEE Standard 176 (ANSI/IEEE, 1987), it became apparent that one could more easily compare transducers employing the analogous mechanisms of piezoelectricity and piezomagnetism if the same mathematical formulation is used (Ehrlich, 1952). The result was the first IEEE standard on piezomagnetism in 1971, the latest revision being IEEE Standard 319 (IEEE, 1990).

The basic forms of the constitutive equations for piezomagnetism follow the same format as Eqs. (12)–(14):

$$S=s^{H}T+d_{t}H, \quad B=dT+\mu^{T}H, \tag{16}$$

$$T=c^{H}S-e_{t}H, \quad B=eS+\mu^{S}H, \tag{17}$$

$$S=s^{B}T+g_{t}B, \quad H=-gT+\nu^{T}B, \tag{18}$$

$$T=c^{B}S-h_{t}B, \quad H=-hS+\nu^{S}B, \tag{19}$$

where Eq. (16) is the analog of Eq. (12), Eq. (17) that of the simplified Eqs. (10) and (11), Eq. (18) that of Eq. (13), and Eq. (19) that of Eq. (14). The magnetic variables, the magnetic field strength H in amperes per meter and the magnetic flux density B in teslas, are treated as the analogs of the respective electric variables E and D; the magnetic constants are the permeability μ in henrys per meter and the reluctivity ν in meters per henry; and the piezomagnetic constants are d in webers per newton (=meters per ampere), e in teslas [=newtons per (ampere meter)], g in reciprocal teslas (=ampere meters per newton), and h in newtons per weber (=amperes per meter). Where necessary, a superscript m should be used above the piezomagnetic constants to distinguish them from their piezoelectric analogs.

Applications of piezomagnetic materials have included underwater transducers, oil-well logging, drills, soldering tools, and situations where heat conduction away from a relatively closed volume is of major concern. Because eddy-current losses in magnetostrictive metals, which are much better electrical conductors than most piezoelectrics, tend to increase with the square of the frequency, it is usually necessary to use relatively thin laminated materials, similar to those in electromagnetic transformers. Although many designs for use at frequencies up to 100 kHz have been produced, the modern trend is to apply magnetostrictive materials to transducers at low sonic frequencies.

2.3.1 Nickel, 2-V Permendur, and the Rare-Earth–Iron Alloys. Of the three ferromagnetic elements iron, cobalt, and nickel, the more favorable magnetic and piezomagnetic properties of nickel made it the material of choice in the early 1940s. Permanent magnets were most often used with soft annealed transducers to provide the magnetic flux-density bias necessary for linear operation (National Defense Research Committee, 1946d). Development of iron–cobalt alloys was at first found to result in excessively brittle materials; then, by adding small amounts of materials such as vanadium and chromium to the alloy composition, the brittleness problem was effectively overcome. One such alloy that found wide use in the 1940s and early 1950s was 2-V Permendur, an Allegheny Ludlum Co. trade name for an alloy of 49% iron, 49% cobalt, and 2% vanadium. Advantages of 2-V Permendur over nickel included its greater piezomagnetic strain capability and its high remanent polarization after magnetization, which avoided the need for biasing magnets (National Defense Research Committee, 1946d). Then, on the development of the ferroelectric ceramics noted above with their much higher strain capability than then-known magnetostrictive materials, they became preferred for most applications.

In 1963 measurements at low temperatures of the magnetostrictive strain capabilities of terbium and dysprosium of approximately 1% leapfrogged the capabilities of the ceramics. This has generated renewed interest in the piezomagnetic properties of all the rare-earth–iron compounds, which is tempered by the costs of the rare-earth materials and the fabrication of the alloys. A terbium–dysprosium–iron ternary alloy developed at the Naval Surface Weapons Center in White Oak, MD (formerly the Naval Ordnance Laboratory) and called Terfenol-D has been receiving the greatest attention recently (Clark, 1988). It appears to have reasonably favorable mechanical, magnetic, and piezomagnetic properties in combination.

2.4 Surface Tension, Surface Waves in Liquids, and Surface Acoustic Waves in Solids

The free surface of a liquid can support waves, in addition to the elastic waves within the bulk volume discussed above. The surface waves—ripples—are supported by both gravity and surface tension. The nominal speed of sound (elastic waves) in pure water is 1400 m/s. Ripple speed is substantially less and so is independent of the bulk modulus of elasticity of water. In the analysis for ripple motions the water may be regarded as an incompressible fluid. The differential equation for ripple propagation shows that the square of the wave speed c is given by

$$c^2 = g\lambda/2\pi + 2\pi T/\rho\lambda \qquad (20)$$

for sinusoidal waves on the surface of a liquid of depth much greater than the wavelength λ. Here the acceleration of gravity is $g=9.8$ m/s^2; the surface tension T has units of N/m; and the density of pure water is $\rho = 10^3$ kg/m^3.

The speed c varies with the wavelength λ. For a water surface there is a minimum in c near $\lambda = 1.7$ cm, and c is about 23 cm/s. For longer wavelengths c is determined mainly by the acceleration of gravity g, and the waves are deep-water gravity waves. For shorter waves c is determined mainly by the surface tension T, and the waves are surface-tension ripples.

Gravity waves on a liquid surface offer an acoustical method for measurement of g. Apparently no data on such measurement have ever been published. Lord Rayleigh, in 1890, measured T by means of ripples, in spite of the unavailability then of convenient modern-day transducers. The ripple method assures that T is determined free of any assumption respecting angles of contact between water and a solid, as in a capillary tube measurement of T. The acoustical ripple method admits "of application to surfaces purified to the utmost from grease." Some of his results are given in Table I.

Surface acoustic waves in solids were described as early as 1885 by Rayleigh to explain the propagation of seismic disturbances from earthquakes. More recently, the applications to piezoelectric materials of surface acoustic waves (SAW) has resulted in new devices, such as an "interdigital transducer" (Fig. 10), which may be operated as a filter (Apfel, 1974). Apfel, in turn, refers to three earlier review articles on SAW applications in microwave ultrasonics (Kino and Shaw, 1972; deKlerk, 1972; White, 1970). In addition, the reader is referred to Campbell (1990) and the article RESONATORS AND FILTERS, ACOUSTIC.

2.5 Interior of the Earth

Acoustical studies of the interior of the Earth may be directed toward the geological structure of the Earth based on detecting naturally occurring phenomena, or toward the detection, mapping, and exploitation of oil fields based on seismic signals returned following transmitted sound pulses (White, 1965).

The global structure of the solid Earth is spherically layered (see EARTH, INTERIOR STRUCTURE OF). Earthquakes serve as sources of elastic waves in the earth. Both longitudinal and shear elastic waves are radiated from earthquake sources. In addition, Rayleigh (elastic) waves on the Earth's surface, as well as tsunami (gravity) waves on the surfaces of the oceans, are generated by earthquakes. The

Table 1. Surface tension T of water (from Rayleigh, 1894).

Surface condition	T (N/m)
Clean	0.074

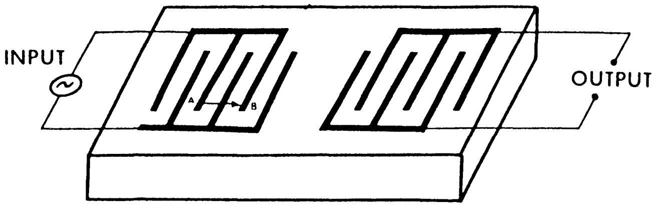

FIG. 10. A schematic of a simple surface acoustic wave (SAW) "interdigital" transducer (Apfel, 1974).

basic theory and mathematical physics for elastic waves on and in the Earth are essentially acoustical. The waves are detected and measured by seismometers that are perforce placed on the surface at various locations around the world. The seismometer transducers measure vibratory displacements at infrasonic (very low) frequencies, usually less than 1.0 Hz. The times of incidence and durations of the several wave types are also measured. These data are basic for a determination of the internal structure of the Earth.

Additional basic data are the observed frequencies and amplitudes of oscillation of the normal modes of oscillation of the whole Earth following a great earthquake. These may be likened to the reverberation of sound in an empty room after a sharp transient sound. The greatest observed period of oscillation may be of the order of an hour or so.

Acoustical methods of analysis are then applied to the basic data on elastic waves transmitted through the interior of the Earth, combined with laboratory data on the speed of longitudinal and shear waves in geological rock. By these means a spherically shaped surface of discontinuity has been found at the boundary between the Earth's mantle and the outer core. This is at a depth below the surface of 2900 ± 10 km. This accuracy comes about from waves originating at earthquakes deep in the mantle.

Both longitudinal and shear waves of sound travel through the mantle. However, only longitudinal waves pass through the outer core beneath the mantle–core boundary. This can mean either that the outer core of the Earth is liquid or that shear waves in it are rapidly attenuated. The acoustical analysis leads also to an estimated distribution of temperature and density as a function of depth below the surface and therefore to an estimate of the hydrostatic pressure at various depths.

Explorations for oil and minerals beneath the surface of the Earth are conducted within the mantle. At the operating depths from the surface (zero depth) up to several kilometers, transmitted acoustic signals may be longitudinal or shear waves. The shear waves may be polarized, analogous to optical waves, and the polarization directions are commonly divided into horizontal shear (SH) and vertical shear (VH) components. When an oil field is discovered and producing wells are operating, the monitoring of a well is called oil-well logging. Bore holes are drilled in the vicinity of the well and transmitting and receiving transducers, an example of which is shown in Fig. 11, may be lowered into the bore holes in a pattern designed for efficient data gathering and signal processing (Leslie and Randall, 1992).

3. HEARING AND PHYSIOLOGY

In the practice of medicine, physicians are called upon to treat difficulties and defects in hearing. A common defect is loss of the ability to hear well such everyday sounds (Stevens and Davis, 1983) as the speech of other persons, music, traffic, etc. Until about fifty years ago, ear-nose-throat (ENT) physicians had used tuning forks, producing sounds at various sinusoidal frequencies, to assess the ability of a patient to hear.

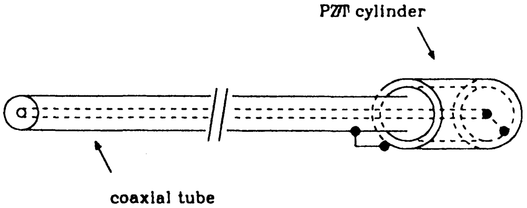

FIG. 11. Seismic micromonopole transducer construction details. PZT is a trade name for a lead zirconate–titanate piezoelectric ceramic material (Leslie and Randall, 1992.)

During the 1930s audiometers were invented, developed, and manufactured to produce sound at various audible frequencies. The audiometer is now used in physicians' offices to measure quantitatively the hearing level (minimum audible sound pressure) of a person under diagnosis. They are used as well in routine general physical examinations. The instrument is basically electroacoustical; voltages at various sinusoidal frequencies in the range 64–8000 Hz and of adjustable amplitude are generated electronically and applied to an earphone. The latter is held against the patient's ear, with guidance by the audiologist. The voltage is then adjusted until the earphone sound is just barely audible to the patient (Fig. 12).

The acoustical (physical) action is production of sound pressure in the ear canal, which vibrates the tympanic membrane. The latter, in turn, vibrates the bones of the middle ear, which finally causes waves on the basilar membrane of the inner ear (cochlea) sensed by the nerves there (von Békésy, 1935; Stevens and Davis, 1983; see also ACOUSTICS, PHYSIOLOGICAL).

The audiometer earphone is essentially the same (electroacoustically) as the receiver of a telephone. However, it is used as a measurement transducer, and so the engineering requirements on its temporal stability of response, freedom from harmonic distortion, etc., are more stringent than they are for telephones. The important point is that the use of the audiometer yields a relatively accurate physical measure of a person's ability to hear.

Vibrations of the skull can be transmitted to the cochlea and are then also perceived as sound. Multielectrode cochlear implants are among the more recent types of hearing prostheses, and new methods are being developed for testing them (McDermott *et al.*, 1992). The transmission is thought to take place directly to the cochlea encapsulated in the temporal bone of the skull and is referred to as "bone conduction" of sound. Audiometers have a "bone vibrator," which like the earphone is a measurement transducer. The vibrator can be applied to the frontal bone of the skull. Sinusoidal vibrations are produced at the same frequencies as those of the sound pressures produced by the earphone, and the threshold of hearing by bone-conduction vibrations is measured. From a comparison of air-conduction and bone-conduction measurements, the otologist can make an improved diagnosis of impaired hearing.

Other physiological acoustics tests can now be employed by internal-medicine physicians in such procedures as the diagnosis of tumors (Romijn *et al.*, 1991), *in utero* examination of a fetus, and measurement of blood flow (Embree and O'Brien, 1990). Sonar methods are used, in which ultrasound is introduced at the skin surface by means of a piezoelectric transducer. Variations in density and elasticity of the internal tissues scatter the ultrasound, which is reflected back to the same transducer. Extensive computer-aided tomography (CAT) signal processing techniques (Muller *et al.*, 1979; Devaney, 1985) are applied to the received sound, which is finally displayed

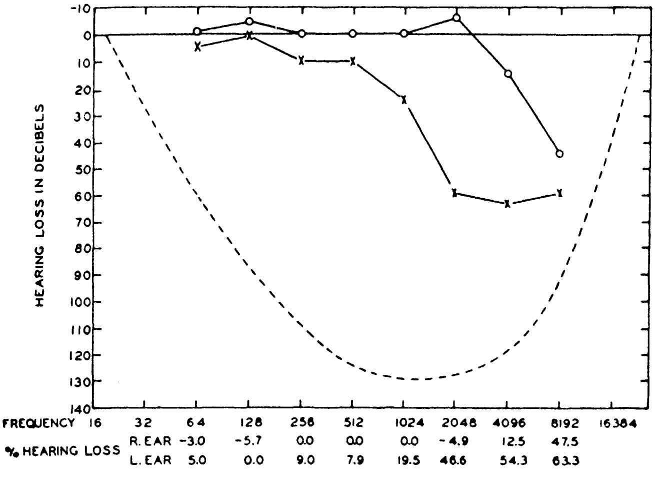

FIG. 12. An audiogram for a person suffering from high-tone loss of hearing. The circles are for the left ear, the crosses for the right. The zero ordinate represents normal hearing; the dotted curve represents 100% loss of hearing (Stevens and Davis, 1983).

continuously as a two-dimensional visual image, or sonogram, as in a motion picture. Synthetic receive aperture (SRA) imaging is an important technique applicable to the study of tissues in that it offers a significant reduction in the number of transducer elements required (Nock and Trahey, 1992). The advantages of ultrasonic tomography are that it is nonintrusive medically and that it causes no structural atomic–molecular changes of body tissue. Further discussion of sonar methods for other applications is set forth in Sec. 5.

4. TELEPHONY

The earliest development of electroacoustical transducers was in the telephone industry, in the 1870s (Bell, 1876; Martin, 1951; Hunt, 1982). The sounds of speech were transduced into electrical signals by "transmitters" (microphones). Then after transmission over wire lines the electrical signals were transduced into sound waves in air, at the listener's ear, by "receivers" (quadratic earphones). Modern telephone transmitters are usually electret capacitive microphones (Sessler and West, 1962), and receivers are modified loudspeakers. Until recently, the receiver has been basically a small piston, driven electromagnetically, which produces sound in the enclosed volume of air formed by the receiver and the ear to which it is applied. Newer receivers are more likely to be electret capacitive loudspeakers, primarily because they can be produced at lower cost. The electromagnetic receivers had the advantage of being compatible with electromagnetic pickup devices in hearing aids before conversion to sound in the hearing aid. With the newer electret receivers it is necessary to employ a sound-to-electromagnetic converter between the telephone receiver and a hearing aid, and these devices are manufactured to meet this newer requirement.

The action of a telephone system has, however, very little to do with the physics of sound in the atmosphere. The principal dependence of the telephone industry has been on applications of psychoacoustics to the intelligibility of speech sounds in the presence of possible electric-circuit noise and of excessive distortion in the wave form of the voice signal.

Also, the industry applies extensively the principles of electroacoustics. The audio-frequency bandwidth of the entire system, from transmitter through the electrical circuits to the sound radiated into the ear of the listener, is limited to the range for acceptable speech intelligibility. The voice currents may travel over wire lines thousands of miles long, over land and under water, having numerous "repeaters" (amplifiers of the voice currents) serving also as electrical filters. The voice currents may be "multiplexed" by using each current to modulate its own ultrasonic carrier frequency, well separated from all the other carriers. Then a coaxial conductor can have hundreds of conversations on the line simultaneously, with no noticeable interference between individual voice currents.

Some or all of the transmission may be by means of modulated radio waves. This may involve reflection by or retransmission by satellites as well as the direct transmission between radiating and receiving antennas. The latter have become especially popular in the development of cellular telephones and "cordless" telephones, making it convenient to move about in a house, to telephone from automobiles and other moving vehicles, and for emergency communication such as is often necessary following earthquakes, hurricanes, etc.

The development of long optical fibers with low transmission loss is a newer alternative for the transmission of multiplexed telephone signals. They have the advantage of much greater bandwidth capability for a given diameter, permitting greater signal-handling capacity. Furthermore, optical fibers are much less sensitive to electromagnetic interference and produce much lower output levels of electromagnetic radiation. The development of optoacoustic and acousto-optic transducers for direct conversion of acoustic signals from and to optical signals has been a natural consequence (Tsai, 1992). See OPTICAL COMMUNICATION.

Among the by-products of telephone voice signal transmission, an important one is digital data transmission. This may be done either by assignment of separate telephone channels or by piggybacking on existing channels in the frequency band below 300 Hz. Telephone lines are readily adapted to facsimile (FAX) transmission of documents and to electronic mail (e-mail), for example.

Telephone transducers are not used as measuring instruments. Nonetheless, they are measured acoustically during manufacture to ensure that they meet specification requirements. Such test measurements are made with condenser microphones calibrated to yield, from the voltage output, the amount of sound pressure that produces the voltage. Receivers are placed on an artificial ear that has a condenser microphone to measure the amount of sound produced by the receiver when test audio-frequency voltages are applied to it. Similarly, a transmitter has test audio-frequency sound pressures, measured by a condenser microphone, applied to the transmitter's membrane diaphragm. Its voltage output is then measured with electronic circuitry. In brief, telephone transducers are not required to have precisely controlled responses. Their phases and amplitudes, for signals sinusoidal in time, may vary from transducer to transducer over small ranges.

5. SONAR METHODS

Sonar is a word coined by F. V. Hunt as the acoustical analog of radar. Where radar was devised as an acronym for "radio detection and ranging," an attempt to find suitable words to make sonar also an acronym resulted in "sound navigation and ranging." The classical uses of sonar are detection, classification, tracking (and localization), navigation, communication, and countermeasures (see Horton, 1957; Urick, 1983; Bartram *et al.*, 1982).

Table 2. Military operational uses of sonar (underwater transducer applications in naval sonar).

Missions	Platforms
Area (volume) search	Submarines
Detect, classify, and track	Surface ships
Hold, harass, and/or attack	Fixed-wing aircraft with sonobuoys
Ballistic missile submarine defense	Rotary-wing aircraft
Detect and evade	Torpedoes
Counterattack	Mines
Convoy defense	Fixed-position systems

Sonar methods are those in which steady-state, transient, and pulsed sound waves, including their reflections and scattered secondary waves, are applied to determine internal physical features of materials and gases. Some typical applications are

1. the determination of the locations of internal flaws and the gross structural features of materials used in engineering, particularly during industrial processing;
2. in the natural waters of the seas and oceans, the depth of the waters beneath a ship under way and the locations of icebergs (historically, the latter was the earlier application, following the sinking of the Titanic in 1912);
3. detection and location of underwater objects and vehicles such as submarines (Tables 2 and 3), and the location for commercial fishing and environmental studies of schools of fish and crustacea;
4. for geophysical prospecting in the earth, the determination of subsurface structures, such as salt domes having petroleum and natural gas, and for oil-well logging;
5. in the laboratory, convenient measurement of sound speed and attenuation in liquids by means of pulsed ultrasound, and also for the measurement of elastic and transducer properties of solids by resonance techniques, including vector and tensor quantities;
6. in natural waters, the direct measurement

of local sound speed *in situ* by means of velocimeters, which record continuously in a sing-around electronic circuit the travel time of an ultrasonic pulse between two piezoelectric transducers;

7. in the human body, examination of internal structures by ultrasound introduced at the skin surface, with the scattered sound being received and displayed continuously in a visual image.

The applications employ a fairly wide variety of transducers, depending on factors such as spatial-resolution requirements, size limitations, attenuation in the transmitting medium as a function of frequency, ease of access to the object of interest, and the normal engineering cost problems. For many of the applications ultrasonic frequencies are used. The transducers are usually either polarized piezoelectric ceramics, such as one of the lead zirconate–titanate compositions, or piezoelectric crystals, such as quartz. One transducer serves as a source for an ultrasonic pulse of sound and another to receive the reflected waves from the object insonified; an alternative is for the same transducer to perform both functions with electronic switching to convert between the source and the receiver configurations. The electronic methods for the generation and detection of pulsed ultrasound are similar to those used with electromagnetic waves in radar systems. For most modern long-range sonar system applications, sonic frequencies are used to take advantage of the lower sound attenuation in seawater at lower frequencies. The transducers tend to be larger and the piezoelectric materials get some competition from polarized piezomagnetic, or magnetostrictive, materials as the transducing mechanism of choice. Flextensional transducers (Royster, 1970; Rolt, 1990; Decarpigny *et al.* 1991; Boucher, 1992; Ring, 1992) that use longitudinal active elements to drive shells in bending modes are often employed to limit transducer size (Fig. 13); also, arrays of large numbers of elements of longitudinal transducers are commonly used (Fig. 14). In geophysical prospecting for minerals and oil in the near-surface layers of the earth, the frequencies used tend toward the very low sonic and infrasonic. The transducers used tend to be impulsive, such as

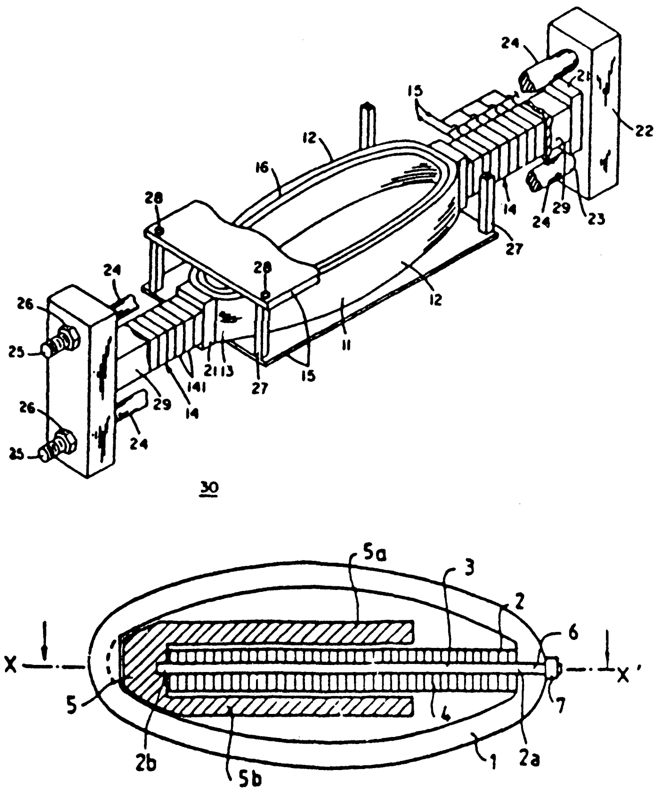

FIG. 13. Two recent flextensional transducer patents (Royster, 1970; Rolt, 1990; Decarpigny *et al.*, 1991; Boucher, 1992; Ring, 1992).

produced by hydraulic mechanisms or by explosives, to produce elastic waves. Detection of the waves generated and the waves scattered from underground structures often employ geophone transducers at the surface of the earth in the vicinity. Where the location of an oil well is known, the process of oil-well logging employs higher frequencies than those used in prospecting, permitting the use of more conventional or smaller transducers, especially where the use of explosives is not tolerable. Natural phenomena, such as earthquakes, are detected by seismographs, often at frequencies below 1 Hz; that is, the number of seconds, or even hours, for each cycle is measured.

6. SONICS

Sonics is the application of acoustical technology to industrial measurement, testing, analysis, and processing of materials (see Beranek, 1988; Hueter and Bolt, 1955). Many standards for sonics equipment have been developed under the auspices of the International Standards Organization (ISO), the International Electrotechnical Commission (IEC), a variety of national agencies, such as the American National Standards Institute (ANSI), and scientific and engineering societies, such as the Acoustical Society of America (ASA) and the Institute of Electrical and Electronics Engineers (IEEE); some of the specific standards are cited in Beranek (1988).

Aerosols of fine particles in the atmosphere are agglomerated by intense sound waves. In liquids used for cleaning small manufactured parts, intense sound causes cavitation, which accelerates the cleaning process. Sonic cavitation also accelerates chemical reactions, homogenization of liquid mixtures, and dispersion of solids into liquids. Internal flaws in the materials of engineering are detected by irradiation with ultrasound (sound waves at ultrasonic frequencies). The continuous monitoring of the dimensions of manufactured objects is accomplished. An example is thickness measurement and detection of defect laminations in strip steel as the strip leaves the rolling mill. Controlled intense sound is used to drill very hard materials; one example is the use of a conventional piezoelectric transducer with an inverted horn (Fig. 15) to produce a large amplitude over a small area (Tierce and Decarpigny, 1988). In other applications, large shaker transducers are at-

tached to conventional drilling equipment to speed up the drilling process by orders of magnitude. Only two of the many applications of sonics noted above are discussed further in this section.

6.1 Flaw Detection

Acoustical methods for detection of flaws in manufactured articles, particularly those made of metal that are required to carry large loads and stresses, are extensively used in the manufacturing industry. The methods are referred to as nondestructive evaluation, often abbreviated to as NDE, or NDT, where the T stands for testing (Firestone, 1945). A commonly used technique is the generation of ultrasonic pulses and measurement of the sound scattered by flaws. The basic concept is virtually the same as the sonar concept for some of the underwater applications of acoustics; see Sec. 5. Typical articles to be tested for internal flaws are metallic load-bearing plates, axles in rotating machinery, laminated strips and plates, the walls of tanks and pipelines subjected to substantial internal hydrostatic pressures, etc.

We describe here a hypothetical system for flaw detection (Fig. 16). The piezoelectric crystal transducer radiates longitudinal (or shear or surface, depending on the angle of

the wedge) waves of ultrasound into the relatively long cylindrical steel pipe (Hueter and Bolt, 1955). Sound is scattered by the flaw, a thin disklike cavity in the metal, and there is sound reflected from the end of the pipe. The same crystal transducer serves as a microphone for detection and measurement of scattered and reflected ultrasound. The results of the electronic processing of the microphone signal are displayed on an oscilloscope-video screen.

The electroacoustic source for this hypothetical system produces (a) a sinusoidal wave at 1.0 MHz, which is the resonance frequency of the piezoelectric crystal source; (b) a pulsed output 5 periods ($=5$ μs) long; (c) a time delay (between successive pulses) long enough to allow the crystal source to be used in the interim as a microphone and to allow the ultrasound in the metal to die away to zero; (d) a display, sequential in time, of the signals received by the microphone.

When the process of flaw detection is difficult because of the presence of interfering and random echoes, called "clutter," one method of overcoming the problem is the application of constant false-alarm rate signal processing (Saniie and Nagle, 1992). A system block diagram is shown in Fig. 17 and the signal-processing schematic in Fig. 18.

6.2 Thickness Metrology

The measurement of the thickness of metal parts is often required during a manufacturing process. The needs are (a) for rapid and accurate measurement of nominally identical parts coming off an assembly line; (b) for measurement with access limited to only one side of the part; and (c) for measurement of curved-surface as well as flat-surfaced pieces.

A basic acoustical technique is detection of the resonance frequencies and/or transit times of ultrasound radiated into the metal part. This is accomplished by means of a piezoelectric transducer, usually quartz or lead zirconate–titanate, coupled to the metal by a thin film of oil to assure acoustical contact. Typical thicknesses tend to be from 1.0 to 40 mm. The transducer transmits longitudinal waves of frequency-modulated ultrasound at an accessible face of the metal part. Reflection of sound at the opposite face creates a standing elastic (acoustic) wave between the two faces of the piece. At a resonance frequency there is a whole number m of half wavelengths in the thickness of the piece, and the effect in the electronic circuit connected to the transducer is maximum. The ultrasonic signal is frequency modulated, so that m varies repetitively from m to $m+a$. The velocity of sound c in the metal must be known. The repetitive standing-wave pattern in the electronics is displayed on an oscilloscope-video screen showing the resonance frequencies produced by the oscillator. An example is a stainless-steel plate $h=3$ mm thick, sound velocity $c=5790$ m/s; the difference between successive resonance frequencies is $\Delta f = c/2h = 965$ kHz. The electronic display is designed and calibrated so that the indicated (or calculated) thickness is uncertain by less than 1.0%.

GLOSSARY

Acoustic-Gravity Wave: A wave in the atmosphere, whose phase velocity is dependent on both the bulk modulus of elasticity of the atmosphere and the acceleration of gravity.

Acoustic Impedance: Ratio of sound pressure to volume velocity.

Electroacoustics: The science whose main objective is the study of the conversion of sound energy into electrical waveforms, and conversely the conversion of electrical waveforms into vibration and sound waves.

Geophone: A transducer, from motions of the surface of the earth to an electrical waveform.

Hydrophone: A transducer, from underwater sound to an electrical waveform.

Non-Destructive Testing (NDT) and Evaluation (NDE): The use of sound waves, particularly ultrasound, to examine the interiors of optically opaque solids. Voids and inclusions, which can impair the strength of the material, scatter ultrasound which can be detected by transducers on the surface.

Particle Velocity: The velocity of small displacements in the medium that mark the passage of sound waves.

Projector: A transducer, from an electrical waveform to underwater sound.

Rayleigh Wave: A SAW on the surface of the earth.

Reciprocity Method: A protocol for calibration of microphones and hydropones, for which the reciprocal theorem is valid in the transducer, and from which an absolute measure of the transducer response to sound waves can be obtained.

Sing-Around Circuit: A closed electroacoustic loop, in which one link is a short fixed-length path underwater for an ultrasonic pulse which travels recurrently around the loop. The greater the speed of sound in the water, the higher is the frequency of recurrence of the pulse around the loop.

SOFAR: An acronym for "sound fixing and ranging," by means of the "sound channel" of minimum sound speed, at a depth of about 1000 meters in many of the natural seas and oceans.

SONAR: An acronym for "sound navigation and ranging" by means of underwater sound, in the seas and oceans.

Sound Pressure: The small fluctuations in pressure that mark the passage of sound waves through gases and liquids

Specific Acoustic Impedance: Ratio of sound pressure to particle velocity.

Surface Acoustic Wave (SAW): An elastic wave on the surface of a solid, whose particle motions are in ellipses normal to the solid surface, and whose phase velocity is slightly less than the shear-wave velocity.

Volume Velocity: The arithmetical product of a plane area in the medium, and the component of particle velocity normal to the plane.

Further Reading

Cady, Walter G. (1946) *Piezoelectricity*, New York: McGraw-Hill. The applications of piezoelectricity have been dominated by the usage of piezoelectric-acoustical resonators. The usages include physical standards of time and frequency (quartz), the accurate control of radio-frequency oscillators (quartz), narrow-band electroacoustical filters used

in multiplexed telephone lines (ethylene diamine tartrate), hydrophones and projectors for under water sound (barium titanate), microphones and loudspeakers for audio frequencies in air (Rochelle salt, ammonium dihydrogen phosphate, electrets), and medical ultrasonic applications. Cady's monumental work covers the basic physical principles for these applications.

Hueter, Theodor F., Bolt, Richard H. (1955) *Sonics*, New York: Wiley. The authors describe techniques for the applications of axoustics in engineering and physics. They state that "sonics encompasses the analysis, testing, and processing of materials and products by the use of mechanical vibratory energy." About half of the text is necessarily devoted to explanations of the fundamental principles of electroacoustics. They describe apparatus and instrumention for the industrial application of substantial acoustical power.

Mason, Warren P. (1948) *Electromechanical Transducers and Wave Filters*, 2nd ed. New York: D. Van Nostrand Co. Efficient electromechanical transducers, to transform acoustical energy into electrical waveforms and vice versa, are at the heart of almost all applications of acoustics. Mason's comprehensive treatise summarizes most of the known technology of transducers.

Rayleigh, Lord (1894, 1896), *Theory of Sound*, London: Macmillan and Co. 2nd ed., Vols. I and II. The two volumes were reprinted by Macmillan in 1937 and 1940 repectively, with a few small corrections. This treatise was written before the development and application of modern electronics to acoustical measurements. However, it remains to this day the primary treatise on the theoretical and mathematical aspects of the physics of sound.

Tolstoy, Ivan, Clay C. S., (1966) *Ocean Acoustics*, New York: McGraw-Hill. The book deals with the theory of sound propagation in the oceans, and with the comparison of theory with experiment. The authors use, as the essence of underwater acoustical theory, the simple scalar wave equation in which the propagation of sound pressure depends on the single parameter *c*, the local speed of sound at the point (x,y,z).

INTRODUCTION

Environmental health is a very broad area of study encompassing biological, chemical, physical, sociological, and psychological factors that may affect man's health and well-being. Historically, communicable disease has been at the center of most environmental health and safety concerns. Identification of causative organisms, routes of transmission, populations at risk, and the subsequent development of strategies to prevent transmission

or treatments and cures for communicable diseases have dominated public health activities. Today, while biological hazards such as acquired immunodeficiency syndrome (AIDS) continue to be enormous public health issues, other hazards have emerged and are demanding greater attention and an increasing share of society's environmental health resources.

As countless headlines, special reports, legislative acts, and regulations attest, concerns over the presence of chemicals in the environment and their possible effects upon human health have attained preeminence. It is imperative that we understand the true nature of these chemical hazards and associated risks. It is not enough for us merely to be able to take necessary actions to eliminate unacceptable environmental health hazards. We must also be capable of separating real chemical health hazards from perceived or insignificant ones so that limited health resources are not misappropriated.

Mankind has evolved in continual contact with chemical and physical hazards. Radioactive compounds such as uranium and radon gas, the sun's ultraviolet radiation, extremely low-frequency magnetic fields, toxic organic chemicals such as benzene and benzo(a)pyrene, heavy metals such as lead and mercury, and chemical oxidants such as ozone, nitrogen oxides, and sulfur oxides, have been present in man's environment from our beginnings. As Ames *et al.* (1987) have recently observed, "Nature is not benign." The human diet is laden with a tremendous diversity of naturally occurring toxins, mutagens, and carcinogens. Human activities which accompany technological, industrial, and economic advancement have, in some cases, increased the possibility of exposure to both new and existing chemical or physical hazards. Total elimination of these hazards is not feasible in that we will always be left with exposure to naturally occurring toxins or physical agents.

Effective environmental health and safety management is dependent upon our ability to identify significant health hazards and to take action to protect the public from excessive exposure to the many potentially toxic chemicals present in our environment. This article will focus upon the identification and evaluation of chemical hazards and the assessment of the risks they present through their release to the environment.

The methodologies employed when assessing environmental risks are essentially the same for both chemical and physical health hazards. In particular, the relationship between dose and toxicity was first observed and characterized in studies of the biological effects of radiation. Specific treatment of physical environmental hazards such as UV and ionizing radiation and electromagnetic fields are covered in BIOLOGICAL EFFECTS OF ELECTROMAGNETIC AND PARTICLE RADIATION.

1. TOXICOLOGY AND THE IDENTIFICATION OF ENVIRONMENTAL HEALTH HAZARDS

Toxicology is the study of adverse chemical effects upon biological systems. It has progressed from ancient observations on plant and animal poisons to an understanding at the molecular level of some of the mechanisms involved in chemically induced disease processes, such as cancer. Toxicology is a cross-disciplinary field of study encompassing a number of sciences including chemistry, biology, biochemistry, and pharmacology.

Toxicology has evolved to fulfill a critical need in modern society. With the ever-increasing role that chemicals and chemical technologies play in our daily lives, there has been a commensurate realization of the need to test these materials for possible consequences upon human health and the environment. Industrial chemicals, drugs, food additives, consumer products, cosmetics, etc., must all be evaluated in a manner which enables us to predict possible adverse effects due to their intended use.

The final application of toxicology is in the identification and characterization of chemical hazards. This task is complicated by the fact that the toxicity or effect produced by any one chemical is dependent upon a multitude of factors. The same chemical can elicit beneficial effects under one set of conditions, and harmful or lethal effects under another. Therapeutic drugs, or, in some cases, essential minerals are the most common examples of this phenomenon.

1.1 Hazard vs. Safety

In attempting to characterize chemical hazards, toxicology studies also provide the information necessary for assessing chemical safety. Chemical toxicity is a relative measure defined by both the severity of effect and the dose or exposure necessary to produce the effect. At sufficient dose, all chemicals can produce adverse effects. Oxygen, at high concentrations, can damage the lung, and approximately 100 g of table salt can produce life-threatening electrolyte imbalances.

Although this implies that no chemical is entirely safe, it has also been observed that no chemical should be considered entirely harmful. Even the most toxic chemicals exhibit minimally effective doses, below which adverse effects can be avoided. In fact, use of a very toxic chemical may be less hazardous than use of a relatively nontoxic one, depending upon differences in the resulting exposures.

1.2 Descriptive Toxicology

Descriptive animal toxicity testing under well-defined conditions of exposure forms the foundation of chemical hazard evaluation. These studies are the starting point for evaluating the health and safety ramifications of chemicals in the environment. Most descriptive toxicity testing follows guidelines prescribed by regulation and is designed to predict possible effects in humans (Environmental Protection Agency, 1985a; Hayes, 1989). In general, animal models have been found to be very good predictors of possible human responses.

1.3 Regulatory Toxicology

From these experimental results, regulatory toxicologists must extrapolate findings, most often from homogeneous animal colonies, to a heterogeneous human population. Regulatory toxicologists provide agencies, legislators, and consumers with information on the hazards or risks associated with the use and occurrence of chemicals in our daily lives. This activity usually culminates in the setting of standards which limit the quantity of a chemical to which an individual may be exposed through air, food, water, or the use of chemical materials at work or home.

2. DEFINING CHEMICAL TOXICITY

Chemicals can affect virtually every biological system of the body. From a biochemist's perspective, life itself can be viewed as a sophisticated and complex series of interrelated chemical reactions and equilibria. Perturbation of any of these reactions by a foreign chemical could be considered an effect. Whether this effect is considered a toxic or adverse effect or merely an adaptive response in order to maintain homeostasis depends upon the severity of the effect.

2.1 Severity of Effect

Severe toxic effects are most often thought of as life-threatening or debilitating. They can manifest themselves rapidly after short-term single exposures, or can be delayed and appear after some passage of time. Certain chemical carcinogens have exhibited latency periods of 20–30 y from time of initial exposure before onset of clinically observable symptoms or tumors.

Severity is also related to whether the effect is reversible or irreversible. The capacity of a tissue to repair itself or of an organ's ability to regain function influences severity. The liver possesses significant regenerative capacity and, thus, toxic effects which manifest in the liver are often reversible. Cells of the central nervous system do not replicate and tend to be the site of more severe effects.

2.2 Systemic Toxicity

With the exception of the lung, the most severe chemically induced environmental health effects appear at sites distant from the point of entry. These are termed "systemic effects" and are usually somewhat selective in that they are produced at exposures below those concentrations which would normally elicit a local effect. Chemical selectivity is a product of both the specific target or site of action for the exogenous compound and the importance of this reactive site to the viability and function of the tissue or organ.

2.3 Dose

The single most important factor determining the toxicity of a chemical is dose. As first expressed by Paracelsus in the 1500s, all chemical substances are potentially harmful to living organisms. The level of exposure or amount of a chemical to which an individual is exposed will decide the effect.

The total dose received by an individual is a function of the exposure concentration, duration, and, for intermittent exposures, frequency. Animal toxicity testing is classified into acute, subacute, subchronic, or chronic on the basis of duration of exposure. Toxicity is generally a function of the total dose. At lower concentrations of exposure, toxicity is more likely to be manifested by exposures of longer duration or greater frequency.

Acute effects, produced by short-term exposure to high doses of a chemical, often produce different effects than long-term, low-level exposure to the same chemical. Ethanol is a familiar example of a chemical which produces primary acute effects upon the central nervous system, and long-term effects in the liver. Toxicity, or the severity of response, tends to decrease as the dose administered is dispersed over time. The effect produced by consumption of six 1-oz servings of alcohol in 6 h is less than that produced by six 1-oz servings in 1 h. If the dose is spread out over a great enough length of time, there may be no observable effects (e. g., one-tenth of an ounce of alcohol per day for 60 days).

This decrease in severity of effect as the dose is fractionated over time occurs in large part through detoxification and excretion of the chemical between successive doses. Diminished effects may also be observed when the cumulative effect or injury produced by each administered dose is partially or fully reversed before the subsequent dose is administered.

3. DOSE-RESPONSE RELATIONSHIPS

The dose-response relationship is the most fundamental and important concept in toxicology. It is derived from the premise that biological responses to a chemical will increase in magnitude or frequency as dose is increased. Characterization of the effects produced by a chemical at varying doses or concentrations of exposure, via different routes, and with changing exposure duration and frequency define chemical hazards. Chemical safety then becomes an exercise in determining where on the dose-response curve a specific individual's potential dose or exposure may lie.

3.1 The Dose-Response Curve

The generalized sigmoid curves depicted in Fig. 1 are classically observed in toxicity testing, provided sufficient numbers of animals and doses are employed over a broad enough range of concentrations. The *y* axis corresponds to the magnitude or frequency of the response produced. It can be representative of the severity of an effect produced in an individual (i.e., low, moderate, or severe irritation) or be a measure of the percentage of individuals exhibiting a response in an exposed population (e.g., one in one million persons exposed may develop cancer).

The *x* axis corresponds to the dose or level of exposure. Doses are most often described as the weight of test substance per weight of animal (i.e., milligram per kilogram). Airborne exposures are expressed as parts of toxicant per parts of air (parts per million—ppm) or, for suspended particulate matter, quantity per volume of air (mg/m^3).

The sigmoid dose-response curve is representative of a normally distributed test population. All biological responses to chemicals exhibit some degree of individual variability, which accounts for the shape of this curve. At low doses only sensitive individuals in a population will respond to a chemical insult. As dose increases, the percentage of individuals responding will increase, and at the highest doses only resistant individuals will not exhibit a response.

3.1.1 LD_{50}. One of the most frequently monitored toxicological endpoints is acute lethality. Lethal-dose studies act as a starting point for the design of subsequent long-term exposure investigations. The acute dose of a substance producing death in 50% of the animals exposed is termed the lethal dose–50, denoted LD_{50}, and is shown graphically in Fig. 1 for two different compounds, A and B.

3.1.2 Thresholds. Figure 1 also depicts a point for both chemicals A and B where the percentage of animals responding is essentially zero. The corresponding dose is termed the threshold, or no-observed-effect level (NOEL). Estimation of chemical no-observed-

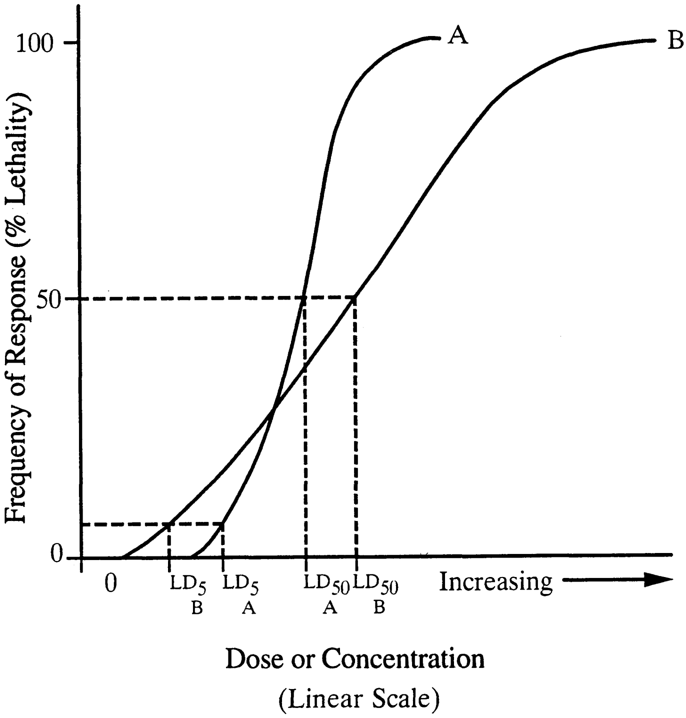

FIG. 1. Hypothetical dose/response curves for two compounds, A and B, depicting lethal dose-50 and lethal dose-5 intercepts.

effect levels from animal studies is fundamental to the evaluation of chemical hazards and risk assessment.

3.1.3 Potency. Common endpoints, such as lethality, provide a means for comparing the toxicity of chemical substances. Figure 1 indicates that the dose of compound A needed to produce lethality in 50% of the animals is less than that for compound B. Compound A would be considered more toxic or potent in producing death in 50% of the animals exposed than Compound B.

In comparing potency of chemicals, it is important to consider the anticipated level of exposure. As Fig. 1 demonstrates, the shapes of the dose-response curves for two chemicals may reveal that differences in potency can arise depending upon the dose levels being compared. While Compound A appears more potent with respect to LD_{50}'s, the doses required to produce death in 5% of the animals indicate that compound B is more potent. Moreover, compound B appears to have a lower threshold dose, indicating a greater hazard than A at lower exposure levels.

3.1.4 Multiple Chemical Responses. An added dimension of chemical dose-response evaluation is the fact that almost all chemicals are capable of producing more than one effect. Each of these effects has its own characteristic dose-response relationship. As Fig. 2 indicates, the no-observed-effect level for one effect may be observed at a dose producing nearly maximal response for other effects. One of the objectives of toxicological testing is to identify the most sensitive adverse effect and determine the lowest level of exposure necessary to produce it.

In some cases, the spectrum of effects produced by a chemical with increasing dose may reflect an increase in severity of response. For example, at very high doses a chemical may kill a large number of liver cells, destroying liver function and causing death in some or all of the animals exposed. At lower doses, fewer cells may be killed and the animal survives, but the affected cells produce other types of functional detriment, which may be observed as jaundice. At still lower doses, no cells are killed but alterations in cell function or structure may occur that can be observed only through specialized biochemical tests or histological examination. Finally, a dose may be achieved at which no effects are

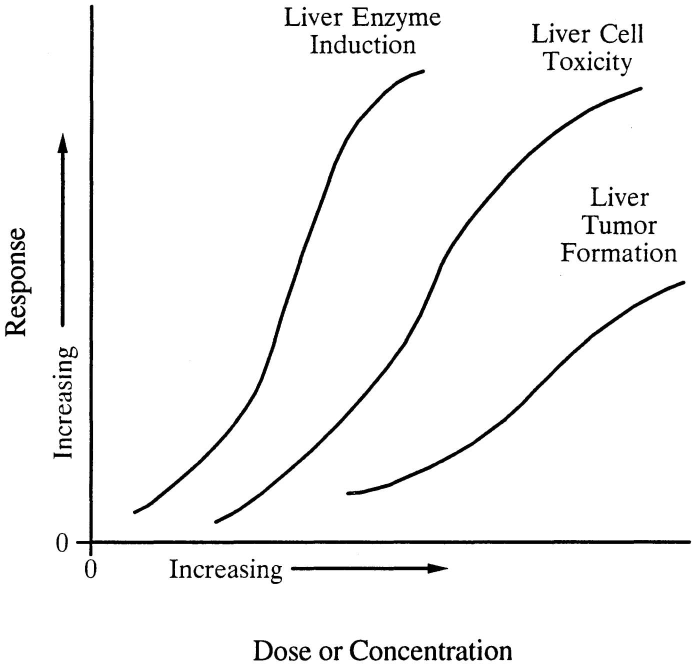

FIG. 2. Hypothetical dose/response curves for three effects produced by administration of the same compound.

observed or only changes that have no adverse impact upon the animal.

4. PHYSIOLOGICAL AND BIOCHEMICAL DETERMINANTS OF TOXICITY

The physiological and biochemical determinants of chemical toxicity are intimately related to the dose-response relationship. While administered dose is what is measured in classic toxicity testing, it is the target-site concentration that ultimately determines the response. The factors that establish and modify the relationship between the administered dose and the actual chemical concentration produced at the target site are absorption, distribution, metabolism, and, excretion.

4.1 Absorption

The physical chemical properties of a substance, the dose coupled with the route of exposure, determine how readily a chemical is absorbed across the body's epithelial surfaces. The surface areas exposed and, thus, the potential for chemical absorption vary with route of exposure. While the average individual has a skin surface area of approximately 1.8 m^2, chemicals are rarely absorbed via whole-body immersion. In contrast, the lung, with an average alveolar surface area of 50–100 m^2, and the small intestine, with a microvilli-enhanced surface area of approximately 185 m^2, present very large continuous surfaces for exposure. With every inspiration of chemical-contaminated air and for ingested chemicals along the entire length of the gastrointestinal tract, chemical absorption takes place. In general, and with decreasing effectiveness, toxic chemicals produce their most severe and most rapid effects upon inhalation, ingestion, and, lastly, skin absorption.

Absorption of a chemical into the body, as well as distribution of the chemical to its ultimate target site, is dependent upon passage of the compound across cellular membranes. Membranes represent barriers to chemical absorption only for compounds possessing specific chemical properties. For example, ionized chemicals do not cross membranes to the same degree as their nonionized forms. Nonpolar and lipid-soluble chemicals cross biological membranes more readily than water-soluble compounds. Mechanisms of transport across membranes can involve passive diffusion, active or facilitated transport, as well as endocytosis.

4.2 Distribution

Upon absorption of a chemical into the body fluids, distribution determines specific target-tissue concentrations. The circulatory system is the principal pathway for chemical distribution. While some toxicants are sufficiently soluble to be transported in solution, the majority move through the circulatory system in association with plasma proteins. Transport through the blood can result in accumulation of a chemical at its site of action, storage in tissues which do not manifest toxicity, or passage to tissues which metabolize or eliminate the chemical.

Chemicals can bind plasma proteins through covalent, ionic, hydrogen, van der Waals, or hydrophobic interactions. Dissociation of the ligand- (toxicant-)protein complex occurs when the affinity of a chemical for another biomolecule or tissue component is greater than that of the plasma protein to which the toxicant was originally bound. If binding is assumed to be reversible, redistribution of a chemical will occur in order to restore equilibrium whenever the concentration in one tissue is diminished.

4.3 Metabolism

Metabolism of chemicals is a major factor which changes parent-compound tissue concentration and, thus, shifts chemical equilibrium and distribution. Xenobiotic (foreign chemicals) metabolism is also a major determinant of chemical toxicity, either increasing the toxicity through bioactivation of a compound to a more reactive form, or detoxification, which decreases the toxicity of a chemical, usually rendering it in a more readily excretable form (Anders, 1985; Caldwell and Jakoby, 1983).

4.4 Excretion

Chemical excretion decreases whole-body concentration and causes chemical redistribution as equilibrium between body compartments is reestablished. Chemical removal from the body is expressed in terms of biological half-lives or the time required to remove one-half of the chemical from the body. Chemical elimination rates may have several phases depending upon the specific biological mechanisms involved. In general, nonpolar chemicals, which are readily absorbed, will not be excreted until in a more polar, water-soluble form. Metabolic conversion critical to removal of these compounds may often be the rate limiting step for chemical excretion.

5. THE ASSESSMENT OF RISKS DUE TO CHEMICALS IN THE ENVIRONMENT

The previous discussion was intended to highlight the complexities involved in attempting to define chemical toxicity, the first step in identifying potential environmental health hazards. Hopefully, it is evident that chemical toxicity is not a single value or determination, but rather a dependent variable which is particularly sensitive to dose. This complexity and dose dependency is the result of underlying biochemical mechanisms that determine whether a given exposure can be detoxified and eliminated without consequence or results in target-site concentrations of an active compound high enough to produce adverse effects. The greater our understanding of the mechanisms involved in chemical toxicity and detoxification, the more precisely we can identify potentially hazardous exposures, which will ultimately lead to more accurate environmental health hazard assessments.

The formalized process in which experimentally derived health hazard information is compared with estimates of actual human exposure to determine the likelihood of a toxic effect is called risk assessment. Risk assessment can be divided into four steps: hazard identification; dose-response assessment; exposure assessment; and risk characterization.

While the following discussion will highlight chemical risk assessment, the process and the four steps involved are equally applicable to the assessment of environmental risks due to physical hazards. Acceptable levels of exposure to naturally occurring radon gas, as well as allowable levels of exposure to ionizing radiation during medical x-rays, are determined by this process.

5.1 Hazard Identification

Hazard identification involves the evaluation of all available toxicological information on a chemical. Toxic effects most often observed in animals are identified, characterized, and extrapolated to man. Species, sex, mechanism of action, and exposure characteristics utilized in generating the experimental data must be interpreted and their applicability to potential human exposures determined.

An example of the complexity of this type of consideration is the toxicity of *d*-limonene, a naturally occurring monoterpene extracted from orange peels. The use of *d*-limonene as a degreasing solvent has escalated in an attempt to find safer alternatives to the halogenated solvents traditionally used in these applications. *d*-limonene was recently tested in a two-year carcinogenicity study in male and female rats and mice (National Toxicology Program, 1988). Results indicated that *d*-limonene was carcinogenic in male rats only, producing tumors of the kidney. Further mechanistic investigation identified a protein (α-2μ-globulin), found only in male rats, that was structurally altered through binding with a bioactivated form of *d*-limonene. This altered protein then accumulates in the male rat kidney, apparently initiating inflammatory tissue reactions which eventually lead to tumor formation. There is no indication that *d*-limonene binds DNA directly. The hazard identification step of risk assessment includes determination of whether this type of data is relevant to potential human exposures.

5.2 Dose-Response Analysis

The second step in risk assessment arises from the data reviewed in the hazard identification step and involves analysis of dose-response relationships. For each chemical, all potential adverse effects must be examined and the individual dose-response curves evaluated. The effects produced at the lowest level of exposure are usually identified through this procedure. Since environmental exposures are most often well below the concentrations or doses employed in experimental studies, responses must be projected or extrapolated to levels of exposure beyond those actually tested.

5.3 Exposure Assessment

The steps of hazard identification and dose-response assessment provide the risk assessor with a characterization of the potential effects that a chemical might produce and the types of exposures necessary to elicit these effects. Determination of the risk or likelihood that an individual may experience an effect due to the presence of a chemical in the environment requires an estimate of dose or exposure. Estimating environmental exposures to chemicals can be as complex as the evaluation of toxicological information.

Chemicals can enter the environment from point sources, such as the outfall of a waste water treatment plant, or non-point sources, such as the tailpipe of an automobile. Computer modeling is often employed to predict down-range concentrations of chemicals released to the atmosphere or entering surface or ground water.

Human exposures to environmental chemicals can occur via the air, from consumption of food and beverages, and, in some cases, through skin contact with contaminated soil or water. Upon release of a chemical to the environment, numerous factors will determine which of these pathways of exposure is most probable and whether the resulting exposure concentrations are significant.

The environmental fate of a chemical is dependent upon physical chemical characteristics, the point of origin, the medium to which the chemical is released, transport between environmental compartments, and chemical transformation. With the exception of persistent chemicals and chemicals which bioaccumulate, most chemicals from the time of release are either diluted or degraded, decreasing in concentration from their point of origin. Transport between environmental compartments can take place via numerous pathways including evaporation of liquids into vapor or gaseous phases, precipitation of chemicals out of solution, absorption to particulates, particulate fallout from the atmosphere, or atmospheric resuspension of particulates. Chemical transformation or degradation can take place through chemical, photochemical, and biological mechanisms.

Exposure assessment must estimate the resulting human uptake of chemicals that may be widely and unevenly distributed in the environment. Assumptions and estimates are made regarding contaminant concentrations in food, air, water, and soil, as well as quantities of various foods typically consumed, volumes of air inhaled, and amount of skin contact with soil.

5.4 Risk Characterization

The final step in risk assessment is risk characterization. In this process, information from the previous steps is summarized. Risk characterization should not focus upon one estimate of risk resulting from one exposure scenario or measure of toxicity, but rather should compare a range of estimates, identifying the underlying assumptions and uncertainties. "Weight of evidence" is often the phrase used to describe the most accepted approach to risk characterization and includes a maximum likelihood or "best" estimate based upon all available data.

Risk characterization for noncarcinogenic effects centers upon determination of no-observed-effect levels (NOELs) for all adverse effects identified. Human acceptable daily intakes (ADIs) are derived from the experimental NOEL. ADIs usually incorporate safety factors which attempt to compensate for uncertainties involved in extrapolating animal findings to man.

Risk characterization for carcinogens is complicated by the theoretical plausibility that all exposures carry with them some finite risk. This risk may be so extraordinarily small that, in fact, a practical threshold does exist. Cancer risk assessments attempt to provide decision makers with information which allows for the determination of tolerable levels of risk.

The risk-assessment product represents the scientific treatment of all relevant data. This product is presented to a risk manager who must then make decisions as to the necessary course of action. Risk management decisions result in banning of a chemical, limiting use, or imposing no restrictions.

5.5 Uncertainty in Risk Assessments

There are two principal sources of uncertainty when one is assessing the environmental risks of chemicals. The first is that most chemical toxicity data come from animal studies which must be extrapolated to man. The second is the need to estimate possible human exposures to environmentally disseminated chemicals.

Unlike the controlled conditions employed in animal experimentation, real-world exposures to chemicals are often unknown. They can occur via multiple routes, can be of inconsistent duration and frequency, and usually involve very low concentrations that can fluctuate over time. The mere presence of a chemical in the environment does not necessarily represent a hazard or risk. As analytical methods improve, chemicals will be detected more often and at lower concentrations than ever before. The health significance of these findings will be determined by an evaluation of potential exposure.

Precise estimation of dose would require a tremendous amount of data, specific to each individual—unique to his/her environment, personal habits, and preferences. Food consumption and personal activity patterns, such as occupation and amount of time spent indoors or outdoors, are all determinants of potential environmental chemical exposure. In the absence of this type of data, risk assessments utilize estimates of exposure. Given the importance of dose in determining whether a chemical will produce a toxic effect and thus truly represent a hazard, environmental exposure estimates represent a critical underpinning of any environmental risk assessment.

While the many uncertainties involved in the risk assessment process have led some to think that it is of little value to the risk manager, when performed consistently risk assessments do offer a means for comparing risks and separating significant hazards from trivial ones.

6. ENVIRONMENTAL CHEMICALS AND CANCER

The threat of cancer due to chemicals in the environment is the most publicized and possibly most significant chemical health and safety issue confronting society today. Public concern over cancer is justifiable. Approximately 22% of all deaths in the U.S. are now due to cancer. But upon further analysis of age-adjusted mortality rates for all cancers combined, it becomes apparent that overall cancer rates have remained the same or declined since 1950, with the notable exception of smoking-related lung cancer (American Cancer Society, 1988). This trend is contrary to what one might expect after examining the production and use of synthetic organic chemicals since 1945, which has increased from about 5×10^8 kg/y to 1.5×10^{11} kg/y (Davis and Magee, 1979), and is certainly in conflict with the numerous reports of increased cancer risks due to the presence of chemicals such as Alar, PCBs, and formaldehyde in our environment. The reasons for this apparent discrepancy between the perceptions of risks due to chemicals and actual cancer rates are evident after investigation of what we know about the causes of cancer and also how cancer risk assessments are often performed and reported.

6.1 Environmental Factors Associated With Cancer

The causes of cancer are multifactorial and include genetic, biological, and environmental factors. It is generally accepted that 80% to 90% of all cancers are causally associated to varying degrees with numerous types of environmental factors. Environmental factors are those over which we have some control, and for this reason have been the focus of many cancer prevention strategies. One manner in which these factors have been identified is through comparison of the incidences of specific types of cancer in different parts of the world. For example, colon and breast cancer, which are among the major types of cancer in the U.S., are quite rare among the Japanese in Japan, but not among Japanese Americans. Smoking, diet, ionizing radiation, drugs, sunlight, and chemicals are all known to be capable of producing cancer.

Precise determination of the percentage of cancers caused by any one factor is not possible. Estimates have been proposed based upon the limited data available, but with the exception of cancers associated with tobacco, there remains considerable debate over the proportionate causes of cancer. In perhaps the most often cited study, Doll and Peto (1981) have estimated that 30% of U.S. cancers are associated with tobacco, 35% with nutritional factors, 3% with alcohol, 7% with reproductive and sexual behavior, 3% with physical factors such as UV radiation, 10% with infection, 1% with food additives, 2% with pollution, 1% with industrial products, 1% with medicines, and 4% with occupation. While some controversy remains as to whether environmental chemicals may play more or less of a role in the induction of cancer, other studies seem to indicate that the relative hazards presented by environmental chemicals when compared to other sources of exposure to carcinogens may be very low.

6.2 Carcinogenic Mechanisms

Cancer is characterized by the abnormal, uncontrolled, and seemingly unrestricted growth of the body's own cells, giving rise to cellular masses called tumors. Tumors can be benign, remaining at the site of origin, or malignant, spreading or metastasizing from the primary site to give rise to secondary tumors in other areas of the body. The symptoms of cancer are usually the result of tumor growth invading surrounding tissues and interfering with normal body function.

Chemical carcinogens include both naturally occurring and man-made chemicals. While chemical carcinogens exhibit a spectrum of toxic effects and properties similar to other chemical toxicants, they differ through their ability to produce heritable change at the cellular level. The transformation of a normal cell to a cancerous, or neoplastic, cell with subsequent tumor formation proceeds through a complex series of events. The initiating event for many chemical carcinogens is thought to be interaction with DNA. This interaction results in change in the DNA sequence, which ultimately alters cellular growth characteristics giving rise to the transformed cell. Most chemical carcinogens require bioactivation to reactive forms which then bind DNA.

The entire process involved in chemically induced cancer is under intricate control and subject to numerous modifiers. Species, strain, sex, age, and nutritional status have all been observed to alter significantly an animal's response to chemical carcinogens.

6.2.1 Genetic and Epigenetic Carcinogens. Chemical carcinogens have generally been classified into two types based upon mechanisms of action: the genetic and epigenetic carcinogens.

Genetic, or genotoxic, carcinogens are DNA reactive and thought to be directly responsible for DNA alteration and initiation of tumor development. Epigenetic carcinogens do not bind DNA directly and, apparently, facilitate tumor development through other mechanisms.

In general, genotoxic carcinogens are more potent than chemicals working through epigenetic mechanisms. Additionally, there is mounting support for the existence of thresholds or levels of exposure to epigenetic carcinogens which do not induce tumor formation.

6.3 Cancer Risk Assessment

Results from animal experiments have been the major source of data for estimating human risk from exposure to potentially carcinogenic chemicals. Animal tests for chemical carcinogenicity generally employ rodents (mice or rats) exposed to a chemical for a major portion of their life span. Rodents have been found to be very similar to man anatomically and in the way they metabolize chemicals. Generally, the tumors produced by chemicals in rodents have similar characteristics to those found in man.

A limitation in these studies, due to the small number of animals tested, is that weak carcinogens would probably not be identified as cancer causing. In place of increasing the size of the study, which would be costly, large doses (termed the maximum tolerated dose) of chemicals are typically used in order to detect even weak carcinogens. These doses, in virtually all cases, are much larger than those to which humans would be subjected. The rationale for this is that, in general, the number of tumors will increase as the dose of a carcinogen increases. While the use of the maximum tolerated dose in animal studies is controversial and some difficult questions remain to be answered, regulatory agencies, in order to maintain a conservative and prudent public health policy, must rely upon the results of these animal tests.

In general, it appears that animal testing is a very good indicator of a chemical's possible carcinogenicity in humans. Of the 32 chemicals thought to be carcinogenic in humans, 26 have been shown to produce cancer in experimental animals. In these comparisons, the target organ of carcinogenicity was the same 80% of the time.

Beyond the determination of whether a chemical may or may not produce cancer in humans, risk managers are concerned with the probability or risk to humans upon exposure to a suspect carcinogen. From these animal bioassays, regulatory toxicologists attempt to determine the likelihood of humans developing cancer at a particular exposure level. Currently, regulatory agencies, such as the U. S. Environmental Protection Agency (EPA), assume that there is no threshold or dose at which a cancer-causing chemical would not induce tumors. From these animal studies, which are conducted at relatively high doses, regulators attempt to predict the response in humans due to exposures to these chemicals at much lower doses.

These types of extrapolations, while questionable with respect to their relevance to actual human carcinogenic risks, do allow for the establishment of exposure levels to suspect carcinogens which would not be anticipated to produce significant numbers of cancers in exposed individuals. In addition, this type of dose-response analysis allows comparison of the potency of chemicals to induce cancer when tested in similar animal bioassays. Chemicals with a high potency induce higher numbers of tumors at lower levels of exposure or induce tumors in a much shorter period of time. Low-potency carcinogens induce lower numbers of tumors and require greater doses or a greater length of time to produce tumors in animals. As Table 1 illustrates, comparison of carcinogenic potencies indicates that all carcinogens are not alike. There do exist real and measurable differences in the capacity of chemicals to produce tumors in animals; in this example bis(chloromethyl)ether is approximately 100,000 times as potent as chloroform.

6.3.1 Acceptable Risk. While the analyses in Table 1 are useful when comparing carcinogenic potencies of chemicals within the dose ranges studied, the actual tumor incidence rates produced in these studies are beyond acceptable limits for potentially ex-

Table 1. Comparison of carcinogenic potencies.[a]

1 000	1.8×10^{-4}	2.0×10^{-4}	2.0×10^{-5}	1.3×10^{-9}
10 000	1.8×10^{-3}	2.0×10^{-3}	6.1×10^{-4}	2.4×10^{-1}

[a] Environmental Protection Agency (1985b).

posed human populations. Animal carcinogenicity testing is limited in its power of detection by a combination of the numbers of animals typically employed and the spontaneous background rates of tumor formation observed in control animals. Most animal studies identify tumor incidence rates of 10% or greater, which would translate into 1 cancer per 10 individuals exposed.

EPA policy has established an acceptable level of risk for suspect carcinogens to be one cancer per one million individuals exposed. This necessitates the extrapolation of experimentally derived tumor incident rates in the range of one cancer per ten animals exposed to doses which might induce tumors in one individual per one million exposed.

Current EPA policy requires the use of a linearized multistage extrapolation model to derive 95% upper confidence limits for these doses. Other models for extrapolation have been proposed, which utilize equally valid but less conservative mechanistic assumptions.

Table 2 compares estimates generated by use of the EPA multistage model with those produced by three other models. These data were derived by the EPA in assessing health risks due to airborne methylene chloride exposure (Environmental Protection Agency, 1985b). At varying air concentrations ($\mu g/m^3$) the corresponding estimates of numbers of cancers produced per population exposed are presented for the four models. Depending upon the model employed, a lifetime (70-y exposure) risk to humans exposed at 1 $\mu g/m^3$ can range from two cancers per 10^7 individuals exposed (one-hit model) down to 3.5 cancers per 10^{31} persons exposed (log-probit model).

It is important to understand that these incidence rates are hypothetical extrapolations and do not represent actual cancer rates. Misrepresentation of these estimates without explanation of the numerous assumptions which go into their generation, and with no indication of the full statistical range of possible outcomes, has led to much of the public's confusion and perception of cancer risks due to chemicals in the environment.

6.3.2 Relative Risk. In the absence of accurate quantitative methods to evaluate potential carcinogenic hazards, attempts have been made to provide risk managers, policy makers, and the public with qualitative measures of the relative hazards or risks attributable to environmental chemicals. Utilizing carcinogenic potencies and estimates of human exposure, relative risks can be used to assist in prioritizing environmental health needs.

Ames *et al.* (1987) have used a hazard ranking system which computes a HERP index (human exposure dose/rodent potency dose) for comparing carcinogenic risks. Table 3 presents rankings from these data for several chemicals with known human exposures. The greater the HERP percentage, the greater the relative hazard.

This type of comparison provides risk managers and the public with an intuitive aid to understanding the health significance of chemicals in the environment. Hazards from environmental pollutants can be compared to naturally occurring carcinogens in the diet, such as aflatoxin and nitrosamines, or to chloroform in tap water (which is formed as a byproduct during drinking-water chlorination to protect us from pathogenic viruses and bacteria).

Table 3. Relative risk based upon human exposure dose/rodent potency dose (HERP) (Ames *et al.*, 1987).

Daily human exposure	Carcinogen dose per 70-kg person	HERP%
Tap water (1 L)	Chloroform, 8.3 μg (U.S. average)	0.001
Well water (1 L, Woburn, MA)	Chloroform, 12 μg	0.0002
Conventional home air (14 h/day)	Formaldehyde, 598 μg	0.6
Mobil home air (14 h/day)	Formaldehyde, 2.2 μg	2.1
PCBs: daily dietary intake	PCBs, 0.2 μg(U.S. average)	0.0002
Bacon, cooked (100 g)	Diethylnitrosamine,0.1 μg	0.006
Peanut butter (32 g, one sandwich)	Aflatoxin, 64 ng	0.03
Ethylene dibromide: daily dietary (from grains and grain products)	Ethylene dibromide, 0.42 μg (U.S. average)	0.0004

7. SOME ENVIRONMENTAL AGENTS OF CONCERN

Environmental health questions today and in the future will ultimately be resolved through the use of the risk assessment process. As detailed in the previous discussions, toxicity is determined by dose or level of exposure. This precept is equally applicable when considering both chemical and physical agents. Environmental exposures of concern will most often arise as the result of either persistent chemicals which bioconcentrate or bioaccumulate through the food chain to produce elevated body burdens, or widespread emission sources which may result in exposure of large populations. Heavy metals and polychlorinated biphenyls (PCBs) represent persistent chemicals which have been the subject of numerous investigations and public health initiatives. Ozone and extremely low-frequency magnetic fields represent environmental agents with widespread sources of exposure.

7.1 Heavy Metals

Heavy metals are naturally occurring elements which are present throughout the Earth's crust. They are unlike many organic chemicals in that they are neither created nor destroyed by human activities. Environmental health hazards due to heavy metals often arise from their redistribution in the environment giving rise to an increased likelihood of exposure. Industrial, agricultural, and mining operations may enhance the bioavailability of these metals. The toxicity and resulting hazard of a specific heavy metal can vary dramatically depending upon form and route of exposure. In the general population, food sources represent the greatest source of exposure to metals.

Several heavy metals, because of a combination of their persistence in the environment as well as their ability to bioaccumulate through the food chain or bioconcentrate in human tissues, are of particular environmental concern.

7.1.1 Lead. Environmental lead is the result of both natural and anthropogenic sources. In the recent past, combustion of leaded gasoline was the primary source of lead from human activities. Today, with the removal of tetraethyl lead from gasolines, lead emissions have been dramatically reduced. Other sources of concern have included lead pigments used in paints and lead solder used in plumbing. Now, nonferrous smelters, battery plants, and chemical plants remain the principal sources of anthropogenic lead, although these sources have decreased significantly due to improvements in control technologies.

7.1.1.1 Fate. In air, lead exists as a particulate. Atmospheric transport depends in large part upon the aerodynamic diameter of this particulate. Large particulates (those generally greater than 2 microns in diameter) are removed through settling relatively rapidly, and deposited close to the source. Smaller particulates may be transported up to 1000 miles.

Concentration of lead in surface waters is largely dependent upon solubility of the specific lead compound, *p*H, and dissolved salt content. Solubility tends to increase as salt content decreases. A significant proportion of lead in surface waters can be carried as suspended particulates of large, undissolved lead precipitates.

Lead in soil is affected by a large number of factors including absorption and chelation with organic substrates. Most lead is retained very strongly in soil and little is tranported into surface waters or ground water. Lead leaching in soil is normally very slow. Factors which may increase lead migration include the presence of water-soluble chelators and decreased soil *p*H.

Plants and animals may bioconcentrate lead, but biomagnification through the food chain has not been observed. Lead exposure in the general population is most likely through ingestion of food and drinking water. Airborne particulates containing lead can result in inhalation exposure and are important in the transport and deposition of lead-containing dusts and soils onto vegetation and into surface waters. On the basis of 1982 data, the U. S. Food and Drug Administration (FDA) has estimated that the average daily intake of lead by consumption of food, water, and beverages is 25.1 μg/d for two-year-old children, 32 μg/d for adult females, and 45.2 μg/d for adult males (Environmental Protection Agency, 1986). More recent analysis indicates lead intakes have continued to decrease through 1988.

7.1.1.2 Health Effects. Health concerns regarding lead in the environment have focused upon effects upon children. Young children are more susceptible to the effects of lead exposure because of greater intakes (principally through ingestion) on a body-weight basis compared to adults, greater absorption and retention rates, and incomplete development of the blood-brain barrier, which tends to limit lead distribution to the brain in adults. Lead concerns have also arisen from the use of lead-containing solders in water distribution systems and lead-containing paints in older homes. The health effects of lead exposure have most often been correlated with total body burden. The distribution of lead in the body is ultimately dependent upon the relative affinity of tissues for the element. Steady-state intercompartmental distribution is achieved upon consistent and extended exposure, and is reflected in blood lead concentrations.

Lead is capable of producing a wide spectrum of human health effects depending upon exposure, dose, and duration. At high levels of exposure lead can produce cardiovascular effects resulting in high blood pressure; hematological effects, including anemia due to the inhibition of heme synthesis; and toxic effects upon the kidney.

Most environmental concerns have focused upon potential central nervous system effects due to lead overexposure. Symptomatic encephalopathy is most often observed in overexposed children, producing effects ranging from ataxia to stupor, coma, and convulsions. This form of lead poisoning is uncommon in North America and is seen most often at blood lead levels of greater than 100 μg/dL. Low-level lead exposure has recently become a concern because of possible subclinical effects upon the central nervous system. Neurobehavioral effects, such as hyperactivity, poor classroom learning behavior, and small decrements in I.Q. scores have been studied in association with various bloodlead levels of generally 50 μg/dL and below. A major problem with these studies is that the possible effects upon I.Q. and other neurobehavioral endpoints are very small in comparison to other competing factors such as parents' I.Q. or vocabulary, and thus become very difficult to identify (Agency for Toxic Substances and Disease Registry, 1988).

7.1.2 Mercury. Mercury presents a wide spectrum of potential biological effects depending upon whether it is in an elemental, inorganic, or organic form. The major source of mercury in the environment is natural degassing of the Earth. Anthropogenic sources include mining, smelting, and burning of fossil fuels.

7.1.2.1 Fate. Once released to the environment, mercury may undergo significant transformation. Metallic mercury is readily oxidized to divalent mercury in aquatic environments. There, it may be methylated by anaerobic bacteria. Methyl mercury may bioaccumulate, eventually finding its way into the human food chain.

7.1.2.2 Health Effects. Elemental mercury vapor is lipid soluble and readily crosses the membranes of the lung. Upon entry into the bloodstream, it has a high affinity for red blood cells as well as the high lipid content of the central nervous system. In contrast, metallic mercury when ingested is very slowly absorbed in the gastrointestinal tract and is generally thought to be of little toxicological concern via this route of exposure. Gastrointestinal absorption of inorganic salts of mercury is approximately 7% and that of methyl mercury, 90–95% (Goyer, 1986).

All forms of mercury cross the placenta, presenting a potential risk to fetal development. Concentrations of mercury in the fetus after maternal exposure to alkyl mercury are twice as high as those found in maternal tissues. The developing fetus apparently acts as a sink following maternal exposures and thus is particularly sensitive to the effects of mercury.

Mercury vapor is most often encountered in industrial settings, although some studies have focused upon the use of mercury in dental fillings and potential exposures in dental-health care workers.

Acute high-level exposure may result in corrosive effects upon the lung or gastrointestinal tract and central nervous system excitability resulting in tremors. Chronic exposure to mercury vapor affects the central nervous system. Symptoms include tremors of muscles involved in fine motor functions such as the fingers and eyelids, progressing to generalized trembling of the whole body. There may also be changes in personality and behavior, loss of memory, depression, and hallucination. Gingivitis and severe salivation are two distinctive characteristics of mercury toxicity.

Acute ingestion of inorganic salts of mercury causes ulcerations and necrosis of the gastrointestinal tract. Within 24 h, effects upon the kidney proximal tubules are observed resulting in oliguria, anuria, and uremia. Chronic low-level exposure to mercury salts may induce an immunological glomerular nephritis, again resulting in renal dysfunction.

Organic mercury is the most readily absorbed form of mercury and represents the form of greatest toxicological significance. Studies of human populations exposed to methyl mercury have produced most of the data regarding potential toxicological effects. Several significant environmental exposures have resulted from industrial and agricultural incidents. In Japan, industrial release of mercury compounds into Minamata Bay resulted in bacterial methylation and subsequent bioaccumulation of mercury in fish. Contaminated fish were caught and ingested by local populations. Fish were found to contain approximately 11 mg/kg mercury. A second incident, in Iraq, involved the ingestion of bread made from seed grain which had been treated with a methyl mercury fungicide. During the period of exposure, mercury intake was estimated to range from 80 μg/kg d to 250 μg/kg d. Principal effects observed were upon the central nervous system including degeneration of neurons of the cerebral cortex, particularly in the visual areas. Progressive clinical features included paresthesia, ataxia, dysarthria, and deafness.

Prenatal exposure from the Minamata incident produced effects upon psychomotor development, including delays in the time required to learn to walk and talk, as well as seizures. Severe *in utero* exposures may be observed to produce symptoms similar to those observed in cerebral palsy.

7.1.3. Cadmium. Cadmium is produced as a by-product of zinc and lead in mining and smelting. Its principal use is in electroplating or galvanizing. In addition, it is used as a color pigment in paints and plastics, and as cathode material in nickel-cadmium batteries.

7.1.3.1 Fate. Cadmium is found in water in the 2^+ oxidation state. Chemically, cadmium is very similar to zinc, and many of its biological activities are the result of competition for zinc binding sites in biologically active proteins.

Depending upon chemical form and solubility, cadmium can be found in water and sediment. In one study of a marine estuary system, it was observed that water cadmium concentrations varied significantly with depth during the summer months. It was determined that during stagnant periods the aerobic surface water contained relatively high concentrations of dissolved cadmium, predominantly as a soluble ion, $CdCl^+$. The anaerobic bottom layers of water contained relatively low cadmium levels, as a result of microbial reduction, to produce insoluble cadmium sulfides (Manahan, 1991).

Cadmium is known to bioconcentrate in shellfish and plants. Muscles, scallops, and oysters may contain 100 to 1000 μg/kg of cadmium. Cadmium is more readily taken up by plants than other heavy metals such as lead. Wheat and rice have been shown to concentrate cadmium when grown in highly contaminated soils. In nonpolluted areas, content may range from 0.01 to 0.1 $\mu g/g$ and in polluted areas, 0.1 to 1 $\mu g/g$. A major source of human exposure in the general population is through cigarette smoke. One cigarette contains 1 to 2 μg of cadmium. Smoking one pack or more per day can double an individual's total body burden of cadmium (International Agency for Research on Cancer, 1976).

7.1.3.2 Health Effects. The principal human health effects observed due to cadmium have resulted from occupational exposure to relatively high airborne levels of cadmium fumes. Acute exposure can produce acute chemical pneumonitis and pulmonary edema. Long-term occupational exposure has elicited chronic obstructive pulmonary disease and emphysema, and chronic renal tubular disease. Animal studies indicate that cadmium ingestion can produce nephropathy when cadmium levels in the kidney reach approximately 200 $\mu g/g$. Other evidence suggests that effects of cadmium include hypertension and effects upon both male and female reproductive systems. More recently cadmium chloride aerosols have been found to produce lung cancer in rats.

7.2 PCBs

PCBs were commercially produced in the U.S. from 1929 through 1977. By 1970 it was estimated that approximately one billion pounds of PCBs had been sold in North America. PCBs were used principally in transformers and capacitors because of dielectric properties and fire resistance. The environmental persistence of PCBs, and potential toxicity, vary with the specific isomer. The resistance to biodegradation and relative toxicity appear to increase with increasing chlorine content.

7.2.1 Fate. Current sources of PCB release are relatively minor since their manufacture has been discontinued. While potential emissions from landfills containing PCB-contaminated waste have generated public concern, the low water solubility of PCBs and relatively low vapor pressure, in addition to their affinity for organic substrates, minimize migration into the air and water. The higher chlorinated PCBs (Aroclor 1248, 1254, and 1260) are resistant to biodegradation and have been found to bioconcentrate in fish, shrimp, and oysters by factors ranging from 26 000 to 660 000.

Air concentrations for PCBs have been found to be very low. Means for remote locations have been measured at approximately 0.1 fg/m^3 ranging to 5–10 fg/m^3 in urban environments. The low water solubility of PCBs limits the significance of this potential route of exposure. A survey of finished water supplies from 113 cities, conducted by the EPA between 1975 and 1977, identified PCBs in only 4 water supplies. PCB concentrations were all detected at levels near or below the limits of detection, which are 0.1–0.2 ppb (Agency for Toxic Substances and Disease Registry, 1990).

7.2.2 Health Effects. Exposure to PCBs in the general population occurs principally through the consumption of fish, with dairy products ranking second. Average daily intake via food for adult males has been estimated at 0.56 μg.

The toxicity of PCBs has been studied extensively in animals. Acute exposures via inhalation, ingestion, and dermal contact indicate that PCBs are low in toxicity.

PCBs are highy lipophilic and tend to accumulate in fat, skin, and other high-fat-containing organs. Upon chronic low-level exposure they can be detected in blood and lipid biopsies, and attempts have been made in human studies to correlate these levels with possible effects. Long-term exposure to low levels of PCBs have produced a number of effects upon the liver, ranging from enzyme induction to hepatocellular necrosis, depending upon dose. Other studies in animals have suggested subtle effects upon the immune system and possibly fetal toxicity. Studies of human populations exposed to PCBs have indicated that high level of exposure can produce changes in liver function and effects upon cutaneous tissue exhibited as an acneiform skin lesion termed "chloracne". Aroclor 1260 has been shown to produce liver tumors in animals. Environmental and occupational epidemiological studies have failed to detect any similar activity in human populations (Silberhorn *et al.*, 1990).

7.3 Ozone

The generation of ozone in the troposphere is discussed in AIR POLLUTION: COMPONENTS, CAUSES, AND CURES. Ozone is the highly reactive triatomic form of oxygen and is a major constituent of photochemical smog. It is formed primarily via atmospheric reactions between nitrogen oxides and organic hydrocarbons. Highly reactive oxidants, such as ozone and other similarly generated smog constituents (i.e., organic peroxides, aldehydes, and free radicals), usually produce acute and immediate effects upon biological tissues.

The lung is the most important target organ impacted by reactive airborne contaminants such as ozone, and has been the subject of numerous toxicological investigations. In animals, at very high levels of exposure, ozone produces deep lung tissue destruction leading to pulmonary edema and death. Three-hour LD_{50}'s range from 20 to 50 ppm depending upon the species tested (Lippmann, 1989).

Atmospheric concentrations of ozone range from 40 ppb in rural areas to 300 ppb in heavy-smog urban areas. Animals exposed to ozone in the 300-ppb range have exhibited subtle changes in pulmonary function, including increased respiratory frequency and a decrease in tidal volume. In addition, mild changes in the morphology of lung cells have been noted.

Pulmonary-function investigations of human populations exposed to ozone in the 300-ppb range have produced both subtle positive effects and negative findings. It appears that certain individuals of the population may be more susceptible to the effects of ozone upon lung function. In addition, it is possible that over time, low-level exposures may lead to a greater ozone tolerance in exposed individuals (Folinsbee *et al.*, 1988).

7.4 Extremely Low Frequency (ELF) Magnetic Fields

The potential biological effects of extremely low-frequency magnetic fields have been the subject of a number of *in vitro* and epidemiological investigations. Extremely low-frequency magnetic fields (frequencies below 300 Hz) are generated both naturally and through man-made sources. Naturally occurring time-varying fields include those arising from solar activity and thunderstorms, and can reach intensities of 0.5×10^{-3} tesla (0.5 mT). Two manmade ELF magnetic field types of recent environmental concern are those generated by high-voltage transmission lines (intensities of approximately 15 μT) and land-based naval communication systems (approximately 14 μT) (World Health Organization, 1987). In addition, household appliances operating on a 60-Hz line voltage source can produce immediate field intensities as high as 2.5 μT. These field strengths decrease rapidly with distance, the ambient field strength in most households being less than 0.3 μT.

Time-varying magnetic fields induce electronic fields and currents in biological tissues. *In vitro* studies have shown that these fields, when of sufficient intensity, can alter cell surface binding properties, an effect which leads to a number of secondary events in biological tissues. Biological effects include altered cell surface binding of calcium, suppression of T-cell lymphocyte cytotoxicity, and inhibition of human lymphocyte activation (Tenforde, 1990).

Most biological effects have been studied utilizing peak field intensities greater than 0.5 mT with current densities induced in the exposed samples exceeding 10 mA/m^2. These levels of exposure are greater than expected from most man-made environmental sources. ELF magnetic fields have not been reported to induce mutations or cytogenetic changes.

The greatest concern regarding ELF magnetic fields has resulted from possible associations with human cancer. Several environmental and occupational epidemiology studies have suggested weak associations between the presence of an ELF magnetic field source and incidence of cancer. Other studies, similarly conducted, have failed to observe this relationship. Measurements of the magnetic field dose were not available in these studies and analysis of confounding factors, such as smoking habits, diet, etc., were not considered. It is likely that the general population is not at risk from environmental sources of ELF magnetic fields. Ground-level power-line field strengths and household appliance ambient levels of exposure are all generally less than those occurring naturally. To date, no convincing association between any human exposure to ELF magnetic fields and cancer has been established. This lack of significant effects is supported by the relatively high ELF magnetic field intensities required to produce effects *in vitro*. Because of the lack of a direct effect of ELF magnetic fields upon the genetic makeup of the cell, it is likely that if any association with cancer is observed it will be the result of an indirect effect exhibiting a practical threshold.

8. CONCLUSION

Environmental health and safety expectations will continue to evolve as the relative significance of factors potentially affecting man's health and well being change. Certain risks will continue to be reduced with medical, technological, and engineering advances, while other new risks may appear. As the major historical causes of mortality and morbidity, such as communicable disease and famine, are brought under control, we will be left to deal with less obvious environmental health and safety issues. The success of efforts to improve health and safety further will become increasingly dependent upon distinguishing between potential risks. Risk assessment will play a greater role than ever before in directing future environmental health and safety initiatives. True health and safety benefits will only be realized if the science involved in this process is separated from science policy and perceptions of risk.

ACKNOWLEDGMENT

The authors would like to thank Mrs. Claudia Kinman for her inestimable assistance in the preparation of this manuscript.

GLOSSARY

Bioactivation: Biological metabolism of a substance to a more reactive form.

Carcinogen: Agent that has been found to induce abnormal uncontrolled growth of cells (tumors) in laboratory animals or in humans.

Detoxification: Biological metabolism of a substance to a less reactive, more readily excretable form.

DNA (Deoxyribonucleic Acid): Biomolecule found in the nucleus of cells; thought to be the repository of hereditary charcteristics.

Endocytosis: Process whereby materials are taken into a cell by invagination of the plasma membrane.

Toxicology: The study of adverse effects of chemicals on biological systems.

Xenobiotic: Compounds foreign to the normal metabolism of an organism.

INTRODUCTION

The equation of state (EOS) of a system describes the relationship between its thermodynamic variables. The simplest example is a gas of noninteracting particles, an ideal gas, in which the relationships between pressure P, volume V, temperature T, the number of molecules N, Boltzmann's constant k, and the energy E are given by

$$PV=NkT, \quad E=\tfrac{3}{2}\,NkT. \tag{1}$$

Real systems involve interactions between particles, and a knowledge of the EOS requires an understanding of the relationship between interatomic forces and the observed macroscopic thermodynamic properties.

In principle, the existing theoretical formalism allows the equation of state and the properties of matter to be determined once these forces are known. In practice, the barriers to *ab initio* calculations are formidable because of the difficulty of solving the many-body problem. Consequently, it has proven necessary to introduce simplifying assumptions into the governing equations. The price of simplification, however, is a loss of generality, and the resulting theory is adequate over only a limited region of the phase diagram. Liquids, solids, and gases have distinctive patterns of electronic structure and atomic ordering, leading to different theoretical approximations. Some well-known approximations are the Thomas-Fermi model of dense matter, the van der Waals model of the liquid, and the Debye model of the solid. Each of these contains certain features essential for characterizing the material properties over a limited range of conditions or of a region of the phase diagram (Eliezer *et al.*, 1986; Godwal *et al.*, 1983; Ross 1985).

1. FUNDAMENTAL PRINCIPLES

On the most fundamental level the forces between molecules are manifestations of the electromagnetic interactions between electrons and nuclei of the entire system (Torrens, 1972). For many systems the sum of these interactions may be expressed as effective intermolecular potentials. The connection between interatomic forces and EOS is provided by thermodynamics and statistical mechanics (McQuarrie, 1976; Goodstein, 1975).

1.1 Intermolecular Forces

Some typical rare-gas pair potentials are shown in Fig. 1. One of the best-known functional forms, the Lennard-Jones (LJ) potential, for a pair of atoms separated by a distance r can be written as

$$\phi(r)_{\mathrm{LJ}}=\epsilon\left[\left(\frac{r^*}{r}\right)^{12}-2\left(\frac{r^*}{r}\right)^{6}\right], \qquad (2)$$

where ϵ and r^* are the depth and position of the potential well. The attractive r^{-6} term represents the long-range dipole-dipole interaction. In particular, the r^{-12} repulsion has been found to be too stiff, and theory tells us that an exponential repulsion should be the proper form. A more useful function, particularly for examining high-pressure data, has been the exponential-six (exp-6) potential,

$$\phi(r)_{\text{exp-6}}=\frac{\epsilon}{\alpha-6}\left\{6\exp\left[\alpha\left(1-\frac{r}{r}\right)^{*}\right]-\alpha\left(\frac{r^*}{r}\right)^{6}\right\}. \qquad (3)$$

The parameter α regulates the stiffness of the interatomic repulsion. For most systems $\alpha \sim 13$–14. The LJ and exp-6 potentials are referred to as van der Waals–type potentials. Higher accuracy can be achieved by introducing additional parameters, higher multipole attractive interactions, or three-body terms (Barker, 1986).

The potential in an ionic crystal may be expressed as the sum of a Coulomb and a van der Waals potential. For example, the potential between ions i and j with charges Z_i and Z_j may be written as

$$\phi(r_{i,j})=\frac{Z_iZ_je^2}{r_{i,j}}+\phi(r_{i,j})_{\text{exp-6}}. \qquad (4)$$

Metals constitute a particular difficulty because of the inherently many-body nature introduced by itinerant electrons. For the case of simple polyvalent metals, practical pair potentials have been derived from theory (Shimoji, 1977).

Consider a system of ions placed in a neutralizing background electron gas. The electrons will tend to accumulate near the ions, screening the ion-ion interaction. A formal treatment of this problem leads to an effective pairwise interaction potential for a pair of ions,

$$\phi(r)=\frac{Z^2e^2}{r}+\frac{1}{2\pi^2}\int_0^\infty\frac{\sin qr}{qr}\,\phi_{\mathrm{BS}}(q)q^2dq. \qquad (5)$$

The first term is the bare Coulomb repulsion between ions, and the second is the screening correction due to the modulations in electron density near the ions. $\phi_{\mathrm{BS}}(q)$, referred to as the band-structure term, is a function of the electron-ion potential and dielectric constant and is in general density dependent. A typical metal ion-ion potential is shown in Fig. 2. The electrons piling up near the ion lead to a diminished charge elsewhere and to the oscillations in the potential.

Apart from the density dependence, the simple metal pair potentials are similar to those of rare gases. The potentials of both

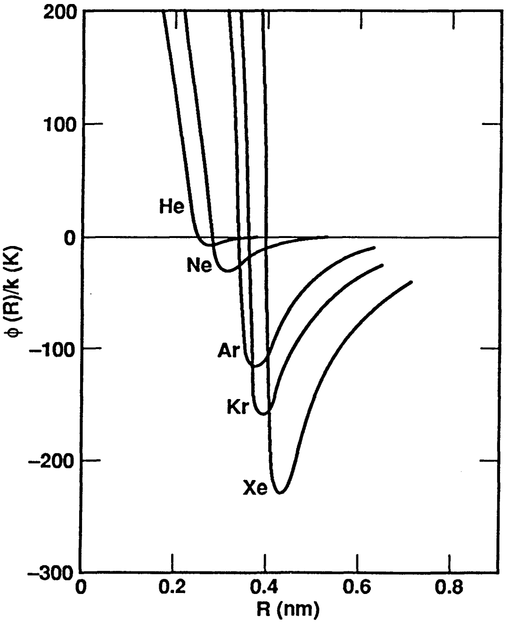

FIG. 1. Comparison of rare-gas pair potentials.

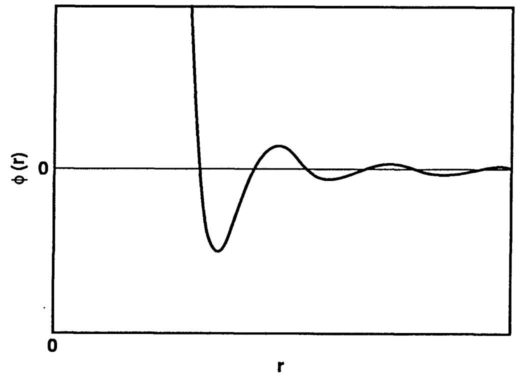

FIG. 2. A typical metallic pair potential.

have minima roughly near the average nearest-neighbor separation, and a steeply repulsive behavior at small interatomic spacings, although the metal repulsion tends to be less steep. For covalently bonded systems such as carbon or quartz, three-body potentials are required (Tersoff, 1989).

1.2 Statistical Thermodynamics

The pressure and energy for a closed isothermal system, with independent variables N,V,T, are linked to the interatomic forces through the Helmholtz free energy,

$$A(N,V,T) = -kT \ln Z(N,V,T), \tag{6}$$

where Z is the partition function

$$Z = \sum_{c} \exp[-E_c(N,V,T)/kT]. \tag{7}$$

The sum is over all possible configurations of the system in which E_c is equal to the total kinetic and potential energy for all particles of the system in that configuration. For the case of simple atoms interacting via pairwise additive potentials, we may write

$$E_c = \sum_{i} t_i + \sum_{i<j} \phi_{ij}. \tag{8}$$

Pressure and energy are obtained from the partial derivatives of Eq. (6),

$$P = -\left(\frac{\partial A}{\partial V}\right)_{T,N} = kT\left(\frac{\partial \ln Z}{\partial V}\right)_{T,N} \tag{9}$$

and

$$E = -T^2\left(\frac{\partial A/T}{\partial T}\right)_{V,N} = kT^2\left(\frac{\partial \ln Z}{\partial T}\right)_{V,N}. \tag{10}$$

The Gibbs free energy is $G = A + PV$.

2. OVERVIEW OF THE PHASE DIAGRAM

Figure 3 is a schematic phase diagram of a typical simple substance (Young, 1991). In the region of high pressures or densities and low temperatures, the substance is a solid; at higher temperature and lower pressures it is a gas, and there is a liquid region at intermediate values of P and T below the critical point. For $T > T_c$ and $P > P_c$, the substance is generally referred to as a fluid. The lines that separate these phases are called *coexistence curves*. At very high temperatures gases dissociate and ionize to become plasmas, sometimes referred to as the fourth state of matter.

2.1 Critical Point

Two points of special interest on the phase diagram are the triple point and the critical point (CP). At the triple point, solid, liquid, and gas all exist in equilibrium. The critical point is the end point of the vapor-pressure curve. A liquid cannot exist at any temperature higher than T_c or pressure higher than P_c. At the critical point, the volumes of a specific amount of liquid and gas become equal to each other, and above the critical point there is only a homogeneous fluid phase with no distinction between liquid and gas. By following a path around the critical point, a homogeneous liquid can always be transformed into a homogeneous gas without pass-

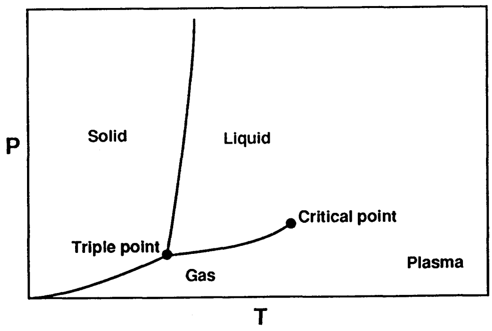

FIG. 3. A typical phase diagram.

ing through a phase transition. Figure 4 represents the isotherms of xenon near the critical temperature (Hapgood and Schneider, 1954). From the curves, we see that, at the critical temperature,

$$\left(\frac{\partial P}{\partial \rho}\right)_{T_c}=0, \quad \left(\frac{\partial^2 P}{\partial \rho^2}\right)_{T_c}=0.$$

In contrast to simple insulating fluids such as Xe, in which atoms interact through weak van der Waals forces, the interactions in liquid metals are more complicated. The change of state from liquid to gas across the vapor-pressure curve is often accompanied by a transition from metallic to nonmetallic behavior. At temperatures below the critical point, metallic properties, such as electrical conductivity, change discontinuously from vapor to liquid and continuously for temperatures above. This behavior seems to be typical for liquid metals and has been observed for Hg, Cs, Rb, and K (Freyland and Hensel, 1985). Some typical critical temperatures are, for argon, cesium, and molybdenum, respectively, 151, 1924, and (estimated) 14 300 K.

According to experiments, when the critical temperature T_c is approached, several physical quantities such as density, compressibility, and heat capacity have been observed to vary in a manner proportional to powers of $|T-T_c|$. For example, in the case of density $|\rho-\rho_c| \sim |T-T_c|^{\beta}$; or the compressibility $-(1/V)(\partial V/\partial P)_T \sim (T-T_c)^{-\gamma}$. The exponents characterizing the relationship are called critical indices (Baker, 1990).

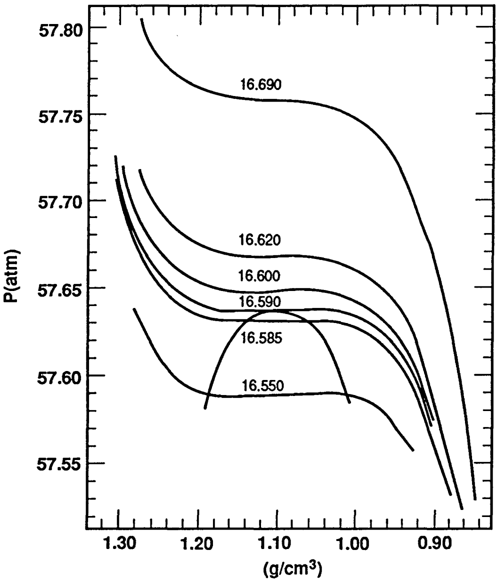

FIG. 4. Isotherms of xenon near the critical temperature. The numbers on the curves represent the temperature in degrees Celsius. The inverted parabola is the liquid-gas critical curve.

2.2 Law of Corresponding States

The ratios of P, V, and T to the critical values P_c, V_c, and T_c are called the reduced pressure, volume, and temperature. These may be written

$$P_r=P/P_c\,, \quad V_r=V/V_c\,, \quad P_r=T/T_c\,.$$

To a good approximation, especially at moderate pressures, all gases obey the same equation of state when described in terms of the reduced variables, P_r, V_r, T_r. This approximation is called the *law of corresponding states*. This is illustrated in Fig. 5 for a number of different gases, where the compressibility factor $Z_r=P_rV_r/RT_r$ is plotted at various reduced temperatures against the reduced pressure. The law of corresponding states stems from the fact that most molecules have similar functional forms for their intermolecular potentials. For example, although N_2 and n-heptane are very different in size, the spatial dependence of their interaction energies is similar and can be approximately described by Eq. (1) or (2). Thus the potential parameters ϵ and r^* can be rewritten in terms of reduced variables such as ϵ/kT_c, etc., leading to reduced expressions for thermodynamic properties.

In contrast, a comparison of the coexistence curves of the rare gas argon and the metals cesium and mercury (Fig. 6) shows a lack of correspondence when the interatomic forces are fundamentally different as in Eqs. (3) and (5). Note that even the metals cesium and mercury do not correspond, suggesting that the force laws operating in these fluids differ fundamentally. Melting data for rare gases also show that these systems obey corresponding states (Fig. 7).

2.3 Melting of Solids

From purely thermodynamic considerations, the fundamental theory of melting can be summarized as

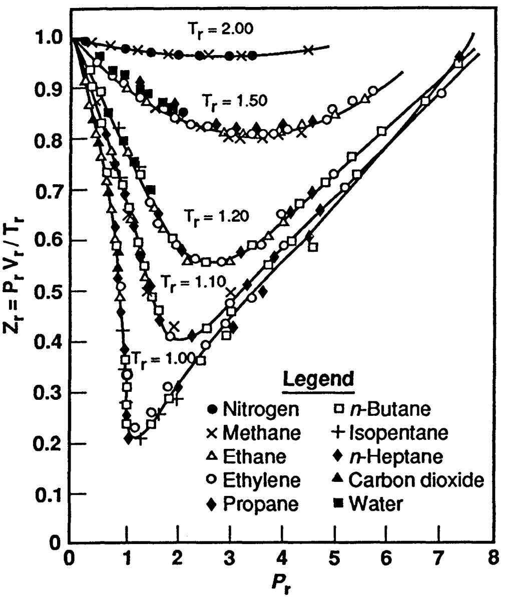

FIG. 5. Reduced compressibility factor Z_r, as a function of reduced temperature and pressure for a variety of gases (Su, 1946).

$$T_s = T_f, \quad P_s = P_f, \quad G_s(P,T) = G_f(P,T),$$

where s denotes solid and f fluid. The three conditions correspond to thermal, mechanical, and chemical equilibrium. Each of the quantities must take the same value in the solid as in the fluid phases. The traditional difficulty in calculating melting curves of real substances arises from uncertainties in statistical mechanics, particularly of the fluid free energy, and a lack of knowledge of the intermolecular forces. With an improved understanding of the forces and better statistical and quantum theories, accurate calculations of phase boundaries are now possible (Vos *et al.*, 1991).

However, for many applications where the forces are poorly known or the systems are beyond the scope of present methods, it remains necessary to rely on simpler and more empirically based methods such as the Lindemann rule.

Lindemann assumed that a solid melts when the mean square amplitude of vibrations of atoms about their equilibrium positions reaches a certain fraction of the lattice spacing, found empirically to be about 10%. He then arrived at a relationship between the melting temperature T_m, the Debye temperature Θ_D, the atomic mass M, the melting volume V_m, and a constant C that depends on the material,

$$T_m = C\Theta_D^2 (M V_m^{2/3}). \tag{11}$$

A liquid analog of the Lindemann law states that the hard-sphere liquid packing fraction (η), which is the ratio of the effective atomic hard-sphere volume v^* to the volume per atom for the system, v, has a constant value at freezing equal to about 0.46.

The Simon equation,

$$P_m = P_0 + a(T_m/T_0)^n, \tag{12}$$

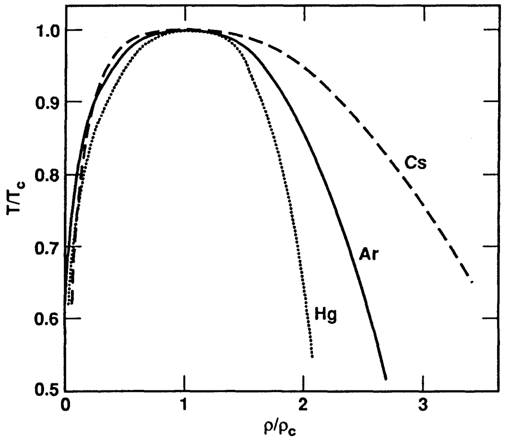

FIG. 6. Comparison of T/T_c vs ρ/ρ_c coexistence curves for argon, cesium, and mercury.

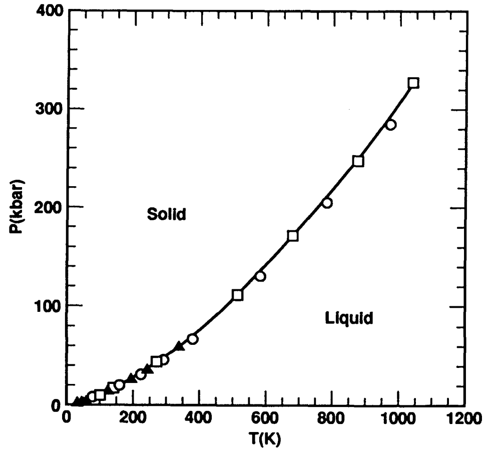

FIG. 7. Neon melting data (▲) compared with scaled helium (○) and argon (□) data (Vos *et al.*, 1992).

is a widely used equation for fitting melting data. P_0 and T_0 refer to some initial set of conditions, and a and n are constants.

Solid–liquid coexistence curves are occasionally found to have negative slopes in the P-T plane. For example, in the case of water, the liquid is denser than the solid and the melting curve of water slopes backward.

2.4 Superfluids

Helium is a simple substance with a unique phase diagram. The combination of weak attractive forces and a large zero-point motion prevents the liquid from freezing below 25 bar. Figure 8 shows the phase diagram for ^{4}He (Wilks and Betts, 1987). There are two liquid phases (I and II). Near 2.17 K the specific heat rises in a λ-like shape.

The properties of helium I above the λ temperature are not very different from those of normal classical liquid, but helium II below the λ line exhibits superfluid properties. A model to understand this behavior postulates a mixture of a superfluid and a normal fluid with thermal excitations obeying Bose statistics. The fraction of superfluid decreases with increasing temperature and only normal fluid exists above the λ line. The model also predicts that thermal excitations increase with increasing pressure, leading to the negative slope of the λ line. The phase diagram for ^{3}He shows a similar solid-liquid-vapor scheme but a superfluid does not appear until cooled below 2.6 mK, where it also exhibits a λ transition. Normal ^{3}He is governed by Fermi statistics and the superfluid properties are associated with the formation of ^{3}He pairs behaving as bosons much as in the BCS theory of electron superconductivity.

2.5 Plasmas—The Saha-Boltzmann Ionization Equation

At very high temperatures gas molecules dissociate and atoms are found in multiply ionized states (Ebeling *et al.*, 1977; Zel'dovich and Raizer, 1966). Under conditions of local thermodynamic equilibrium and negligible interatomic interactions, the ratio of the densities of the different states of ionization is given by the Saha equation. N_r, the number density of atoms in the rth stage of ionization, is related to that of the $(r+1)$th stage, N_{r+1}, by

$$\frac{N_{r+1}}{N_r}N_e=\frac{u_{r+1}}{u_r}\frac{2(2\pi mkT)^{3/2}}{h^3}\exp\left(\frac{-I_r}{kT}\right), \tag{13}$$

where N_e is the free-electron density, u_r is the internal partition function of the rth stage, I_r is the energy required to remove an electron from the ground state of the r-times ionized atom (its ionization potential), m is the electron mass, and h is Planck's constant. The Saha equation can be derived by minimizing the Gibbs free energy of a reacting mixture.

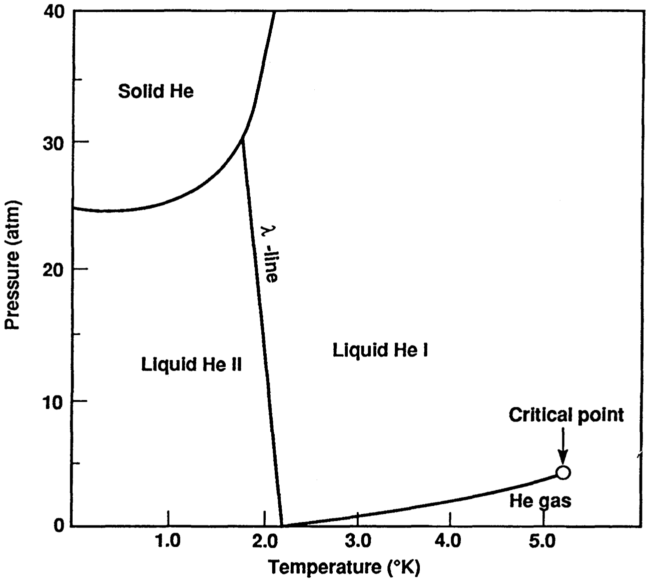

FIG. 8. The four states of ^{4}He in the *PT* plane.

The pressure, for negligible interactions, is that of a perfect gas [Eq. (1)], where N is the number of free atoms, ions, and electrons.

Ionization of atoms begins at values of kT much lower than the ionization potential. The reason here is that the statistical weight of the free-electron state is very large. With the exception of the alkali metals, which have very low ionization potentials, the first ionization potentials of the majority of atoms and molecules vary between 7 and 15 eV ($I/k \sim 80\,000$–$170\,000$ K). Ionization usually begins at thermal energies of the order of a few tenths of the ionization potential. The degree of ionization increases with temperature. When the temperature is of the order of several tens of thousands of degrees practically all of the atoms are singly ionized and the gas contains multiply ionized atoms.

The effect of small nonideal contributions from interparticle interactions is to lower the ionization potential and therefore enhance ionization. The corrections are collectively responsible for the phenomenon of "pressure ionization." For the conditions under which the Saha equation has been derived, nonideal effects only produce a slight enhancement of the degree of ionization. The Saha equation is widely used for astrophysical applications where the properties of stellar and interstellar matter are determined by the chemical composition and the degree of ionization and state of excitation (Clayton, 1983).

3. STATISTICAL MECHANICS OF FLUIDS

The equation of state of a fluid can be expressed concisely in terms of the intermolecular potential and the radial distribution function $g(r)$ (Hansen and McDonald, 1986; Allen and Tildesley, 1987). The radial distribution function measures the probability of finding a particle at a given distance from a fixed particle in the fluid. A typical form for $g(r)$ is shown in Fig. 9. In the case of a solid, $g(r)$ would be seen as a series of narrow isolated peaks corresponding to shells of neighbors. For a spherically symmetric potential the energy and pressure can be written as

$$E=\frac{3}{2}NkT+2\pi N\rho\int_0^\infty \phi(r)g(r)r^2dr \qquad (14)$$

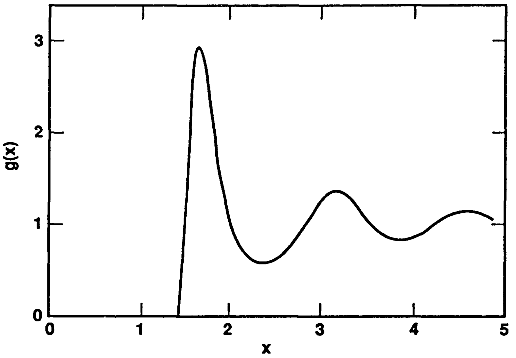

FIG. 9. A typical $g(r)$ function for a liquid.

and

$$PV=NkT-\frac{2\pi N\rho}{3}\int_0^\infty r^3\frac{d\phi(r)}{dr}g(r)dr. \qquad (15)$$

The first term corresponds to the kinetic energy of an ideal gas and the second part arises from interactions between the particles, where $\phi(r)$ is the interatomic potential and ρ is the number of particles per unit volume. When three-body and higher-order interactions are present, additional integral terms include the many-body distribution functions, $g^{(3)}(r_{12},r_{13},r_{23})$, etc. $g(r)$ can be obtained experimentally by neutron diffraction, or by theoretical methods using computer simulations or solving integral equations.

3.1 Virial Expansion for a One-Component Gas

The equation of state of a sufficiently dilute gas is $P=\rho kT$. At higher densities the equation of state can be put in the form

$$\frac{P}{kT}=\rho+B_2(T)\rho^2+B_3(T)\rho^3+\cdots, \qquad (16)$$

known as a virial expansion. The $B_n(T)$ are the virial coefficients and depend on intermolecular forces. The second virial coefficient of a classical monatomic gas is

$$B_2(T)=-\frac{1}{2}\int_0^\infty (e^{-\phi(r)/kT}-1)4\pi r^2dr, \qquad (17)$$

B_3 involves the interaction between three molecules, etc. With increasing density higher coefficients become significant. For a (hypothetical) gas of hard spheres,

$$\phi=\begin{cases}+\infty, & r<d\\ 0, & r\geqslant d\end{cases}$$

and

$$B_2=2\pi d^3/3\ ,$$

where d is the diameter or distance of closest approach of the centers of two spheres. The virial expansion for a hard-sphere fluid has been determined by Ree and Hoover (1964).

3.2 Van der Waals Equation

Many empirical equations of state are useful for representing fluid *PVT* data. One of the best-known examples is the equation of van der Waals,

$$P=\frac{NkT}{V-b}-\frac{aN^2}{V^2}\ . \tag{18}$$

An expansion in powers of $\rho=N/V$ leads to a virial series. The constants a and b are evaluated by fitting the equation to experimental *PVT* measurements, or more usually from the critical constants of the gas. At the critical point both the first and second derivatives vanish, $(\partial P/\partial V)=0=(\partial^2P/\partial V^2)$. Solving these equations for the critical constants yields

$$T_c=\frac{8a}{27bR}\ ,\quad V_c=3b,\quad P_c=\frac{a}{27b^2}\ .$$

The van der Waals equation can be understood in terms of the thermodynamic EOS,

$$P=\left(\frac{\partial P}{\partial T}\right)_V T-\left(\frac{\partial U}{\partial V}\right)_T\ . \tag{19}$$

The first term is the contribution from the kinetic pressure and the second relates to the volume dependence of the internal energy. The van der Waals equation can be derived from simple kinetic theory, viz., b is the volume occupied by the effective hard-sphere repulsions and $-a/V^2$ is the attractive pressure due to intermolecular attraction. The van der Waals equation provides a reasonably good representation of the *PVT* data of gases in the range of moderate deviations from ideality. It contains most of the essential features of a fluid and is the starting point for more complicated empirical models. The basic realism of the model has been confirmed by computer simulations and fluid perturbation theory.

3.3 Computer Simulations—Exact Results

The most important recent advances in the theory of fluids have come from computer simulations carried out by Monte Carlo (MC) and molecular dynamics (MD) methods (Ciccotti and Hoover, 1986; Allen and Tildesley, 1987) (see MOLECULAR DYNAMICS; MONTE CARLO METHODS) and the development of approximate but computationally fast and accurate models. In both methods, N molecules are confined to a box of volume V at temperature T. Computer size and speed limit N to several thousand particles. But these practical limitations are continually decreasing. To minimize surface effects, periodic boundary conditions are employed. This consists of filling three-dimensional space by replications of the original cell in which the molecules in each cell occupy the same relative positions. In the MD method, properties are simulated using numerical methods to solve Newton's equations for N particles. The MC method employs probabilistic or stochastic methods and is limited to equilibrium properties. The MD method is the more versatile and is applicable to the study of nonequilibrium systems (Hoover, 1991).

Computer simulations should be viewed as experiments producing exact data that complement laboratory experiments. For the case of strongly coupled degenerate plasmas with densities comparable to those found in high-energy astrophysics and laser-fusion-compression experiments, computer simulations are the only "experimental" data. Simulations have been used to determine the pair distribution and thermodynamic and transport properties over a wide range of conditions. One of the most useful models has been the hard-sphere system. Its isotherm is shown in Fig. 10. The pressure data for the fluid may be expressed as

$$P_{\mathrm{HS}}/kT\rho=(1+\eta+\eta^2-\eta^3)/(1-\eta)^3. \tag{20}$$

Here η is the hard-sphere packing fraction, $\eta=(\pi/6)\rho d^3$. The Helmholtz free energy A_{HS} in excess of that for a perfect gas is then

$$A_{\mathrm{HS}}/NkT=(4\eta-3\eta^2)/(1-\eta)^2\ . \tag{21}$$

Simple analytic expressions exist for exact thermodynamic results on model systems such as the Lennard-Jones (Ree, 1981) and inverse-power potentials (Young and Rogers, 1984) and one-component plasmas (Stringfellow *et*

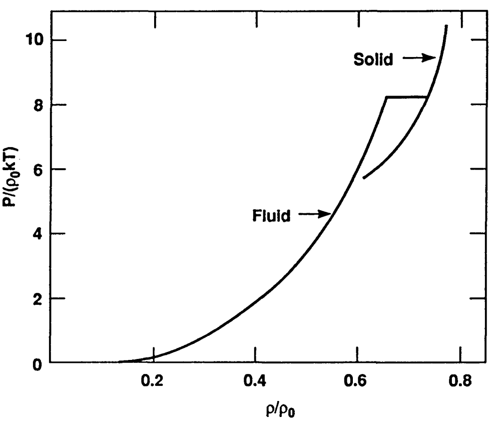

FIG. 10. Isotherm of a hard-sphere system shows the solid and fluid branches and the freezing line. The quantity ρ_0 is the close-packed density. Systems with purely repulsive forces do not have gas-liquid coexistence curves.

al., 1990). These results have been extremely valuable in the development and testing of computationally simpler approximate methods such as perturbation theories and integral equations. The books by Hafner (1987) and Shimoji (1977) contain many useful applications to real liquids.

3.4 Perturbation Theory

The idea of representing a fluid as hard spheres or charged ions moving in a background of interatomic interactions forms the basis of the van der Waals model and perturbation theory, the rationale being that if the free energy and pair distribution function of a reference system are well known, as, for example, from computer simulations, then the properties for a model system can be computed as corrections to those of the reference system. For example, if we divide the pair potential into a hard-sphere repulsion for $r<d$ and an attraction $u_1(r)$ for $r>d$, then the free energy of the system can be written

$$A=A_0-\frac{N}{2}\int_d^\infty d^3r\, g(r)u_1(r)+\cdots,$$

where A_0 is the free energy of the reference system and the second term is the correction. The "closeness" of reference and model fluids largely determines the accuracy of theory. For the case of a hard-sphere reference fluid, there is no unique way to choose the value of a diameter.

In the variational formulation, the Helmholtz free energy of an interacting system is approximated by the use of the Gibbs-Bogolyubov inequality

$$A\leqslant A_0+(\phi-\phi_0)_0. \tag{23}$$

This equation states that the free energy of the interacting system is bounded above by the free energy of a reference system (A_0) plus the difference in energy between the actual system and the reference, averaged over all configurations of the reference. For a hard-sphere reference system this equation can then be simplified to

$$\frac{A}{NkT}<\frac{A_{\rm HS}(\eta)}{NkT}+\frac{\rho}{2kT}\int_d^\infty \phi(r)g_{\rm HS}(r,\eta)4\pi r^2dr. \tag{24}$$

The correct value of A (and d) is obtained by minimizing A with respect to d. The pressure and energy are obtained from partial derivatives of A [Eqs. (9) and (10)]. Since the hard-sphere potential is unrealistically stiff in comparison with realistic intermolecular potentials, the pressures obtained are typically too high. This deficiency has been remedied by the use of inverse-power (soft-sphere) reference systems (Young and Rogers, 1984). For many simple liquid metals, the one-component plasma has provided a useful reference system (Ross *et al.*, 1981).

3.5 Integral-Equation Theories

The equations for thermodynamic properties of fluids are valid at all densities but require accurate values for the radial distribution function. Although computer simulations generate the most accurate results, integral equations are the best of the approximate methods.

Integral equations result from the combination of two relations. The first one, which is exact, is the Ornstein-Zernike relation between the pair correlation function $h(r)=g(r)-1$ and the direct correlation function $c(r)$,

$$h(r)-c(r)=\rho\int h(r')c(|r-r'|)dr'. \tag{25}$$

The second is a closure relation between these functions, examples of which are given by the

Percus-Yevick (PY) and hypernetted-chain approximations (HNC), respectively:

$$g(r)=\begin{cases}\exp[-\beta\phi(r)][1+\gamma(r)] & \text{(PY)}, \quad (26)\\ \exp[-\beta\phi(r)]+\gamma(r) & \text{(HNC)}, \quad (27)\end{cases}$$

where $\gamma(r)=h(r)-c(r)$. For purely repulsive potentials, the PY and HNC equations of state bracket the "exact" computer simulation results. This suggests that some interpolation of the two equations would provide improvements. In the scheme introduced by Rogers and Young (1984) the PY and HNC closures are interpolated by a function that depends on the interparticle distance,

$$g(r)=\exp[-\beta\phi(r)]\left(1+\frac{\exp[f(r)\gamma(r)]-1}{f(r)}\right), \tag{28}$$

where $f(r)$ is the "mixing function" ($0\leqslant f\leqslant 1$). A convenient form is the mixing function

$$f(r)=1-\exp(-\alpha r), \tag{29}$$

where α is the adjustable parameter used to achieve thermodynamic consistency. Equations (25), (28), and (29) together constitute the thermodynamically consistent approximation. In this scheme the integral equation is reduced to the PY closure at $r=0$ and HNC closure at $r=\infty$. This feature is intuitively satisfying since it is known that PY is better for treating short-range repulsive forces and HNC for long-range forces. Pressure and energy may be calculated with Eqs. (14) and (15).

4. THE THEORY OF SOLIDS

The most fundamental property of a solid is its ground-state electronic energy E_0, to which must be added a vibrational contribution (E_{vib}) arising from atomic motion and thermally excited electrons (E_{el}). Thus

$$E(V,T)=E_0(V)+E_{\text{vib}}(V,T)+E_{\text{el}}(V,T), \tag{30}$$

$$P(V,T)=P_0(V)+P_{\text{vib}}(V,T)+P_{\text{el}}(V,T). \tag{31}$$

4.1 The Local-Density Approximation

Current theoretical methods for determining E_0 use the local-density approximation (LDA) (Lundquist and March, 1983). This method simplifies the many-body fermion problem into a mean-field approximation in which each electron moves in the self-consistent average field of all the electrons and the nuclei (V_{en}). The complicated many-body exchange and correlations included in the average field are conveniently approximated by a functional $\epsilon_{\text{xc}}(\bar{r},[\rho])$ of the local electron density. The total ground-state energy is

$$E=T[\rho]+\int d\bar{r}\; V_{en}(\bar{r})\rho(\bar{r}) -\frac{e^2}{2}\int d\bar{r}'\,\frac{\rho(\bar{r})\rho(\bar{r}')}{|\bar{r}-\bar{r}'|} +\int d\bar{r}'\rho(\bar{r})\epsilon_{\text{xc}}(\bar{r},[\rho])+U_{\text{ion-ion}} \tag{32}$$

and

$$\rho(r)=\sum_j |\phi_j(r)|^2. \tag{33}$$

In simpler terms, these are, respectively,

$$E=T+U_{en}+U_{ee}+U_{\text{xc}}+U_{\text{ion-ion}}, \tag{34}$$

where T is the total electron kinetic energy and the remaining terms are the ion-electron (U_{en}), electron-electron (U_{ee}), and electron exchange and correlation (U_{xc}) energies, and $U_{\text{ion-ion}}$ is the ion-ion Coulomb energy. The energy is minimized using a wave-function gradient method ($\partial E/\partial\phi_j=0$), which leads to one-electron Schrödinger equations in which the potential field is the same for each electron:

$$\left(-\frac{\hbar^2}{2m}\nabla^2+V_{en}(r)+e^2\int dr'\,\frac{\rho(r')}{|r-r'|} +\frac{\partial U_{\text{xc}}}{\partial\rho(r)}\right)\phi_j(r)=\epsilon_j\phi_j(r), \tag{35}$$

ϕ_j and ϵ_j are the single-particle wave functions and eigenvalues. The methods for solving these equations are referred to as "electron-band theory" and are described in detail in the article ELECTRON STRUCTURE OF SOLIDS. The pressure can be obtained from the virial theorem,

$$PV=2T/3+U/3, \tag{36}$$

where U, the total potential energy, is the sum of the U terms in Eq. (34).

In general, the local-density approximation works surprisingly well for solids and even for free atoms and small molecules, using only a fraction of the computer time required by the Hartree-Fock approximation. For example, extensive sets of self-consistent field calculations (Moruzzi *et al.*, 1978; Skriver, 1984) demonstrated that electron-band calculations can accurately describe the lattice constant, cohesive energy, and compressibility of the full range of metals, given only the atomic number. It has also been capable of providing accurate predictions of many high-pressure phase transitions (McMahan, 1986; Yin and Cohen, 1982).

4.2 The Mie-Grüneisen Equation of State

The total zero-point and thermal energy of the crystal is given by

$$E_{\text{vib}} = \sum_{\alpha=1}^{3N} \left(\frac{1}{2} h\nu_\alpha + \frac{h\nu_\alpha}{e^{h\nu_\alpha/kT} - 1} \right). \qquad (37)$$

The summation is over the $3N$ normal modes (ν_α) of the crystal, N being the total number of atoms. If the interatomic potential is known, then ν_α can be calculated from lattice dynamics (Maradudin *et al.*, 1971). The Mie-Grüneisen equation of state (Girafalco, 1973)

$$E = E_0 + E_{\text{vib}}, \qquad (38)$$

$$P = -\frac{dE_0}{dV} + \frac{\gamma}{V} E_{\text{vib}}, \qquad (39)$$

is obtained by assuming that the dimensionless variable γ_α for each mode

$$\gamma_\alpha \equiv -\frac{d \ln \nu_\alpha}{d \ln V} \qquad (40)$$

can be replaced by its average over all the normal modes, $\gamma = \bar{\gamma}_\alpha$. γ is referred to as the Grüneisen constant. In the classical limit, for a system of harmonically vibrating atoms $E_{\text{vib}} = 3NkT$, and the pressure becomes

$$P = P_0 + 3\gamma NkT/V. \qquad (41)$$

In the Debye model the sum in Eq. (37) is replaced by an integral over a continuum distribution of frequencies,

$$\sum_{\alpha=1}^{3N} \rightarrow \frac{9N}{\nu_m^3} \int_0^{\nu_m} \nu^2 d\nu.$$

This leads to a modified expression for E_{vib}; however, the remaining formalism [Eqs. (36)–(39)] is unchanged. For either model γ must be determined as a function of volume. With the exception of simple metals and small molecules, this procedure is generally not feasible. Instead, approximations are introduced that bypass a knowledge of the microscopic physics and rely on macroscopic variables—the pressure-volume curve—to obtain useful approximations for γ. Several models for γ can be expressed in a single equation (Ross, 1985):

$$\gamma = -\frac{V}{2} \frac{\partial^2 (P_0 V^{2m/3})/\partial V^2}{\partial (P_0 V^{2m/3})/\partial V} + \frac{1}{3}(m-2), \qquad (42)$$

where $m=0$ is for the elastic continuum model of Slater, $m=1$ is obtained from a harmonic expansion of the static lattice energy of Dugdale and McDonald (Rice *et al.*, 1958), and $m=2$ is based on the harmonic vibration of an atom in the spherically symmetric field of neighbors. A number of useful empirical relations have been offered that bypass these models. These assume $\gamma/V = \text{const}$ or $\gamma = CV + \frac{1}{2}$, where C is a constant fitted at normal density. $\gamma = \frac{1}{2}$ is the limiting case for lattice of positive ions in a background degenerate electron gas in which both T and $V \rightarrow 0$. In the perfect-gas limit of $T \rightarrow \infty$, $\gamma = \frac{2}{3}$. A particularly large number of applications of the Mie-Grüneisen equations are to be found in Zharkov and Kalinin (1971).

4.3 Thermal Electron Properties

Contributions from thermally excited electrons may be obtained from finite-temperature self-consistent band calculations for electrons in a rigid lattice, using Fermi statistics to determine the energy-level occupation numbers (McMahan and Ross, 1977). Accordingly,

$$E_{\text{el}}(V,T) = \sum_i \epsilon_i(V) [n_i(T) - n_i(0)], \qquad (43)$$

$$P_{\text{el}}(V,T) = -\sum_i \frac{d\epsilon_i(V)}{dV} [n_i(T) - n_i(0)], \qquad (44)$$

where $\epsilon_i(V)$ are the ground-state eigenvalues obtained from the same electron-band calculations used to generate $E_0(V)$ and $P_0(V)$, and $n_i(T)$ is given by the Fermi-Dirac distribution function. For $T < 0.1T_F$, the electron thermal components E_{el} and P_{el} are obtained from the exact low-temperature expansions for the free-electron gas,

$$E_{\text{el}}(V,T)=\frac{\pi^2}{6}N(E_F)(kT)^2+\cdots \tag{45}$$

and

$$P_{\text{el}}(V,T)=\frac{\pi^2}{6}\frac{\partial N(E_F)}{\partial V}(kT)^2+\cdots, \tag{46}$$

where $N(E_F)$ is the density of electron states at the Fermi energy E_F.

4.4 Empirical Equations of State

The finite-strain model developed by Birch (1978) provides a convenient analytic fit to data that makes it possible to determine the initial bulk modulus and its pressure derivatives. In the absence of phase transitions, it has also provided a reasonably reliable method for extrapolating EOS data.

An expression for the pressure is written as an expansion in terms of a strain function f,

$$P=3f(1+2f)^{5/2}K_0(1-2af+4bf^2+\cdots), \tag{47}$$

where

$$f=\frac{1}{2}\left[\left(\frac{\rho}{\rho_0}\right)^{2/3}-1\right],$$

and with ρ and K_0 being the density and bulk modulus, respectively (subscript 0 indicates zero pressure). The higher-order terms are related to the first and second pressure derivatives of the bulk modulus (denoted by primes):

$$a=\frac{3}{4}(4-K_0'),$$

$$b=\frac{3}{8}\left[K_0K_0''+K_0'(K_0'-7)+\frac{143}{9}\right].$$

The bulk modulus K_0 and its pressure derivatives K_0' and K_0'' can be obtained from a fit of $F=P/3f(1+2f)^{5/2}$ versus f.

The Murnaghan equation is a simpler, but less accurate, function often useful for the same purposes. It is written as

$$P=\frac{K_0}{B_1}\left[\left(\frac{\rho}{\rho_0}\right)^{B_1}-1\right], \tag{48}$$

which leads to the expression for the bulk modulus

$$K=K_0\ (\rho/\rho_0)^{B_1};$$

here B_1 is a fitting parameter found empirically to be about 4.

Vinet *et al.* (1989) have proposed an EOS of the form

$$P=3K_0(V/V_0)^{-2/3}[1-(V/V_0)^{1/3}] \times\exp\{\eta[1-(V/V_0)^{1/3}]\}, \tag{49}$$

where $\eta=3/2(K_0'-1)$. They have shown that this function is capable of fitting the EOS of a wide variety of materials to high compression.

5. MATTER AT EXTREME CONDITIONS

Systematic investigations of high-pressure properties date back to the 18th century. By the latter part of the 19th century, Amagat had extended the pressure measurements on gases to about 3 kbar. P. W. Bridgman, of Harvard, ushered in the modern age of high-pressure technology. Bridgman was actively engaged in high-pressure research from 1906 to his retirement in 1954 and received a Nobel prize in 1946. During and immediately after World War II, shock-wave research appears to have developed independently in the United States and the former USSR. References to the early history can be found in the reviews by Rice *et al.* (1958) and Al'tshuler (1965). A more detailed account of shock compression experiments is to be found in this encyclopedia (see HIGH-PRESSURE EFFECTS IN SOLIDS: SHOCK WAVES).

The Universe is a natural high-pressure laboratory where existing conditions may dwarf any conditions attainable in terrestrial laboratories. The center of the Earth has pressures of about 3.5 Mbar and estimated temperatures of 6000 K. The conditions in Jupiter's center are believed to be about 100 Mbar and 24 000 K. The centers of stars and white dwarfs have pressures in excess of thousands of megabars and with temperatures of tens of millions of kelvins. In neutron stars, pressure of millions of megabars are believed to exist. In an indirect way physicists have access to a laboratory in which densities go beyond 10^{15} g/cm^3 (Eliezer and Ricci, 1991).

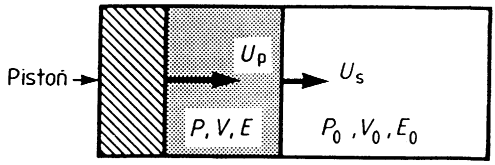

FIG. 11. Schematic of a shock wave traveling at a velocity U_s, driven by a piston moving with velocity U_p. In an experiment the piston is typically a metal plate accelerated to a constant velocity by means of a high explosive or a laser.

5.1 Static Experiments

In static experiments, the sample is squeezed between a set of opposing pistons or anvils (Jayaraman, 1983; see also HIGH-PRESSURE TECHNIQUES). Temperatures seldom exceed several hundred degrees Celsius. The highest pressures are obtained using opposed diamonds as anvils holding a sample between them. These are called diamond-anvil cells (DAC) and are currently capable of achieving maximum working pressures up around 400 GPa (4.0 Mbar) for transition metals and 200 GPa (2.0 Mbar) for rare-gas solids and hydrogen. The pressure is determined from a secondary standard such as the shift in the fluorescence frequency of ruby or the measured lattice parameter of a standard material such as platinum obtained from shock-wave studies (see Sec. 5.2).

5.2 Shock-Wave Experiments

In shock-wave experiments, a supersonic wave is passed through the material under investigation (Rice *et al.*, 1958; Al'tshuler, 1965; Zel'dovich and Raizer, 1966). A measurement of the shock wave and mass velocity are sufficient to determine the *P*, *V*, and *E* of the compressed state. Figure 11 illustrates a one-dimensional, steady, planar shock wave moving at a velocity U_s, generated by accelerating a piston from rest to some final constant velocity U_p, referred to as the mass or particle velocity. The width of the discontinuity is generally a few molecular mean-free-path lengths. The thermodynamic pressure, volume, and energy (P,V,E) behind the shock front are related to the initial properties (P_0,V_0,E_0) in front of the shock wave by the dynamic variables U_s and U_p through the Rankine-Hugoniot equations: conservation of mass,

$$V/V_0=1-U_p/U_s, \tag{50a}$$

conservation of momentum,

$$P-P_0=U_sU_p/V_0, \tag{50b}$$

and conservation of energy,

$$E-E_0=\frac{1}{2}(P+P_0)(V_0-V). \tag{50c}$$

Thus a measurement of U_s and U_p, with a knowledge of initial conditions, is sufficient to determine the *P*, *V*, and *E* of the compressed state. The resulting *P*-*V* curve is known as a Hugoniot and represents the locus of points that can be reached from an initial condition. Shock compression is typically accompanied by a large rise in temperature. Figure 12 shows some sample Hugoniots measured for various metals. Measurements have been carried out on most elements and a very large number of compounds (Marsh, 1980). Chemical explosives have been used to obtain pressures up to 1 Mbar in liquids and up to 13

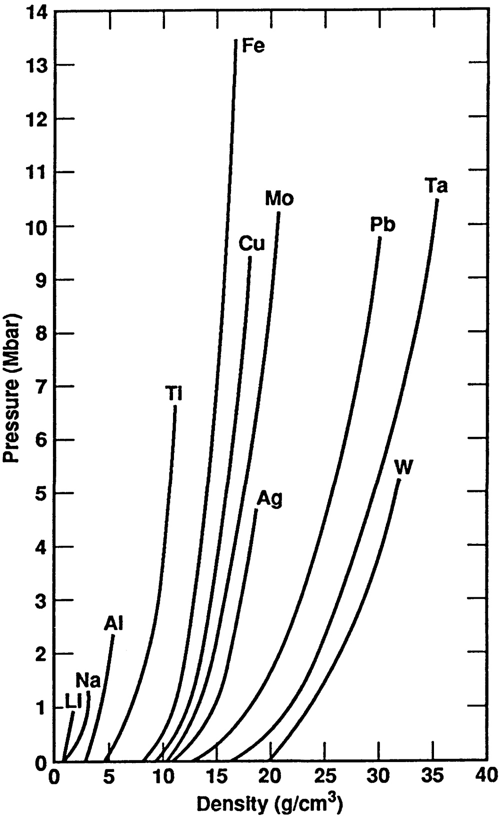

FIG. 12. Experimental Hugoniots for metals.

Mbar in metals, with accompanying temperatures of tens of thousands of kelvins. Final pressures ranging from 20 to 1000 Mbar have been reported using underground nuclear explosions (Avronin *et al.*, 1987). In inertial-confinement studies, pellets of liquid deuterium are subjected briefly to laser-driven dynamic pressures of about 1000 Mbar and temperatures in excess of 10^7 K.

Theoretical Hugoniots have been calculated for metals (Sec. 4), combining the zero-temperature pressure-volume isotherm calculated by electron-band theory with electron and ion thermal pressures as functions of volume [Eqs. (30)–(31)]. Figure 13 shows results for platinum (Holmes *et al.*, 1989). The isotherms obtained from reductions of Hugoniots are accurate to about 10% in pressure at a given density and can be used as pressure EOS standards for diamond-anvil-cell static compression experiments.

5.3 Pressure-Induced Transitions

With increasing pressure many solids undergo a series of structural transitions to more densely packed systems characterized by a greater number of nearest-neighbor atoms. At sufficiently high pressure all materials are expected to become metallic. Metallization may occur by the delocalization of valence electrons, as in the case of diatomic molecules and covalently bonded semiconductors, or with the crossing of an empty conduction band with a filled valence band as in closed-shell insulators such as the case of xenon (Reichlin *et al.*, 1988). The driving force in all insulator-to-metal transitions is electron delocalization, which lowers the kinetic energy by increasing the volume available to an electron.

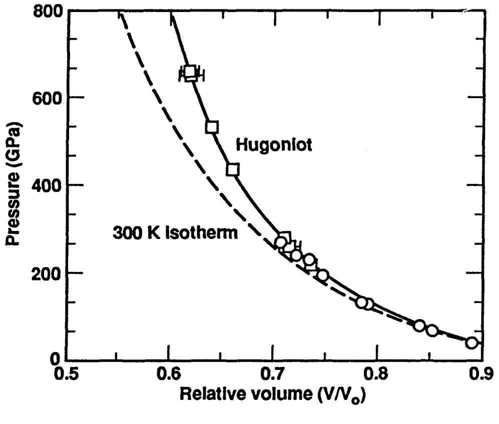

FIG. 13. Theoretical Hugoniot (solid line) for platinum and 300-K isotherm (dashed line), as compared against the Hugoniot data (squares and circles) (Holmes *et al.*, 1989).

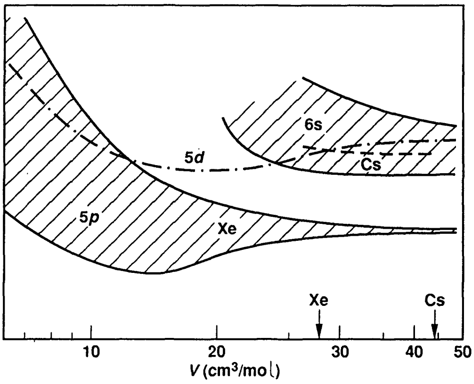

FIG. 14. 5*d* band effects in Cs and Xe. The location of the 5*p*, 5*d*, and 6*s* bands are shown schematically, plotted against atomic volume (in cm^3/mol). The Fermi energy of Cs is shown as a dashed line; the zero-pressure volumes by arrows. In Xe the Fermi energy is at the top of the 5*p* band.

Many of the interesting high-pressure structural phase transitions and irregularities in the equation of state can be understood in terms of systematic changes with compression in the electronic structure (McMahan, 1986). In most metals, valence *d* electrons are relatively localized and are closer to the nucleus than *s* electrons. Thus compression raises the energy of the *s*-state electrons, which transfer into *d* states, causing changes in the compressibility and structural stabilities. This is shown schematically in Fig. 14. Cesium, with a single conduction electron that is transferred from an *s* to *d* state, presents the most striking illustration of the rich pressure-induced effects in the phase diagram, Fig. 15. At higher pressures the *d* state, which is empty in xenon, crosses the filled 5*p* band, leading to metallization.

A feature of the trivalent rare earths is the sequence of structures hcp→Sm types →dhcp→fcc that are observed for decreasing atomic number from right to left across the series. Duthie and Pettifor (1977) have shown that it is the degree of *d*-band occupancy or the *s*-*d* transition that is responsible the for the observed crystal structure sequence without any significant participation of *f* electrons.

The high-pressure sequence of structures for the individual elements also follows this pattern. With a change in the lattice parameter, s electrons are transferred to d states and, in effect, change the properties of an element to resemble those of a neighbor.

5.4 Metallic State at Ultrahigh Density

The simplest model of a solid at extremely high density is the system of N ions in a volume V immersed in a uniform neutralizing background of electrons with density $\rho = N_e/V$ (Lundquist and March, 1983). A convenient parameter r_s is defined by $4/3\pi\, r_s^3 = 1/\rho$. Then the total energy is given by

$$E = \frac{2.21}{r_s^2} - \frac{0.916}{r_s} - 0.115 + 0.031 \ln r_s - \frac{A_M}{r_0} \text{ Ry per electron,} \tag{51}$$

where r_0 is the nearest-neighbor distance.

The first term is the electron kinetic energy. The second is the electron exchange, and the third and fourth are the Wigner approximation to the electron-gas correlation energy. Therefore the first four terms add up to the uniform electron-gas energy E_g. The final term, the Madelung energy, comes from the energy of point lattice charges in the uniform negative background. For the close-packed and body-centered lattices $A_M = 1.792$ and for the simple-cubic case $A_M = 1.760$. Structural stability calculations require more precise values. The Madelung term favors the bcc structure as the most stable. This implies the existence of a bcc phase at some very high density where electron band effects have been leveled out.

The one-component plasma (OCP) is a generalization of the electron-gas model to include the thermal motion of classical ions. The total energy is written as

$$E = E_g + \frac{3}{2} NkT + U_{\text{th}}, \tag{52}$$

where E_g is the uniform electron-gas energy, the second term is the ion kinetic energy, and third term is the ion thermal energy. Monte Carlo simulations have been used extensively to obtain the OCP solid and fluid equations of state and the location of the melting transition. DeWitt and co-workers (Stringfellow *et al.*, 1990) have reported accurate fits to U_{th} for the solid and fluid as a function of temperature and density. These fits are of the form

$$U_{\text{th}} = a\Gamma + b\Gamma^{1/4} + c + d\Gamma^{-1/4}, \tag{53}$$

where Γ, the plasma parameter, is defined as $\Gamma = (Ze)^2/a_s kT$, where $4/3\pi\, a_s^3 = N/V$. These data have been widely used to model liquid metals, dense plasmas, and ion mixtures.

5.5 Statistical Atom Models

Thomas-Fermi statistical atom models are probably the best known extreme-density theories and are often synonymous with the subject (Lundquist and March, 1983; More, 1979). These may be derived from the LDA to the total energy (Sec. 4.1) by introducing a local-density free-electron approximation for the kinetic energy as well as for the exchange and correlation. This further simplifies the numerical solution, but removes any vestige of the quantum shell structure. The description of the kinetic energy by a local approximation is only valid for sufficiently slowly varying electron densities. Accordingly, the replacement of the quantum-mechanical ki-

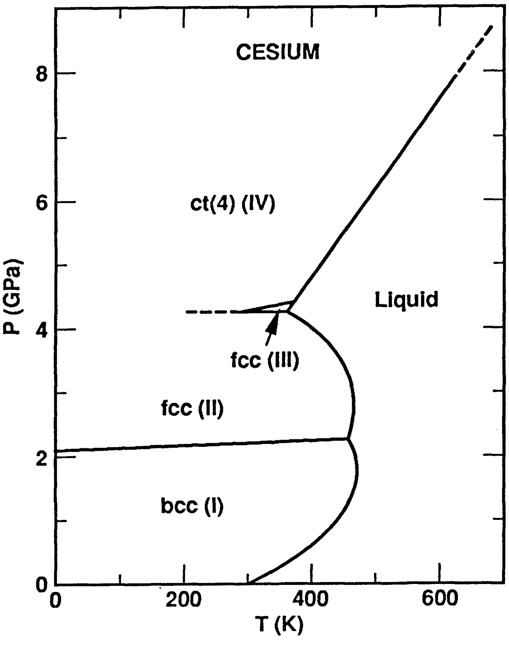

FIG. 15. Cesium phase diagram.

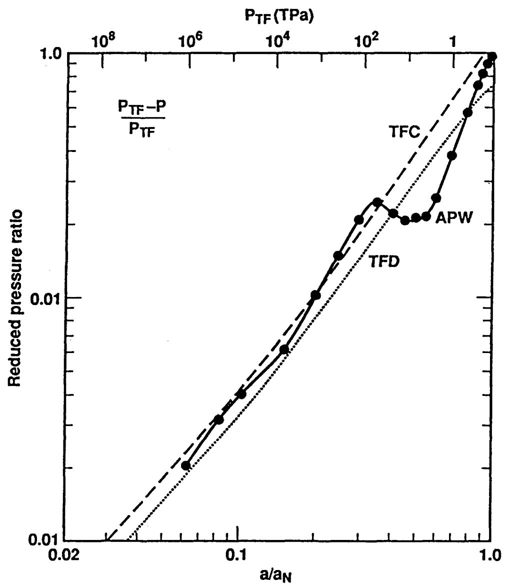

FIG. 16. Comparison of augmented-plane-wave (APW), TFC, and TFD pressures for aluminum. Pressures are given relative to P_{TF} as shown, and are plotted against reduced lattice constant. The data points indicate the actual APW calculations.

netic energy by its statistical analog should be carried out as an expansion in $\nabla\rho(r)$ and leads to

$$E=C_k \int \rho^{5/3}dV+\frac{1}{72}\int \left|\frac{\nabla\rho}{\rho}\right|^2 \rho\, dV+U_{ei}$$
$$+U_{en}+U_{xc}+U_{\text{ion-ion}}, \tag{54}$$

where

$$C_k=(3\hbar^2/10m)(3/8\pi)^{2/3}\ .$$

The gradient term has the virtue of preventing a large electron density near the nucleus. Statistical theories are generalized to finite temperatures by replacing $\rho(r)$ with the Fermi function $\rho(r,T)$. In this case the thermal contribution from $U_{\text{ion-ion}}$ can be approximated by U_{th} [Eq. (53)] using an appropriate value of Z. The requirement that E be minimized with respect to variations in the electron density is subject to the condition that the number of electrons N remains fixed and leads to an integral equation from which the local charge density may be obtained:

$$\frac{5}{3}C_k\,\rho(r)^{2/3}+\frac{1}{72}\left|\frac{\nabla\rho}{\rho}\right|^2\ \frac{1}{36}\frac{\nabla\rho}{\rho}+V_{en}(\bar{r})$$
$$+e^2\int d\bar{r}'\,\frac{\rho(\bar{r}')}{|\bar{r}-\bar{r}'|}+\frac{d(U_{xc})}{d\rho}=\mu. \tag{55}$$

This is the statistical-model analog of the one-electron Schrödinger equation [Eq. (35)] where μ, the chemical potential, replaces the one-electron eigenvalue. The pressure may be determined from the virial theorem [Eq. (36)].

The neglect of the gradient term and correlation energy leads to the Thomas-Fermi-Dirac (TFD) theory, and the additional neglect of exchange leads to the Thomas-Fermi (TF) model. The great virtue of TF is that all its properties scale with Z, and a single set of calculations at all densities for one Z suffices for all Z. This feature is not present in the other statistical models. The TFC theory is an attempt to include exchange in TF while retaining its advantageous scaling features by using the TF charge densities (ρ_{TF}) to approximate ρ in TFD.

5.6 Shell-Structure Effects in Compressed Solids

The major disadvantage of the statistical models is that although they often predict average properties reasonably well at very high pressure, they fail on details because they ignore the electron shell structure of the atoms. A more satisfactory treatment of electrons in solids rigorously including shell structure is the self-consistent LDA method.

In Fig. 16, the LDA pressure-volume isotherm as calculated by LDA methods is compared with predictions of the TFD and TFC statistical models. All results are shown relative to the larger Thomas-Fermi pressures according to the reduced pressure ratio ($P_{TF}-P)/P_{TF}$. The calculations show two well-defined deviations in pressure from predictions of the statistical models for the aluminum isotherms. These occur as first the L- and then the K-electron shells are pressure ionized. The pressure deviation due to shell effects in the first case corresponds to an oscillation of about 13% amplitude about the statistical-model pressures, and occurs over the range 5 to 75 TPa.

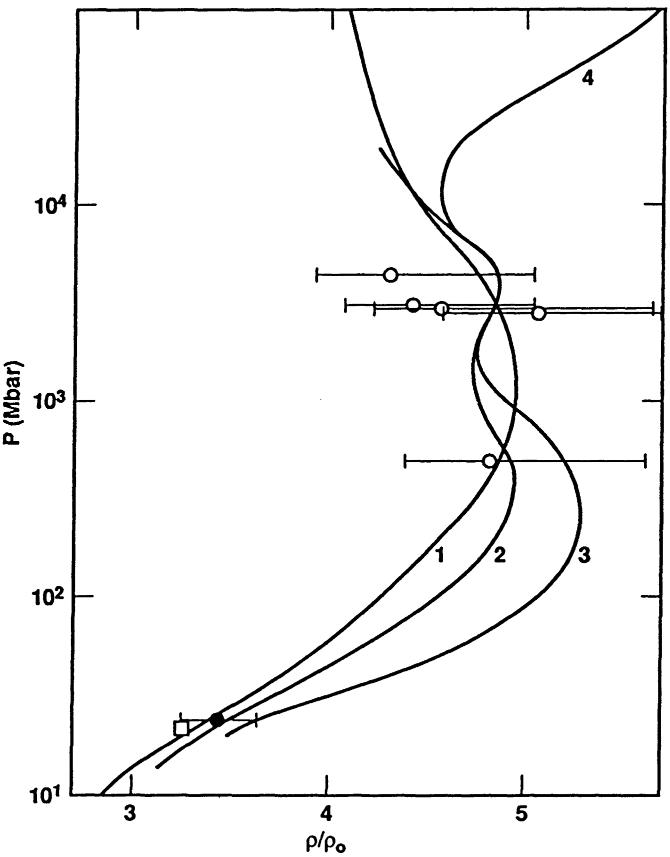

FIG. 17. Experimental data (of pressure versus compression ρ/ρ_0) for shock-compressed Al compared to a Thomas-Fermi calculation (curve 1) and two LDA-type models (curves 2 and 3). Note the oscillations in the latter. Thermal radiation effects (curve 4) appear above 10^4 Mbar. (Vladimirov *et al.*, 1984.)

Underground nuclear explosions have been used to generate pressures of up to 10^3 Mbar in shock experiments with metals an attempt to discover possible shell effects (Avrorin *et al.*, 1987). Figure 17 shows some experimental data for aluminum. They are compared to theoretical calculations made with a temperature-dependent Thomas-Fermi and local-density model that includes electron structure. Although the experiments are not sufficiently accurate to distinguish between theories, the predicted effect of shell structure on the calculated Hugoniot is seen clearly.

ACKNOWLEDGMENT

This work was performed under the auspices of the U. S. Department of Energy by Lawrence Livermore National Laboratory under Contract No. W-7405-Eng-48.

GLOSSARY

Bose-Einstein Statistics: A counting method used in quantum statistical mechanics that allows an unlimited number of particles (bosons) to occupy a single state. This applies to phonons and particles with zero and integer-valued spins.

Corresponding States: The scaling of thermodynamic variables of liquids by taking the ratio of their values in the liquid to those at their critical point.

Diamond-Anvil Cell (DAC): A technique that employs a set of opposing diamonds to obtain measurements of the EOS and optical properties of materials at high pressure.

Electron-Band Theory: A generic term for the collection of methods used in solving the quantum-mechanical (Schrödinger) equations for electrons in a lattice.

Fermi-Dirac Statistics: A counting method used in quantum statistical mechanics that allows no more than one particle (fermion) to occupy a single state. This applies to electrons and particles with half-odd-integer–valued spins.

Grüneisen Constant: Ratio of the logarithmic derivative of the Debye temperature to that of the volume. Used to calculate the thermal properties of a solid.

Hugoniot: Locus of pressure-volume points that can be reached by a shock compression experiment starting from a given initial condition.

Lattice Dynamics: Refers to the vibrations of atoms in a solid about their equilibrium positions and the effect of these vibrations on the properties of the solid.

Local-Density Approximation: The simplification made in atomic and molecular physics for replacing the complicated electron exchange and correlation energies by simple free-electron-gas expressions.

Mie-Grüneisen Equation: An equation of state of the solid that employs the Grüneisen constant to calculate the thermal contribution to the pressure.

Molecular Dynamics: Computer simulation of molecular properties using numerical integration methods to solve Newton's equations for N interacting particles.

Monte Carlo Method: Computer simulation of molecular properties using stochastic methods.

Phase Diagram: A convenient method of representing the stability regions of solid, liquid, gas, and plasma under the various conditions of temperature and pressure.

Plasma: An electrically conducting gas of ionized particles.

Pressure Units: Primary units are force/area or dyn/cm. Literature values are commonly quoted in terms of MPa (10^5 dyn), bar (10^6 dyn), kbar (10^3 bar), GPa (10^{11} dyn or 10 kbar).

van der Waals Equation: The first quantitatively successful equation of state that described the liquid-vapor branches of the phase diagram.

van der Waals Forces: Weak long-range interactions between neutral molecules.

INTRODUCTION

An electronic excitation capable of motion in an atomically dense medium is called an exciton. Frenkel (1931) introduced the concept during an investigation into how absorbed light is turned into heat in a crystal. Because of the translational symmetry of a crystal, the primary excitation resulting from absorption of a photon has no reason to reside at a particular site. Since the eigenstates of a crystal are wavelike, Frenkel argued, the excited state produced should act as a traveling wave packet whose energy is essentially that of the photon absorbed, until it decays into vibrational quanta (heat).

Early research on excitons concentrated on their role in determining the optical properties of crystals. It was concluded that strong exciton-lattice coupling led to broad Gaussian absorption lines; weak coupling, to narrow Lorentzian lines. Absorption features quite distinct from those associated with the production of free electrons and holes were predicted and observed. During the 1950s and 1960s, motion of the exciton was firmly established, either as diffusive, which is the case at virtually any coupling strength, or as ballistic

(describable by a velocity), which occurs in certain ideal cases involving weak coupling. Exciton diffusion is observed largely by experiments on doped crystals, where the dopant acts as a trap and detector (Simpson, 1956). In the ballistic case, the exciton velocity is measured by exploiting a subtle magnetic effect in very narrow spectral lines, as first demonstrated in cadmium sulfide at low temperature (Thomas and Hopfield, 1961).

The decay of the exciton usually results in some product other than pure heat, although a certain amount of heat is inevitably produced. Some possible outcomes are light emitted at a longer wavelength, free electron-hole pairs, bound electrons and holes in the form of stored chemical energy, and fission into two or more excitons. The exciton, whether mobile or not, is thus a very important first intermediate in many of the standard optically induced processes in condensed matter.

Currently the exciton plays many useful roles. The optical properties it contributes are a source of much detail about energy-band structures of solids. Its relatively enhanced absorption strength and nonlinear behavior in quantum wells are important for engineering the optoelectronic properties of materials. Exciton transport is used to transport light effectively through submicron passages. There is a good understanding of how the exciton participates in the initial processes of photosynthesis.

1. GENERAL PRINCIPLES

1.1 Excitons as Excited States

Atoms, molecules, and ordinary condensed materials consist of very well characterized arrangements of nuclei and electrons. When a system is stably bound in its lowest electronic energy state, the electrons occupy certain orbitals. Electronic excitation of the system is well described as the placement of one electron into a different, usually more extensive, orbital.

1.1.1 Frenkel and Wannier-Mott Excitons. Figure 1 shows two limiting cases of the excitation process in condensed material, which for the moment we will assume to be a regular solid. In Fig. 1(a) the erstwhile bound electron, whose new orbital is shown as a stippled region, closely circles the core of an atom from which it has been lifted by the excitation energy. The "+" is meant to indicate two things: that the remaining atomic core is positively charged, having started out to be neutral, and that the electron previously resided in a well-localized position. Absent the remaining atoms, one would have merely an excited atom. It was this limiting case of excitation that Frenkel considered. Let this state of the system be denoted $\Phi_{\mathbf{R}}^{ex}$ and let **R**, the position vector of the excitation, represent any site of the system. In a regular lattice one can show, in analogy with the case of electron and vibrational states, that a good state of the system is $\Phi_{\mathbf{K}}=\Sigma_{\mathbf{R}}\exp(i\mathbf{K}\cdot\mathbf{R})\Phi_{\mathbf{R}}^{ex}$. Here **K** is a wave vector. (Because the lattice is regular, with each site being essentially identical to any other site, the different $\Phi_{\mathbf{R}}^{ex}$ are also essentially identical, except for the shift between cells.) Such a state is more nearly an energy eigenstate and is suited to describe particles or quasiparticles that move. In Frenkel's case the motion is that of a packet of energy, approximately the amount required to produce the related atomic excited state. No net charge is transported.

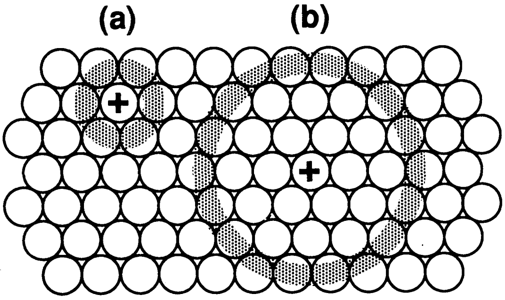

FIG. 1. Sketch of (a) the tightly bound (Frenkel) limiting case of the exciton and (b) the weakly bound (Wannier-Mott) case. In each case the hole, represented by "+," and the electron, shown in terms of a probability cloud around the hole, may move through the lattice as a unit.

Wannier (1937) and Mott (1938) observed that similar motion and energy transport would occur in the limit of a much more extended state, as in Fig. 1(b). There we see the electron quite distant from its associated positive charge. The pair form a quasi-hydrogen atom and Wannier showed that a hydrogenic series of energy levels would be obtained. Their excitation energies E_n would be given by

$$E_n = E_G - R_{ex}/n^2,$$

where E_G is the gap between the bands from which the hole and electron are taken, n is a positive integer, and R_{ex} is the "exciton Rydberg." It is precisely analogous to the hydrogenic Rydberg $R(=13.6\ \text{eV})$, differing from it only by factors resulting from the presence of a medium and the differing masses of the particles involved. The Coulomb attraction between the electron and hole is greatly reduced from that found in atomic hydrogen, because of the polarizable material intervening between them. The Wannier-Mott result was

$$R_{ex} = (13.6\ \text{eV})(1/\epsilon^2)(m^*/m),$$

where ϵ is the dielectric constant, m is the free-electron mass (the mass of the proton in the hydrogen atom is neglected), and $m^* = m_e^* m_h^*/(m_e^* + m_h^*)$ is the reduced mass made up from the effective masses of the electron and hole.

The Wannier-Mott exciton is observed extensively in semiconductors where the dielectric constant is indeed quite large; binding energies (R_{ex}) of tens of meV are common. Frenkel excitons are observed in molecular crystals and some ionic crystals, where binding forces are such that the molecules and ions retain fairly strong identities.

1.1.2 Intermediate Cases. Although we refer to Frenkel or Wannier-Mott excitons, the two are fundamentally the same and should be considered limiting cases of small and large radii, respectively (Knox, 1963, Sec. 5). In many materials, as illustrated especially well in the alkali halide crystals, excitons whose radii are of the order of one or two lattice constants occur. In this case the hole resides on the halide$^-$ sublattice and the electron mainly on the alkali$^+$ sublattice. Since halide$^-$ as a free ion has no bound excited state, there is no "atomic limit" or true Frenkel exciton, but in these materials the radius of the lowest-energy exciton can be relatively small nonetheless. In rare-gas crystals the two limiting cases of exciton clearly coexist. The lowest Wannier-Mott state ($n=1$) has such a small radius that it acts essentially as an excited state of a rare-gas atom; the higher states ($n=2,3,\ldots$) are so extended that they have a hydrogenlike series of energy levels.

1.2 Excitons as Bound Charge Carriers

Many crystal properties, especially the electrical, are best discussed in terms of their energy-band structure. In a typical semiconductor, electrons move relatively freely in conduction bands, holes in valence bands (Fig. 2). The band picture assumes completely independent particles and admits no excitons, which depend for their very existence on the Coulomb interaction between electrons and holes. In the absence of this interaction the lowest electronic excited state of the crystal occurs when an electron is lifted from a filled valence band to the conduction band. The energy required is E_G and there may or may not be a change in the wave vector of the electron [Figs. 2(a), 2(b)].

The band picture must be used with great care when electron-hole interactions become significant—for example, when optical properties at photon energies near E_G are involved or when electron-hole recombination occurs in a stepwise process, the first step being creation of an exciton by mutual electron-hole capture. The exciton is not a one-particle state, but it has a wave-vector–dependent energy that can be superimposed on a one-particle band diagram. In Fig. 2 exciton bands are shown as light dashed lines, and indeed excitonic optical features are observed at energies just below band-to-band optical features in these cases. One problem with generalizing this picture is that exciton bands are not necessarily closely associated with a nearby conduction band. For example, if the valence-band maximum were at the right edge of the zone in each of the two cases in Fig. 2, instead of at the center, the exciton would be indirect in (a) and direct in (b).

1.3 Role in Determining Material Properties

Excitons play a primary role in optical properties and a secondary role in others. One can appreciate the former by reference to the atom: if there were no "exciton effect," every atom would have only a ground state and a continuum of states, and therefore no line spectrum. However, merely taking account of the exciton effect, i.e., not ignoring the interaction between electrons and holes, does not guarantee the appearance of line spectra in solids. First, a band gap must exist in order to

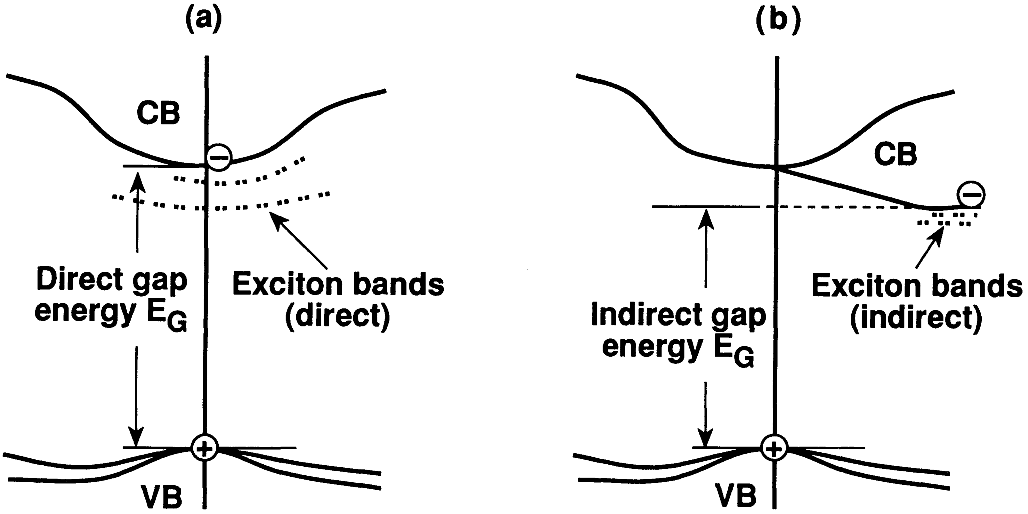

FIG. 2. Band structures in materials typical of (a) direct gaps and (b) indirect gaps. Energy is plotted vertically, wave-vector components (*k*) horizontally. Positive and negative *k* correspond to different directions in *k* space to convey the complexity of band structures. Dotted lines beneath the conduction bands (CB) show energies of excitons, relative to a zero of energy taken at the top of the valence bands (VB). The electron and hole symbols indicate the regions of one-particle space from which the exciton bands are constructed.

permit observation of bound states. Then selection rules, which are atomiclike only for direct-gap excitations, may greatly restrict the formation of lines or change them into continua because of the involvement of phonons.

1.3.1 Optical Properties. The spectral range of interest here spans the visible spectrum and parts of the infrared and ultraviolet. This corresponds to band gaps of 0.5 to 5 eV, typical of semiconductors and insulators, although excitonic phenomena also influence optical properties at even smaller bandgaps.

1.3.1.1 Absorption Figures 3(a)–3(d) show four typical and widely divergent cases that are useful for discussing general principles.

As in the case of any absorption process, the cross section (σ) at photon energy E may be separated into two factors,

$$\sigma(E) = |M|^2 f(E),$$

where $|M|^2$ is an overall strength factor and $f(E)$ is a shape factor. $|M|^2$ depends on the exciton size, on the symmetry of the electronic band states involved, and on exciton-phonon coupling strengths when phonons are required to allow the transition. $f(E)$ is essentially a density of states, weighted by factors depending on the "directness" and "allowedness" of the transitions involved. For excitons constructed from bands resembling those in Fig. 2(a), $f(E)$ can be dominated by strong distinct lines, such as those appearing in the absorption spectra of solids in the Frenkel limit [RbBr, Fig. 3(a)]. In the case of Cu_2O, Fig. 3(b), directness is seen in the sharp lines but a phonon-assisted continuum is seen because the lines have relatively weak transition probabilities compared to the phonon-assisted background. Indeed, the $n=1$ line is so weak as to be virtually invisible in this spectrum. Cu_2O is an example of a solid in which the conduction and valence bands have the same parity, so that the envelope must be *p*-like [not spherical, as in Fig. 1(b)], drastically reducing the factor $|M|^2$.

In GaAs [Fig. 3(c)], an exciton series exists but suffers considerable phonon broadening and blends into the electron-hole continuum. Finally, in AgBr, we see an "indirect" exciton spectrum in which $f(E)$ consists of a series of steps. No lines are seen because exciton-lattice interaction is required to allow any transition at the edge, and the lattice vibrational continuum produces a range of allowed energies. The lowest shoulder, due to simultaneous photon and phonon absorption, disappears at low temperatures because few thermal phonons exist.

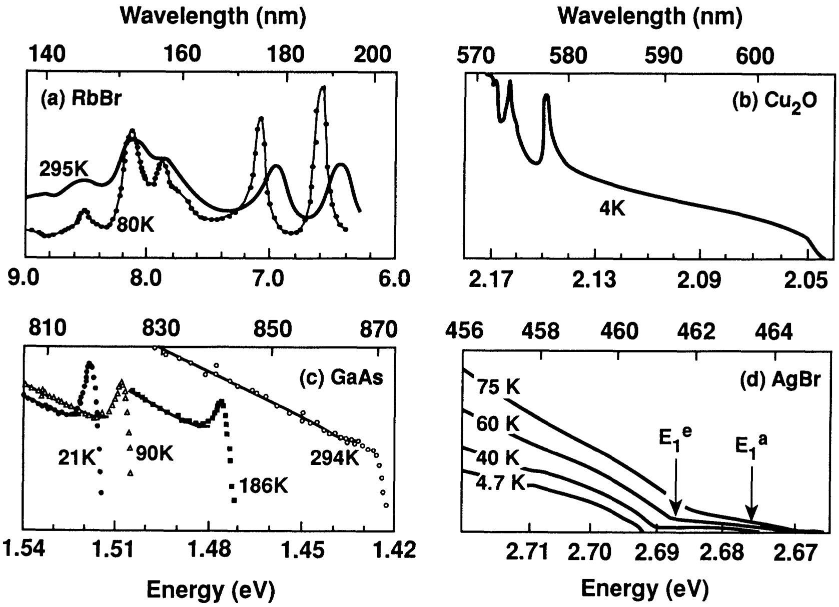

FIG. 3. Optical absorption spectra at temperatures indicated. (a) RbBr, Frenkel/intermediate case with strong lines (after Eby *et al.*, 1959); (b) Cu_2O, clear Wannier-Mott case (after Baumeister, 1961); (c) GaAs, Wannier-Mott case with line broadening greater than the spacing (after Sturge, 1962); (d) AgBr, indirect-gap mixed case showing no spectral lines, but two shoulders, one due to phonon absorption, beginning at E_1^a, and one to phonon emission, beginning at E_1^e (after Joesten and Brown, 1966). Vertical axes represent absorption coefficient in cm^{-1}, with maximum scales of (a) 7×10^5; (b) 320; (c) 1.2×10^5; (d) 4.

1.3.1.2 Emission and Nonlinear Effects. Exciton states may decay radiatively, but this process competes weakly with nonradiative decay modes. Emission is seen at low temperatures as lines near the band-gap energy ("edge") and as a Stokes-shifted band when strong coupling to phonons exists.

At high exciton densities optical properties of a material may be affected significantly. This topic, which is of great practical interest, is discussed in Sec. 2.

1.3.2 Other Properties. As neutral quasiparticles, excitons cannot participate in dc conductivity. However, they act to change the photoionization spectrum from what might be expected on a simple band model and they act as intermediate states in the electron-hole recombination process.

1.4 Other Topics

1.4.1 Exciton Trapping. The interaction of an exciton with crystal imperfections can greatly alter its state during its lifetime. As a moving packet, it is scattered by phonons and point defects. Strong interaction with phonons leads to self-trapping (Toyozawa, 1980), a state in which there is slow diffusive motion or no motion at all. Similarly, the exciton's energy may be transferred to an excited state of an impurity having energy lower than that of the exciton. Then being out of resonance with states of neighbors, the excitation is again immobile or trapped. On the band picture, when a hole is trapped at an acceptor, it may capture an electron into a stable orbit before recombination occurs. The result is again a trapped exciton. In the semiconductor case this state will generally have a large radius, like that of the free exciton in Fig. 1(b), and be fairly easy to ionize.

1.4.2 Exciton-Exciton Interactions. Under high-intensity excitation a material may become populated so densely with excitons that collisions between them are likely during their lifetime. As densities increase, this phenomenon is revealed in one of two ways: the formation of biexcitons (Knox *et al.*, 1969), whose energy is slightly less than twice that of one exciton because of the binding; or annihilation (Northrup and Simpson, 1958), in which a localized Auger process takes place resulting in heat, carriers, and either one exciton remaining or none. Whether biexciton formation or annihilation occurs is a question of competing rate processes. Biexcitons are generally observed in semiconductors and annihilation in molecular crystals.

At fairly high excitation densities in Cu_2O, behavior corresponding closely to Bose-Einstein condensation occurs; the exciton provides perhaps the only example of this phenomenon other than the case of liquid helium (Snoke *et al.*, 1990). Under very high excitation, a new phase can appear in which excitons have coalesced into electron-hole droplets (e.g., in silicon; see Gourley and Wolfe, 1978). These new phases are particularly interesting in the case of Cu_2O because conditions are very favorable for the observation of condensation. Cu_2O has a forbidden direct gap that provides excitons with long lifetimes, a small exciton Bohr radius and large exciton binding energy, and certain characteristics that minimize the likelihood of the presence of stable exciton pairs and the electron-hole liquid (Wolfe, 1992).

2. EXCITONS IN SEMICONDUCTORS

2.1 Crystals: General Remarks

Semiconductors have relatively large dielectric constants and relatively small electron and hole effective masses near the band extrema. Therefore, excitons in bulk semiconductors are spatially extended and are well-described by the effective-mass approximation in the Wannier picture. Excitonic effects appear at the fundamental absorption edge in III–V materials, and also at the direct edge of group IV materials such as Si and Ge with approximately 1–10-meV binding energies. In bulk GaAs material, the exciton Bohr radius is 14 nm, corresponding to a 4.2-meV binding energy. A large body of literature on excitons in bulk semiconductors exists. See, for example, Dimmock (1967), Pankove (1975), and Rashba and Sturge (1982).

The detailed optical characteristics of excitons are excellent probes of the microscopic crystalline quality since they display great sensitivity to crystal growth conditions, defect structures, temperature, strain, and applied electric and magnetic fields. In addition, excitonic absorption properties display dramatic density-dependent effects, with large changes in absorption observed at either high doping densities or high optical excitation levels. These properties bring important new considerations to optical device applications.

2.2 Quantum Wells, Wires, and Dots

2.2.1 Electron and Hole States in Two and Three Dimensions. As a result of recent advances in materials science, it has become possible to fabricate semiconductors one of whose dimensions is of the order of the exciton diameter in the bulk. Layered semiconductor structures have been fabricated by a number of different techniques in different material systems, such as GaAs-AlGaAs and GaAs-InGaAs, with monolayer accuracy. As a result, the densities of states for electrons and holes are significantly altered, and the effects are apparent in the optical properties (Dingle *et al.*, 1974). Figure 4(a) shows the electron density of states for three- and two-dimensional (3D,2D) semiconductors. Whereas the 3D semiconductor exhibits a square-root den-

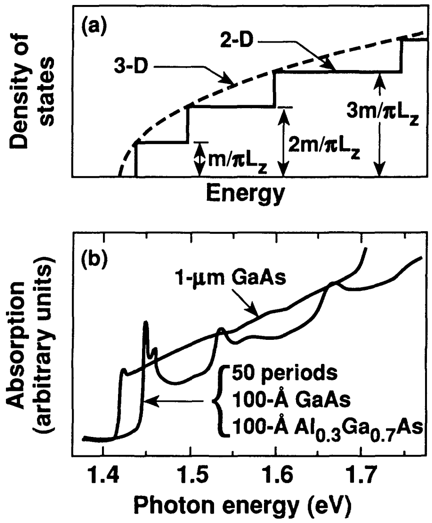

FIG. 4. Effect of dimensionality on properties of GaAs. (a) Densities of conduction electron states in bulk (3D) and in quantum wells (2D). The step heights involve *m*, the electron effective mass, and L_z, the confining well width. (b) Optical absorption in 3D and 2D samples of GaAs, showing the effect of the underlying density of states (after Schmitt-Rink *et al.*, 1989). The horizontal scales are slightly different; the major peaks in (b) correspond to steps in (a).

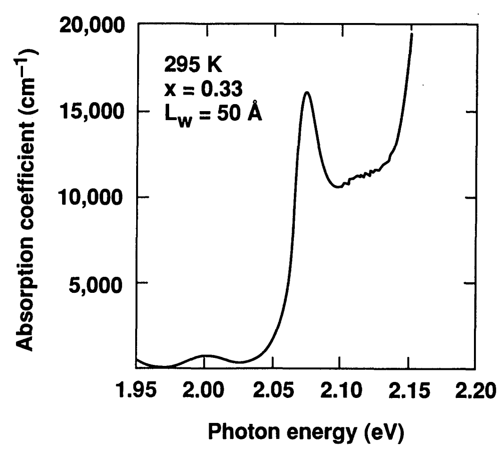

FIG. 5. Excitonic features in quantum wells of CdZnTe/ZnTe at room temperature (after Lee *et al.*, 1991).

sity of states, the 2D, or quantum-well, system exhibits a number of steps, as a result of the quantization of the electron into "particle-in-a-box" states. The effects of this quantization are clearly seen in experiments, as shown in Fig. 4(b) [see Schmitt-Rink *et al.* (1989)], which compares the absorption of bulk and quantum wells of GaAs. The valence bands are also significantly modified in quantum wells. One clear effect of quantum wells is the splitting of the heavy- and light-hole degeneracy at $k=0$ which occurs in bulk GaAs. As a result, two exciton lines are clearly observed near the band gap.

2.2.2 Modification of Exciton Properties in Two Dimensions. Figure 4(b) shows that at room temperature the quantum wells exhibit sharp excitons near each step in the density of states. In fact, each quantum subband has an excitonic feature that appears at a slightly lower energy (the binding energy) than the subband continuum. These sharp excitonic features in quantum wells are important for device applications, since excitons in quantum wells exhibit large sensitivity to applied fields and optical saturation effects. Figure 5 shows that excitonic features have also been obtained with room-temperature quantum wells in II–IV compounds as well: CdZnTe/ZnTe (Lee *et al.*, 1991). These systems are interesting for short-wavelength (<600 nm) applications.

2.2.3 Effects of Applied Electric Fields. Electric fields can be applied to quantum wells in two different field configurations: electric field parallel to and perpendicular to the quantum-well walls. The results are different: in the parallel field case, the exciton is readily field-ionized because there is no bound state in a parallel field. The exciton then broadens as the field is applied (Miller *et al.*, 1985) but does not substantially shift. The parallel-field effect has been used in femtosecond excitonic optoelectronics applications (Knox *et al.*, 1989b).

When the electric field is applied perpendicular to the quantum wells, the exciton shifts to lower energies but only slowly broadens, because the field ionization is significantly suppressed by the confinement of the electrons and holes. This effect (dubbed the "quantum-confined Stark effect") (Miller *et al.*, 1985,1986) forms the basis of a number of new and important optical modulators and related devices. Figure 6 shows the absorption in a quantum well waveguide for optical fields in different modes and for various perpendicular fields (Weiner *et al.*, 1985). In polariza-

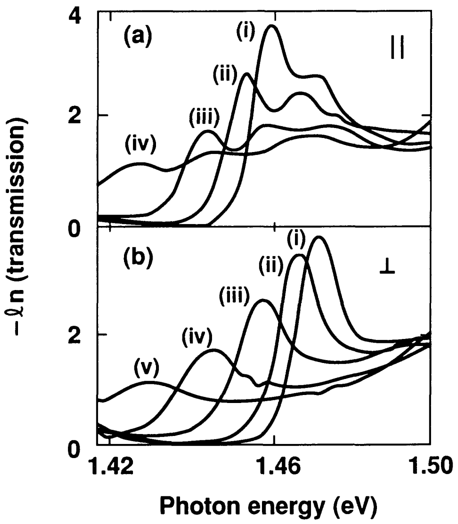

FIG. 6. Effect of electric field on properties of quantum-well excitons (after Weiner *et al.*, 1985). The applied dc field is perpendicular to the quantum-well walls in each case. The polarization of the incident light is (a) parallel and (b) perpendicular to well walls. Applied electric field strengths, in units of 10^5 V/cm and in order of increasing roman numerals: (a) 0, 0.6, 1.0, 1.5; (b) 0, 0.6, 1.1, 1.5, 2.0. Vertical axis: negative natural logarithm of the transmission coefficient.

tion perpendicular to the well walls [Fig. 6(b)] only the light-hole exciton is observed.

2.2.4 Device Applications of Quantum-Well Modulators. The achievement of a material system that offers large, fast, and sensitive light modulation by applied electric fields at room temperature opens the way for optical device applications. One such implementation is the "SEED" or self-electrooptic-effect device, which consists of a quantum-well modulator that contains a feedback loop (Fig. 7). Such a device operates as a light-intensity modulator that sets its own operating voltage, depending on the intensity of the incident light. This device exhibits bistable behavior that has been used to demonstrate a primitive optical computer (Miller, 1990).

2.2.5 Lower-Dimensional Systems. The steplike density of states obtained with quantum wells is further modified when the width of the sample also becomes comparable to the bulk exciton diameter, in a system called a "quantum wire." In a perfect wire, a one-dimensional density of states would result (Sercel and Valhala, 1990).

Although perfect zero-dimensional systems should exhibit a density of states reminiscent of sharp atomlike energy levels, at present inhomogeneous broadening and other effects prevent such an absorption spectrum from being observed. In the case of an applied magnetic field perpendicular to the quantum-well layers, the excitons are confined to essentially zero-dimensional states and a nearly perfect Landau-ladder absorption spectrum results (Akimoto and Hasegawa, 1967). By application of a strong magnetic field, the *ns* states of the excitons can be separated and studied. In CdSe, quantum dots only 3.0 nm in diameter have been prepared by a chemical technique (Brus, 1986). They exhibit a strong exciton peak, but not a characteristic density of states. Inhomogeneous broadening effects can easily mask such structure, since the energy levels depend critically on the particle size, which can vary by 20% or more.

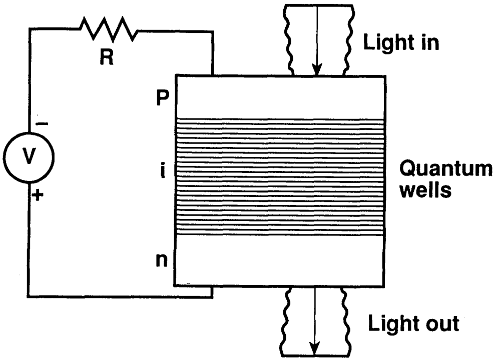

FIG. 7. Schematic of the self-electrooptic-effect device (after Miller *et al.*, 1985).

2.2.6 High-Density Effects. Excitons in semiconductors exhibit interesting and complex effects at high densities, by which we generally mean a density of one exciton per exciton Bohr radius cubed, or higher. Such densities may be achieved either by doping or by high-intensity optical excitations. In the case of quantum wells, excess electrons or holes can be produced by doping the barriers only ("modulation doping"; Dingle *et al.*, 1978). The excess electrons or holes then fill the quantum wells, leaving the ionized impurities in the barriers, and resulting in high in-plane transport mobilities. In such a case, excitonic features near the band edge are severely modified because of many-body interactions, and a correlation singularity called the "Mahan exciton" or "Fermi-edge singularity" results (Mahan, 1967a,b; Skolnick *et al.*, 1987; Livescu *et al.*, 1988).

At high excitation intensities, the excitonic nonlinear optical response is complicated. Excitonic absorption is affected in several ways by the injection of additional carriers. The exciton-exciton interaction contains screening terms, renormalization terms, and exchange terms. In addition, excitons have an ultrafast (300-fs) nonlinear response at room temperature due to exciton-phonon interactions (Knox *et al.*,1985) that has been used in various applications. AC Stark effects are exhibited by excitons when sub-band-gap excitation is used (Mysyrowicz *et al.*, 1986; Knox *et al.*, 1989a). In the case of high densities of optical excitations in modulation-doped quantum wells, carrier-carrier scattering times as short as 10 fs have been measured (Knox *et al.*, 1988).

2.3 Amorphous Semiconductors

Amorphous semiconductors are of great practical importance, but the line broadening resulting from their intrinsic disorder prevents observation of any ordinary exciton effects (see Zallen, 1983).

3. EXCITONS IN OTHER MATERIALS

3.1 Molecular Crystals

Of the many possible examples of molecular crystals, we will discuss a large subset that typifies them, namely, organic crystals. Low-lying electronic excited states of organic molecules usually involve rearrangement of the electron distribution among the same molecular π orbitals without a pronounced change in "size" of the molecule. Therefore, in organic molecular crystals, excitons are close to the Frenkel limit, and, to a first approximation, spectra are essentially perturbed molecular spectra retaining all their structural complexity.

3.1.1 General Characteristics. At normal temperatures, molecular-crystal spectra generally appear simply to be broadened and somewhat shifted spectra of the same molecules in vapor phase. The broadening is due partly to vibrations, partly to disorder, and only slightly to exciton band effects.

At low temperatures, where thermal broadening is greatly reduced, molecular crystal spectra can become exquisitely structured. The primary feature added to the molecular spectrum is "Davydov splitting," which is due to the interaction between like molecules having different orientations in the crystal's unit cell (Davydov, 1948). This effect is seen in Fig. 8. Light polarized in different directions is absorbed maximally at slightly different wavelengths, corresponding to the two Davydov exciton components. The broadened solution spectrum is also shown in Fig. 8 (Wolf, 1958).

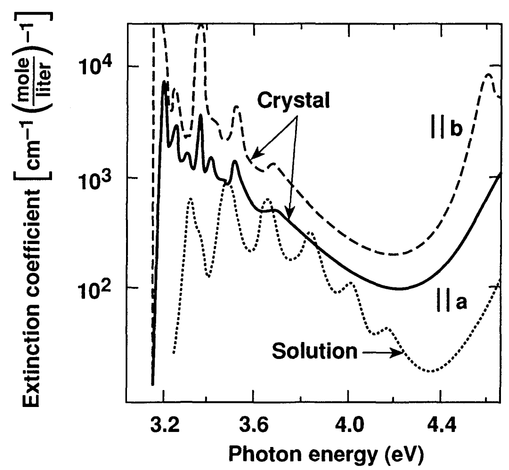

FIG. 8. Absorption spectra of anthracene in solution (lower curve) and as a crystal (two upper curves) (after Wolf, 1958). The crystal curves differ in the polarization of the absorbed light relative to the crystal axes, which are denoted "a" and "b."

3.1.2 Triplet States. The long lifetime of triplet excited states, which are well characterized in organics, affords the chance to examine transport and coherence of excitation over considerable spatial extents.

In most systems triplet states are difficult to observe optically because of the spin selection rule. However, they may be produced as decay products of higher excited states, and their spectral profile can then be found by an up-conversion process: an additional photon absorbed by the triplet itself leads to a highly excited state that (in anthracene, for example) fluoresces in the blue. The excitation spectrum for this process can be converted into what is essentially an absorption spectrum for the triplet (Avakian *et al.*, 1963). Another application of the blue fluorescence is its use as a detector of triplet excitons through their mutual annihilation, an effect that has been used to determine the diffusion constant of triplets (Avakian and Merrifield, 1964).

Exciton coherence is an important but complex topic. An excellent introduction and review, with special reference to organic crystals, is given by Burland and Zewail (1979).

3.1.3 Photon Channeling. The exciton carries the energy of the photon that created it, but need not occupy as large a volume. This fact, along with the ability of the exciton to migrate, has been put to practical use in recent proposals relating to designs of subwavelength-resolution microscopes (Lieberman *et al.*, 1989). Light channeled into a pipette with a gold-coated tip forms a subwavelength source, provided that the light is used sufficiently near the tip that diffraction effects do not wash out the channeling effect. However, the dimensions of the effective light source produced by this method are limited to about > 50 nm by evanescence, which reduces the contrast between tip and channel. The pipette is transformed into an active source by filling its tip with anthracene. The excitons formed in this crystal by the primary light source diffuse to localized emitters in the tip that then act as a secondary source of smaller dimension (Kopelman *et al.*, 1991).

3.2 Other Large-Band-Gap Crystals

3.2.1 Rare-Gas Crystals. In their ground states, crystals of the rare gases (Ne,Ar,Kr, Xe,Rn) resemble molecular crystals, because of their weak interatomic van der Waals attraction. However, exciton states in these crystals are much different because the electron must occupy an orbital of considerably larger spatial extent than the hole it leaves behind. This then places the electron in a region where the dielectric is effective in reducing the Coulomb interaction, and a Wannier-Mott series of exciton states is observed.

In a typical rare-gas atom, the ground state has a filled outer shell of p electrons (p^6), and the first excited state configuration is p^5s. Remarkably, the radius of the lowest-energy exciton is roughly the same as that of the excited s electron of the free atom. This coincidence has made the rare gases an ideal, though not entirely practical, class of solids in which to study the electronic structure of the exciton and its relation to band structures. Recent work has relied almost exclusively upon synchrotron radiation to produce the vacuum-ultraviolet photon energies necessary in these crystals, which exist at normal pressures only at very low temperatures (Schwentner *et al.*, 1985).

3.2.2 Ionic Crystals. Excited states that can now be recognized as excitons were first observed in the ultraviolet absorption spectra of alkali halide crystals. The typical strongly ionic crystal consists of closed-shell ions and is electronically very similar to the rare-gas crystal. For example, in NaCl, Cl^- is isoelectronic to Ar and the Cl^- sublattice has the solid Ar structure. See Knox and Teegarden (1968) for a general review.

Early workers interpreted strong absorption lines in the vacuum ultraviolet to an electron transfer process, in which one of the Cl^- electrons was moved to a neighboring Na^+. The energy required was related to the electron affinity of the halide, the ionization energy of the alkali, and the net difference in the Coulomb interaction felt by the electron. The state created is indeed just the lowest Wannier-Mott state built from hole states in the uppermost valence band (based almost exclusively on Cl^- orbitals) and electron states in the lowest conduction band (based largely on Na^+ orbitals) in which the radius of the exciton is such that is spends much time on the nearest-neighboring Na^+ ions.

Wannier-Mott absorption series exist in the alkali halides, but the existence of polar lattice modes prevents a complete analogy with the rare gases. At higher orbital radii, the low-frequency dielectric constant begins to dominate the effective Coulomb interaction and weakens the binding, so that by the time the electron and hole have enough energy to dissociate, they have become polarons. In addition, the hole usually becomes self-trapped on a pair of neighboring halide ions. This trapping process is so strong that the exciton itself is subject to it. This results in probably the largest known luminescence Stokes shifts (typically 3 to 4 eV) (e.g., Kabler, 1964).

3.3 Biomaterials

The bulk of biological material is transparent in the visible region because it consists of protein, nucleic acids, and lipids, all of which have few π-electron systems that would support transitions in the 2–4-eV range. The exciton is of known importance in certain pigmented proteins (Sec. 3.3.1), and as a radiation by-product may have some role in protein and DNA damage (Sec. 3.3.2).

3.3.1 Photosynthesis. The exciton is prominent in models of "light-harvesting," the first step in photosynthesis (see, e.g., Sauer, 1986). Hundreds of chlorophyll (Chl) molecules are associated with each photochemical reaction center in green plants. It has been found possible to model the Chls as a loosely packed molecular crystal in which excitons diffuse toward the "trap" where photochemistry is initiated.

An absorption spectrum typical of green plant chloroplasts is shown in Fig. 9. The strong bands in the vicinity of 1.88 and 3.1 eV (670 and 430 nm) are directly attributable to Chl; the remaining background absorption is due to "accessory pigments" that transfer energy to the Chl. Energy of light absorbed

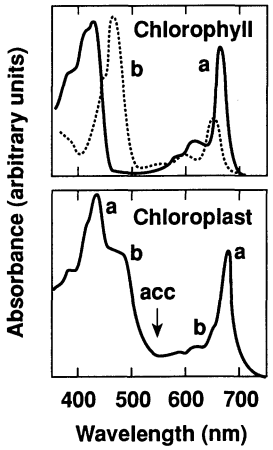

FIG. 9. Typical absorption spectrum of a chloroplast, here isolated from a spinach leaf (lower figure). The "a" peaks are due to chlorophyll-*a*, "b" to chlorophyll-*b*, whose individual absorption profiles are shown in the upper figure. The region "acc" involves accessory pigments that transfer energy to the chlorophylls. Excitons represented by the 670-nm "a" band act to transport absorbed solar energy to chemical reaction centers. (After Lin, 1991.)

anywhere in the spectrum quickly ends up in the 670-nm state of Chl somewhere on the lattice, and then migrates toward a reaction center by exciton diffusion. The several hundred chlorophylls are thus said to act as an "antenna." This colorful terminology refers only to the contribution of the Chls to the effective cross section for absorption.

Photosynthetic bacteria behave similarly, but rely on bacteriochlorophyll (Bchl), a form of Chl with its lowest singlet excited states in the 1.55-eV (800-nm) region.

3.3.1.1 Chlorophyll Aggregates. X-ray crystallography of proteins (see CRYSTALLOGRAPHY) has confirmed the basic hypotheses about the Chl antenna: the chromophores are packed closely enough for efficient energy transfer but loosely enough so as not to form photochemical quenching centers. One of the first antenna protein structures obtained was that of the photosynthetic bacterium *Prosthecocloris aestuarii* (Matthews *et al.*, 1979); see Fig. 10. The protein illustrated is one part of a trimer, and the trimers containing 21 Bchl are arrayed in the membrane to form the "loosely coupled molecular crystal." The excited eigenstates of the monomer are in fact delocalized, being linear combinations of localized excitations on the individual Bchls, and are close indeed to Frenkel's original exciton but on a microscopic to mesoscopic scale (Pearlstein, 1992).

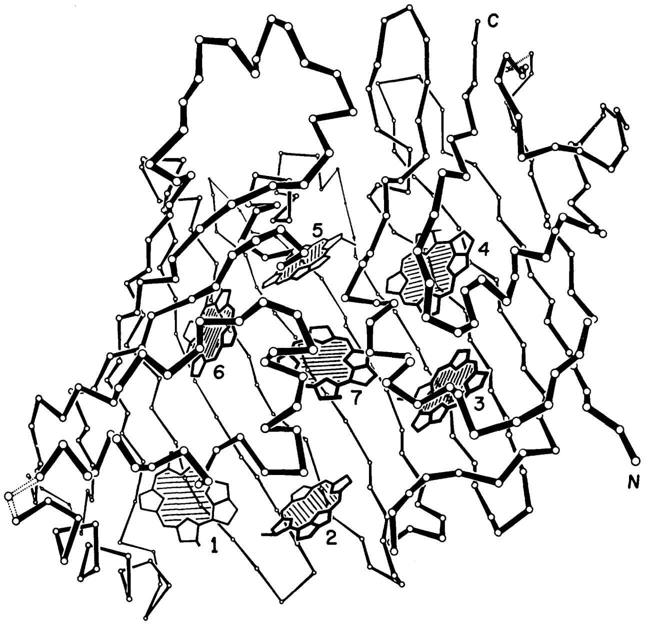

FIG. 10. Organization of a chlorophyll protein, in this case bacteriochlorophyll. The connected line segments represent the sequence of amino acids "packaging" the small numbered rings that represent the chromophores of the chlorophyll molecules. (Matthews *et al.*, 1979. Reproduced by permission of Academic Press, Inc.)

Transport of excitation energy into the trap (see next section) is very efficient. Chl fluorescence in green plants has an efficiency of about 2%, compared with 33% in solution. This corresponds to a trapping efficiency of 94%.

3.3.1.2 A Dimer State as a "Miniexciton." The lowest excited states of two strongly interacting identical molecules are a complete mixture of states of the individual molecules: $\frac{1}{2}(\Phi_A+\Phi_B)$, where Φ_A and Φ_B are states of localized excitation on the two molecules A and B, respectively. These two states are Frenkel's states for the case $N=2$ and have been termed "miniexcitons" in the organic crystal literature. The energy levels of the miniexcitons are above and below those of the monomer (Fig. 11). In photosynthetic organisms, evolution appears to have led to the construction of antenna-trap systems, exemplified by the sketch of Fig. 11. Anywhere from 50 to 300 chlorophyll molecules act as the antenna, supplying energy by exciton diffusion to the dimers, which act as photochemical traps and are the principal component of the reaction center. The traps mediate excitation-induced charge separation and the charges are directed to chemical systems capable of utilizing the energy.

3.3.2 DNA Damage. While their role in propagating destructive packets of energy along the bases in the helix structure of deoxyribonucleic acid (DNA) is not completely established, exciton diffusion is prominent in theoretical models of the process (Gueron and Shulman, 1968).

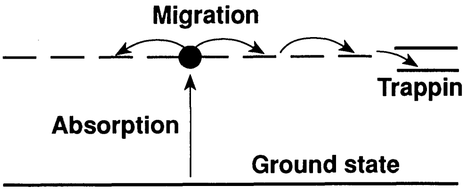

FIG. 11. Illustrating the principle of the photosynthetic antenna-trap system. Excited states of two strongly coupled "trap" chromophores, represented by the thick lines, lie above and below those of five identical weakly coupled "antenna" chromophores. An excitation packet, or localized exciton, makes a random walk over the antenna molecules, eventually falling into the trap. In practice, there are dozens of antenna chromophores arranged in three dimensions about the trap.

4. SUMMARY

The exciton is the first product of light absorption, and its characteristics are therefore frequently revealed by a material's absorption spectrum. The exciton may also be produced by an incident particle or by a quantum of ionizing radiation. It is a system state whose lifetime is usually in the subnanosecond range, but during that lifetime important energy transduction can take place. The exciton has an acknowledged practical importance in natural photosynthesis and it has recently become an increasingly important factor in the design of semiconductor quantum well devices.

GLOSSARY

Absorption Line: A sharp feature in an absorption spectrum characterized by A, an overall strength; ν_0, a center frequency; and Γ, a full width at half maximum. See Gaussian and Lorentzian.

Auger Process: A transition in which two electron-hole pairs recombine, with their mutual energy appearing as one highly energetic pair.

Bands: See energy bands.

Chloroplast: A micrometer-size unit in a cell of a photosynthetic organism. It contains light-harvesting chlorophyll proteins in membranes and much of the primary photochemical apparatus.

Chromophore: That part of a complex molecule containing the orbitals that are active in making optical transitions in the infrared and visible regions of the spectrum.

Coherence: A persistence of a definite phase relation in a state of a system. For the exciton it may be a relation to the phase of the excitation light or relationships between phases of localized wave functions making up the exciton.

Conduction Band: An energy band, normally almost empty in a nonmetal and lying higher than the valence-band maximum energy by an amount E_G, the band gap.

Crystal Imperfections: Any of several standardized departures from ideality in a crystal, important for determining properties of real crystals. Examples are vacancies, dislocations, excess electrons, surfaces, and phonons.

Density of States: The number of energy eigenstates per unit energy range, usually referring to states having a virtually continuous distribution of energies.

Effective Mass: The ratio of force to acceleration of a quasiparticle. In typical semiconductors the electron effective mass m_e^* is often much smaller than the ordinary electron mass, and the hole effective mass m_h^* usually comparable to or somewhat smaller than the ordinary electron mass. Even though no actual mass is transported, the exciton has an effective mass of $m_e^* + m_h^*$.

Eigenstate: The general quantum-mechanical equivalent of Bohr's stationary state. An energy eigenstate can be considered one of any system's "natural" states, one which would not change if the system had no external interaction.

Energy Bands, Energy-band Structure: The energies of orbitals of electrons in solids. The energies of the eigenstates fall into well-defined near-continua known as "bands." Each eigenstate is characterized by a wave vector k.

Exciton-Lattice Coupling: A contribution to the Hamiltonian (energy) of an exciton induced by vibrations of the crystal lattice about its average configuration (phonons).

Gaussian: A function of ν given by $A \times \exp[-(\nu-\nu_0)^2/2\sigma^2]$. See Absorption Line for symbol definitions. Here σ is related to the full width at half maximum by $\sigma = \Gamma\sqrt{8} \ln 2 = 2.355\Gamma$.

Heavy (Light) Holes: Holes in a valence band at whose maximum the effective mass is relatively larger(smaller); applies to cases in which the valence-band energies themselves are equal (degenerate), usually at $\mathbf{k}=0$.

Hole: A missing electron, in particular reference to an almost-filled atomic shell or energy band in a solid. Frequently likened to an empty space in an otherwise filled parking lot. It can move as a result of motion of the other electrons (autos). See also Effective Mass, Quasiparticle.

Landau Ladder: A sequence of quantum states of electrons in a magnetic field, so called because of its equal spacing of energy levels that is in turn due to the isomorphism of the problem with that of the simple harmonic oscillator.

Light Holes: See Heavy Holes.

Lorentzian: A function of ν given by $A(\Gamma/2)^2/[(\nu-\nu_0)^2+(\Gamma/2)^2]$. See Absorption Line for symbol definitions.

Phonon: A quantum of vibrational excitation in an extended system, usually possessing a wave vector $\mathbf{k}$, polarization (transverse or longitudinal), and type (acoustic or optical). The acoustic phonon has vanishing energy as $|\mathbf{k}| \rightarrow 0$.

Quantum Dot: One of an ensemble of small clusters of semiconductor material in a matrix of larger band gap, the ensemble having a very narrow size distribution with dimensions smaller than the radius of an exciton in the corresponding bulk material.

Quantum Well: A physical sandwich structure consisting of very thin (~ 10 nm) layers, usually of semiconductor material, designed such that electrons, holes, and excitons move essentially in two dimensions, confined by the "bread."

Quantum Wire: Similar to quantum dots and quantum wells but confined in two dimensions instead of in three and one, respectively.

Quasiparticle: A term applied to any localizable wavelike state of a condensed system whose motion can be approximated by simple particlelike dynamics. Typically the term is applied when the effective mass is nonzero: electrons (when characterized by an effective mass), holes, and excitons are examples.

Reaction Center: A molecular unit, usually a dimer composed of two identical chromophores, that accepts electronic excitation energy and mediates separation of charge in the first chemical step of photosynthesis.

Selection Rules: Restrictions on the allowedness of transitions between quantum-mechanical states, usually dictated by symmetry of the system.

Stokes Shift: The amount (in energy or wavelength units) by which the peak position of an emission band differs from that of the associated absorption band. It is a measure of the strength of the interaction between the excited state and the lattice.

Valence Band: An energy band normally mostly filled with electrons, often those participating in the covalent bonding of the solid.

INTRODUCTION

When the term "explosion" is mentioned, most people picture a violent, uncontrolled, chaotic event such as shown in Fig. 1. It is a principal purpose of this article to give a qualitatively different view of explosive phenomena. We will present a picture where explosive events are governed and rigorously describable in terms of the conservation of mass, momentum, and energy and certain material specific properties of the explosive material. Furthermore, we present evidence that when viewed experimentally, on the proper space and time scales, the observed phenomena are, in fact, orderly and, when variables are well controlled in the experiment, have some simplicity. The multiple-exposure photograph shown in Fig. 2 shows such a case.

Explosives have the property that they exist in an energetically metastable chemical state that can be controllably destabilized. The result of such destabilization can be extreme levels of power generation and extreme physical states in the explosive and its surroundings (e.g., very high pressure). Energy is released in a reactive wave process in which the passage of a shock wave triggers the stored energy release and, in turn, some of this

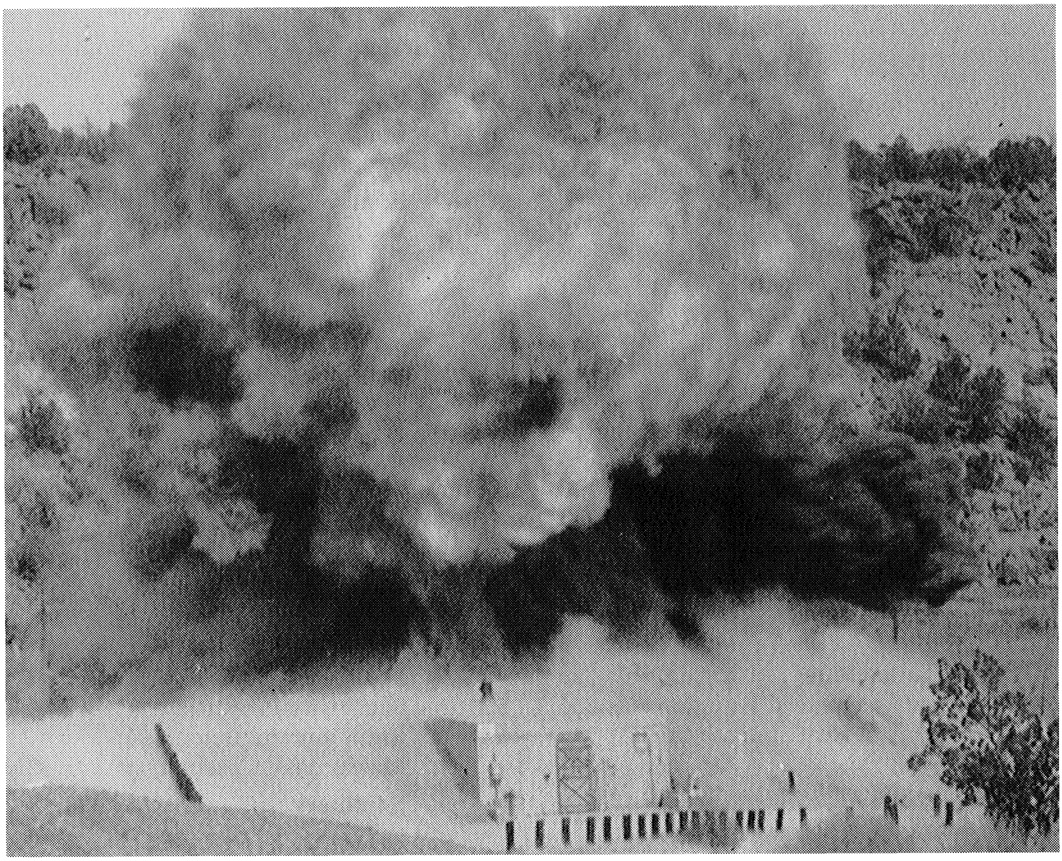

FIG. 1. Photograph of a large explosion at a firing bunker for explosive experimentation.

energy sustains the shock-wave motion: this is called a "detonation wave." Pressures produced in high-performance explosive detonations are typically in the 3×10^5-atmosphere range. The high detonation pressures mean that the explosive and any material (e.g., steel) in contact with it must be treated as compressible fluids using the principles of shock-wave physics.

Explosions and explosive action are not always due to high-explosive detonations; in fact, a wide variety of types and rates of reactions exist (depending on the particular metastable components involved). Types of explosive reactions range from nuclear explosions (the result of a nuclear chain reaction), to rapid first-order phase transitions (for example, vapor explosions such as occurred at Mt. St. Helens in 1980), to rapid burning of gunpowder, pyrotechnics, and propellants (such as occur in guns), to dust/air explosions (that sometimes occur in grain elevators). Detonating gas and condensed-phase explosives represent a significant part of the explosive reactions that occur. Rates of reaction range over six orders of magnitude (from a few millimeters per second to a few kilometers per second) depending on the particular phenomena involved.

Because of space limitations, we concentrate on condensed-phase materials that do work by detonation. Primarily because of their initial high mass density and the associated high energy density, liquid and solid materials have the most practical importance. However, most of the processes to be described are thought to occur both in condensed phases and in gases. The space scales are usually much smaller in condensed-phase materials; this makes it more difficult to measure and understand the processes in detail. Because of this, much of our understanding is

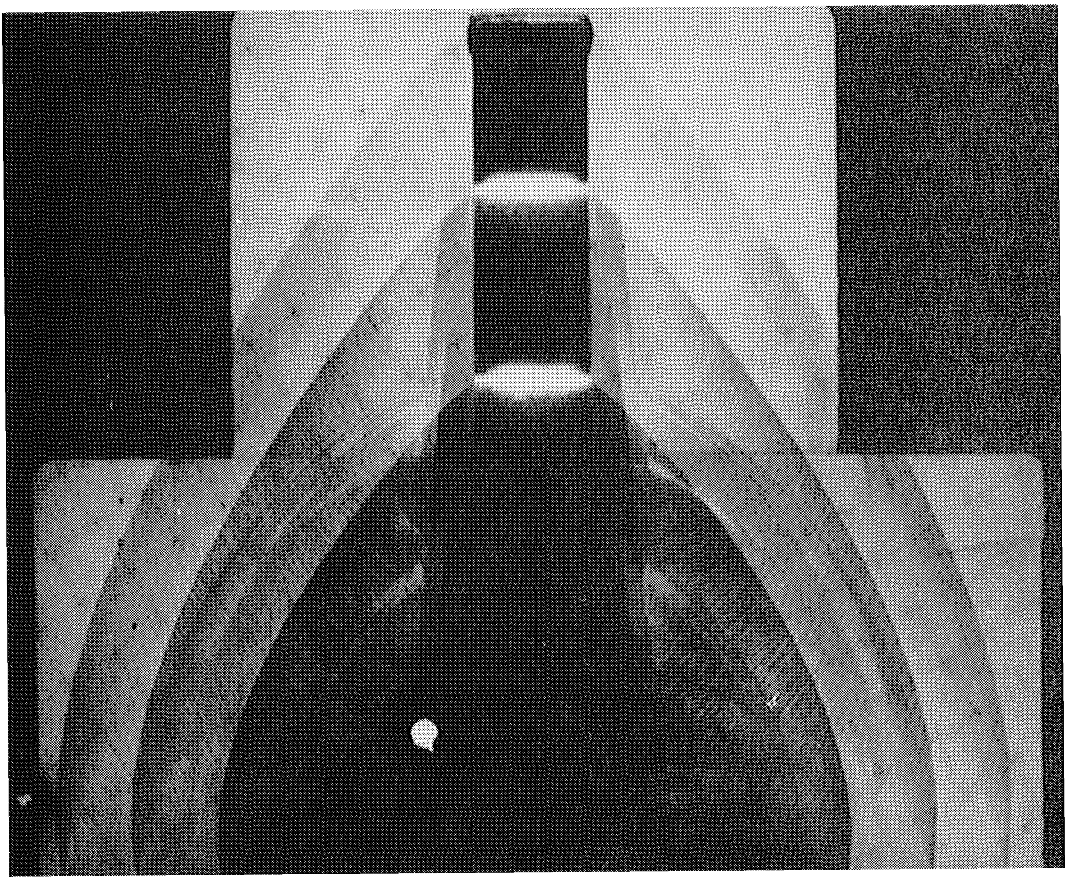

FIG. 2. Triple-exposure image-intensifier camera photograph of a detonation wave propagating in a cylindrical tube (ca. 10 cm diam) loaded with explosive. The detonation front at three locations can be clearly seen, along with the three associated shock waves driven into the surrounding liquid. The image converter tube was electronically shuttered to give an exposure time of 20 ns. This was done at three times about 40 μs apart.

phenomenological and is based on studies of one-dimensional (1D) waves and their interaction with the surrounding "confinement" material.

In chemical explosives, the energy storage is usually via the proximity of a fuel and an oxidizer. In high-performance chemical explosives the fuel and oxidizer are usually present in the same molecule (molecular explosives), but isolated by chemical bonds—e.g., TNT (2,4,6-trinitrotoluene). In lower- or special-performance chemical explosives, the fuel and oxidizers may be contained in components that are mixed together—e.g., mining slurry explosives.

In this article we begin by giving a short history of the theory of detonation and of explosive materials development (Sec. 1); only a few important details are covered to give some idea of the long and interesting history in this area. This is followed by two sections dealing with some of the important theoretical developments that have been made. Section 2 deals with planar steady detonation theory, including the conservation relations, simple shock-wave theory, and the two simple models that describe planar steady detonation. Section 3 discusses the general reactive fluid-flow equations, heat-release functions, equations of state, and various qualitative features of reactive flow. Theoretical solutions relating to complex systems are only briefly mentioned and most of our discussion of such systems is experimentally based. The experimental aspects of initiation and steady detonation are discussed in Sec. 4 including the differences between "homogeneous" and "heterogeneous" explosives. Section 5 contains chemical, detonation, and sensitivity information about certain selected high-explosive materials and discusses how some of the measurements in detonating materials are made.

By necessity, many details relating to explosive materials have been only briefly covered or have been left out altogether. For instance, deflagration, propellants, and pyrotechnics, even though they are important topics in some explosives circles, have only been mentioned. Further information relating to these and other areas can be obtained in the cited references and the articles indicated for further reading at the end of the paper.

1. HISTORY OF CONDENSED-PHASE EXPLOSIVES

Explosive technology has progressed from the use of rapid-burning materials to very sophisticated molecular explosives and explosive mixtures tailored to particular applications. This process has taken place over a period of more than a thousand years; major materials and theory advances have been made in the last 150 years. Our understanding of the physics of initiating and detonating materials is considerable, but much remains to be done to understand the microscopic chemistry. In this section we briefly discuss the history of explosive materials development and in what areas explosive materials are used today. This is followed by a short discussion of the development of theoretical concepts relating to detonation and the accompanying reactive flow.

1.1 Explosive Materials Development and Use

Explosive technology began when the oxidizer potassium nitrate (KNO_3, saltpeter) was discovered, probably in China or India. Fireworks were reported in China in the twelfth century. In England, Roger Bacon made the first pure KNO_3 and mixed it with charcoal and sulfur to make a form of black powder in about 1242. Berthold Schwarz, a German Monk, is credited with using black powder as a gun propellant in about 1300. A formula for black powder (in the weight ratio 75.0/15.62/9.38 wt %KNO_3/charcoal/sulfur, virtually the same mixture used today) was published in Brussels in 1560. This material began to be used as a blasting agent in mines in the 1600s and its use dramatically increased during the next 300 years.

Development of molecular explosives (materials in which the fuel and oxidizer are contained in a single molecule) started in 1846 when Sobrero (a professor at the University of Turin in Italy) discovered nitroglycerin (NG). It was promisingly powerful but dangerously unpredictable. When Immanuel Nobel and his son Alfred built a NG plant in Sweden in 1862 and invented an igniter for initiation in 1863, NG began to be used for blasting applications; this use was accompanied by severe accidents. By 1875 Nobel had learned that safety could be enhanced by absorbing the NG in *kieselguhr* (a porous siliceous earth) or by making a gelatin with a nitrated cotton material (nitrocellulose). These materials were called "dynamites" and gained almost immediate success in blasting operations.

TNT was developed in the late 1800s and became the main explosive used in World War I; it still is widely used today. TNT is relatively insensitive and melts at 79 °C so that it can be easily melted, mixed with other materials (such as aluminum), and then cast to a shape. More powerful materials, such as HMX (cyclotetramethylene tetranitramine), are now of great importance for weapons applications. Today, hundreds of molecular explosives are known, but only a relatively few have wide application.

After a disaster in 1947 in which two ships loaded with fertilizer-grade ammonium nitrate (AN) blew up in Texas City harbor, it became apparent that AN was an explosive. Shortly after, ANFO (a mixture of 94/6 wt % AN and fuel oil) was found to be a commercially valuable explosive. Through its cheapness and ease of preparation, this material rapidly became a very important blasting agent and remains so today. A blasting agents industry has developed, based on mixtures of nitrates, fuels, and other materials, in which explosives (slurries, emulsions, etc.) are tailor made for particular applications. These materials account for the bulk of explosives used today.

The blasting industry worldwide uses billions of kilograms of explosive products every year in mining and construction. Some products are fabricated by the action of explosives on them, e.g., explosive forming of complex metal shapes, production of small industrial diamonds from graphite, dissimilar-metal welding, and fabrication of intermetallics. Explosive materials are used in the space industry as components of the propellant in rocket engines, as well as to control and time events on rocket systems. Explosive devices and materials are used to enhance safety, e.g., auto air bags, aircraft ejector systems, safety flares, and the common safety match. The oil industry utilizes explosives to perforate well casings deep in the ground and to create seismic disturbances so that underground oil reservoirs can be mapped. Explosive materials (pyrotechnics) are used to create brilliant fireworks displays.

The weapons industry relies almost completely on the action of explosives for destructive purposes. Even nuclear weapons rely on specialized chemical high explosives and explosive components to create the proper conditions so that a nuclear explosion can occur. A variety of materials are used for igniters, rocket propellants, gun propellants, shaped charges, bomb fills, flares, etc.

Researchers, particularly physicists, use special explosive devices to create shock waves in inert materials so that states of matter (such as the conditions of pressure and temperature that occur deep in the earth) can be studied. Explosive action on specially designed electrical inductor systems can lead to extremely high electrical power outputs and magnetic fields that can be used to develop one-shot–device plasma guns, x-ray heads, or railgun particle acceleration systems. Transient light sources (useful for illuminating short time-scale events) a hundred times brighter than the sun can be produced by explosively generated shock waves in inert gas.

1.2 Appearance of a Quantitative Picture of Detonation

The first experimental observations (ca. 1880) of detonation waves (in gases) were made by French workers (Berthelot, Vielle, Mallard, and Le Chatelier). Later Chapman and Jouguet, independently, gave a theoretical treatment of detonation in gases (ca. 1900). In the Chapman-Jouguet (CJ) treatment, a detonation is idealized as a planar mathematical pressure discontinuity (shock wave) that propagates steadily. In the CJ picture, the passage of the shock causes complete release of the stored chemical energy; i.e., there is no spatially resolved zone of chemical reaction. The fluid mechanics required to devise the CJ picture comprises primarily the mass, momentum, and energy conservation-law jump conditions across a shock wave (the Rankine-Hugoniot conditions). An important result of the CJ treatment is that, given an energetic material, there is a minimum velocity at which a steady plane detonation wave can be propagated through it. The CJ theory is discussed in Sec. 2.3.

Later (ca. 1940), Zel'dovich, von Neumann, and Doering (ZND), independently, refined the CJ model by assuming that the conservation conditions of mass, momentum, and energy for inviscid flow (the Euler equations) apply, and by relaxing the assumption of an instantaneous heat release triggered by the shock. They modeled the chemical heat release as a single forward exothermic rate process. With the assumption that the chemical energy is released at a finite rate, one finds that a steady planar solution of the flow and shock-jump equations exists. This (ZND) detonation consists of a shock wave followed by a steady zone of chemical reaction. The hydrodynamic state at the end of the steady reaction zone is the CJ state, and the flow variables there are independent of the rate form. The fluid-mechanical state within the ZND reaction zone is *dependent* on the rate form. The ZND theory is discussed in Sec. 2.4.

Quite early on, it was experimentally recognized that detonations exist that show behavior significantly more complex than that described by either the CJ or ZND models. For instance, real detonation waves have (e.g.)

1. time dependence in the way they approach steadiness (see Sec. 4.1),
2. dependence on the lateral size of the explosive charge, even when the detonation is traveling steadily (see Sec. 4.2), and
3. inherent longitudinal and transverse instabilities (see Fickett and Davis, 1979, and Dremin *et al.*, 1970).

All of these complications have been studied theoretically and experimentally.

2. PLANAR STEADY DETONATION THEORY

The purpose of this section is to help the reader form an initial picture of what a detonation is. We give a quantitative treatment of a detonation as a shock-induced exothermic chemical reaction in which the chemical reaction, in turn, drives the shock wave. The reader should note that our treatment is for laminar steady detonation. The picture so derived is a useful reference point for interpreting the more complex space- and time-dependent cases discussed in Secs. 3–5. The laminar steady theories are particularly valuable because the mathematics required to obtain them is straightforward and because of the rarity of analytical solutions in more complex situations.

The simplicity of the theory of laminar steady detonation results from the simple form that the conservation relations for mass, momentum, and energy take in this case. These conservation relations are obtained in Secs. 2.1 and 2.2 and then used to obtain the CJ and ZND theories in Secs. 2.3 and 2.4.

2.1 Hydrodynamic Jump Conditions for Steady Laminar Flow and Across Discontinuities

The fluid flows characteristic of detonation are constrained by the conservation of mass, momentum, and energy. Therefore to discuss such processes quantitatively, we define the relations between mass, momentum, and energy at two locations (stations) in a *steady* planar compressible flow. We will use the term one dimensional (1D) to mean *planar* one dimensional. The fluid flow is viewed from a Galilean reference frame in which matter flows from left to right (see Fig. 3). The pertinent flow quantities at station 1 are the velocity at which matter crosses the boundary (U_s), the mass density (ρ_0), the pressure (P_0), and the internal energy per unit mass (E_0); the analogous quantities at station 2 are $U_s - u_p$, ρ, P, and E. The quantity u_p is the change in the mass velocity of the fluid as it undergoes the fluid-mechanical processes that occur between stations 1 and 2. Note that if the process causing the flow is a detonation wave moving from right to left (at speed U_s) in the laboratory frame, then the Galilean frame used to define stations 1 and 2 and to derive Eqs. (1)–(3) below is the one in which the wave is stationary; i.e., we have transformed from the laboratory frame to one in which the wave is motionless and matter streams through the plane defined by the wave. As drawn in Fig. 3, moving from station 1 to station 2 corresponds to a pressure increase and a mass-velocity decrease. As will be seen, this corresponds to stations 1 and 2 being in the unreacted and detonating material, respectively.

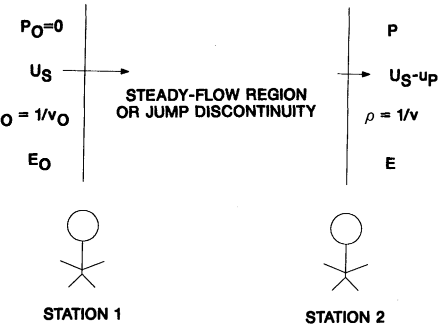

FIG. 3. Locations (stations) and quantities used in obtaining the conservation conditions in steady flow or across discontinuities.

Below we assume a special case where the pressure at station 1 is negligible relative to other pressures in the flow (i.e., $P_0 = 0$). As will be shown, typically in condensed-phase detonation $P_0/P \approx 10^{-5}$ when $P_0 = 1$ atm, and so this is a very good approximation.

The mass conservation condition under the stated conditions is that the mass flux at stations 1 and 2 must be equal, i.e.,

$$\rho_0 U_s = \rho(U_s - u_p). \qquad (1)$$

The momentum flux at a station is given by the mass flux there times the velocity at which matter crosses the boundary. This velocity is called the particle velocity, u_p. For stations 1 and 2, the values of momentum flux are $\rho_0 U_s^2$ and $\rho(U_s - u_p)^2$, respectively. The change in momentum per unit time per unit area between the two stations must be balanced by the pressure difference between the two stations, i.e.,

$$-P = \rho(U_s - u_p)^2 - \rho_0 U_s^2. \qquad (2)$$

Similarly, the change in flux of internal energy plus kinetic energy (per unit area per unit mass) between the two stations must be

12balanced by the rate at which the pressure difference between the two stations is doing work, i.e.,

$$-P(U_s-u_p)=\rho(U_s-u_p)[E+\tfrac{1}{2}(U_s-u_p)^2] -\rho_0U_s[E_0+\tfrac{1}{2}U_s^2]. \qquad (3)$$

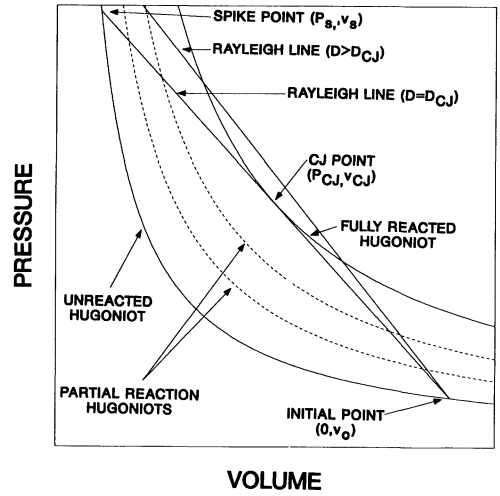
Note that the validity of Eqs. (1)–(3) does not depend on the station spatial separation. Thus, they can be applied to a flow discontinuity by allowing the separation between the two stations to approach zero. Used in this way they define the jump conditions (called the Rankine-Hugoniot conditions) across a detonation or shock wave.

2.2 Rayleigh Line and Hugoniot Curve

Relationships that a steady laminar detonation flow must obey can be obtained from Eqs. (1) to (3) by elimination of u_p and U_s. For example, eliminating u_p from Eqs. (1) and (2) gives

$$P=K(v_0-v), \qquad (4)$$

where $v\equiv 1/\rho$ is the volume per unit mass (specific volume) and $K\equiv\rho_0^2U_s^2$ is a parameter. Equation (4) is a straight line in P,v space. Two such lines, with different K values (slopes), are shown in Fig. 4; note that at fixed ρ_0, a larger slope corresponds to a larger wave speed. All 1D steady flow or flow across jump discontinuities [with initial state ($P_0=0$, v_0)] must have P, v values that satisfy Eq. (4) to conserve mass and momentum. Such a set of P,v points is called a Rayleigh line. The Rayleigh-line concept will prove useful below in defining what detonation processes are possible.



SPIKE POINT (P_s,v_s)
RAYLEIGH LINE ($D>D_{CJ}$)
RAYLEIGH LINE ($D=D_{CJ}$)
CJ POINT (P_{CJ},v_{CJ})
FULLY REACTED HUGONIOT
PRESSURE
UNREACTED HUGONIOT
PARTIAL REACTION HUGONIOTS
INITIAL POINT (0,v_0)
VOLUME

FIG. 4. Pressure-volume plane quantities useful in the discussion of the CJ and ZND models of detonation.

If both U_s and u_p are eliminated from Eq. (3) by use of Eqs. (1) and (2), one finds that

$$(E-E_0)-\tfrac{1}{2}P(v_0-v)=0. \qquad (5)$$

Thus, for 1D steady processes or for flow across shocks that start from the initial point ($P_0=0$, v_0, E_0), the final state must lie on the curve defined by Eq. (5), in order to conserve mass, momentum, and energy. If the process connecting the initial and final states is a single shock process, this E,P,v, relationship is called the Hugoniot curve of the shocked material. The Hugoniot curve defines all possible final shock states reachable from an initial state by a single shock process. The curve labeled "unreacted Hugoniot" in Fig. 4 is such a locus.

2.3 Chapman-Jouguet Theory

The Rayleigh line and Hugoniot curve are two equations in the three variables P, v, and E. A third independent equation $E=E(P,v)$ (i.e., an equation of state) closes this system and allows one to solve for permissible E, P, and v values in terms of the other parameters in the equations. This is how one obtains the Chapman-Jouguet theory of detonation.

In order to make the discussion of the CJ theory concrete we will specialize to a material in which the internal energy per unit mass is given by

$$E(P,v,\lambda)=Pv/(\gamma-1)-q\lambda, \qquad (6)$$

where γ is a constant characteristic of the material, q is the chemical heat stored in the material per unit mass, and λ is a parameter that measures the proportion of the chemical energy that has been released into the flow; $\lambda=0$ and 1 correspond to no and complete chemical reaction, respectively. The $Pv/(\gamma-1)$ part of Eq. (6) is called a "γ-law" equation of state (EOS). For condensed-phase explosives, a γ value of about 3 gives a reasonable description of many observed condensed-phase detonation phenomena. It is important to note that a γ-law EOS is not, necessarily, a "perfect gas" EOS. This can be seen by noting that for a perfect gas, γ (the ratio of specific heats, $C_p/C_v) = 1+2/n$, where n is the number of degrees of freedom available to the particles composing the gas. Thus, since $3 \leqslant n < \infty$, γ is constrained by $\frac{5}{3} \geqslant \gamma > 1$ for a perfect gas. The values $\gamma \approx 3$ useful in condensed-phase detonation allow the gas to be "stiffer" than is possible for a perfect gas.

Now suppose that a steady planar detonation wave moves at velocity D through a material defined by Eq. (6) and, in so doing, instantaneously releases the chemical heat present. The material before shock passage is at zero pressure and specific volume v_0, and is completely unreacted ($\lambda = 0$), i.e., $E_0 = E(0, v_0, 0) = 0$. After shock passage, the material is at pressure P, specific volume v, and completely reacted ($\lambda = 1$), i.e., $E = E(P, v, 1) = Pv/(\gamma - 1) - q$. The question can now be asked: What values of P and v do the conservation laws allow? Using the values of E and E_0 corresponding to before and after detonation wave passage in Eq. (5) gives

$$Pv/(\gamma-1) - q - \tfrac{1}{2}P(v_0 - v) = 0. \tag{7}$$

Equation (7) and the Rayleigh line [Eq. (4)] must both be satisfied if the conservation laws are obeyed.

Elimination of P from Eq. (7) by use of the Rayleigh-line condition yields a quadratic equation for the specific volume of the possible detonation states, i.e.,

$$v^2 - Bv + C = 0, \tag{8}$$

where $B = 2\gamma v_0/(\gamma+1)$ and $C = (\gamma-1)[1+2q/D^2]v_0^2/(\gamma+1)$. The value of $B^2 - 4C$ determines the number of real roots of Eq. (8). At this point, the value of D (the detonation wave velocity) is a free parameter in C, related to the slope of the Rayleigh line. When $D = \sqrt{2q(\gamma^2-1)}$, $B^2 - 4C = 0$ and Eq. (8) has one real root. For D larger (smaller) than this value, Eq. (8) has two (zero) real roots. The CJ detonation velocity is obtained if one assumes there must be a unique solution to Eq. (8). Geometrically this uniqueness of detonation velocity corresponds to tangency of the Rayleigh line and the completely reacted Hugoniot of the material (see Sec. 2.4).

At this point, the conservation conditions have given the important result that for $D < \sqrt{2q(\gamma^2-1)}$, a steady 1D detonation wave is impossible. When $D = \sqrt{2q(\gamma^2-1)}$, there is a unique value of the detonation wave velocity—this is the CJ value (D_{CJ}). It will be shown below that for a wave traveling at D_{CJ}, the flow at the CJ point is sonic relative to the following flow. Consequently, such a wave is immune from hydrodynamic disturbances from the rear (other than shocks).

Next consider the case where $D > D_{\mathrm{CJ}}$; in this situation there are two solutions. The solution with $P > P_{\mathrm{CJ}}$ (see Fig. 4) corresponds to a detonation wave that moves subsonically relative to its following flow and therefore can be attenuated by rarefactions from the rear. This solution is rejected as being uninteresting for this reason. The solution with $P < P_{\mathrm{CJ}}$ travels supersonically relative to the following flow. More will be said about this type of solution in the next section.

The solution of Eq. (8) for the specific volume at the CJ state is $B/2$; i.e., $v_{\mathrm{CJ}} = \gamma v_0/(\gamma+1)$. Substitution of v_{CJ} into the Rayleigh-line equation yields the CJ pressure $P_{\mathrm{CJ}} = \rho_0 D_{\mathrm{CJ}}^2/(\gamma+1)$. For $\gamma = 3$, one sees that $v_{\mathrm{CJ}}/v_0 = \frac{3}{4}$; i.e., the volume per unit mass is reduced by 25% for a γ-law gas at the CJ state relative to the uncompressed state. Typical measured values of ρ_0 and D_{CJ} for condensed-phase explosives are 1.80 g/cm^3 and 8.0 km/s. Use of these values (and $\gamma = 3$) in the P_{CJ} relation yields a CJ pressure of about 29 GPa (290 kbar); as a comparison, the yield strength of common steels is about 0.5 GPa. For these detonation parameters, *1 MW of power* is generated by a 1.9-cm^2 area on the detonation front.

Using results of the last paragraph, one can prove that the flow at the CJ point is sonic. A few other facts are needed for the proof. Firstly, note that if U_s is eliminated between Eqs. (1) and (2), one finds that $u_p = \sqrt{P(v_0 - v)}$. Use of P_{CJ} and v_{CJ} in this equation shows that $u_{\mathrm{CJ}} = D/(\gamma+1)$. Next note that the sound speed in a fluid is given by $c = \sqrt{(\partial P/\partial \rho)_S}$ (the S subscript denotes constant entropy) and that for a γ-law EOS the isentropes are given by $Pv^\gamma = \text{constant}$. Therefore $c_{\mathrm{CJ}} = \sqrt{\gamma P_{\mathrm{CJ}} v_{\mathrm{CJ}}} = \gamma D/(\gamma + 1)$, so that $u_{\mathrm{CJ}} + c_{\mathrm{CJ}} = D$; i.e., a sound signal at the CJ plane travels exactly at the detonation wave speed. We have proved the sonic characteristic of the flow at the CJ point for a constant-γ EOS. It is important to note that the sonic character of the flow at the CJ point is a general result and is true for any reasonably behaved EOS (Fickett and Davis, 1979).

2.4 Zel'dovich–von Neumann–Doering Theory

It is self evident that the CJ model assumption of an instantaneous chemical heat release is, at best, an approximation. Zel'dovich, von Neumann, and Doering (ZND) advanced the theory of steady 1D detonation beyond the CJ theory by finding a solution of the flow equations with a *resolved* chemical reaction zone (see, e.g., von Neumann, 1963). In this section, we derive the ZND model.

In the ZND model one assumes that the detonation process consists of a shock wave that takes the unreacted material from its initial state $(P,v,\lambda)=(0,v_0,0)$ to a "von Neumann spike" point $(P_s,v_s,0)$ that is still on the unreacted Hugoniot (see Fig. 4). Since the chemistry is now resolved, there is a continuum of partial reaction Hugoniots between the unreacted and fully reacted Hugoniots corresponding to different values of λ. For the γ-law form [Eq. (6)] these Hugoniots are given by

$$[Pv/(\gamma-1)]-\lambda q-\tfrac{1}{2}P(v_0-v)=0, \qquad (9)$$

where the value of the variable λ determines which partial reaction Hugoniot is being considered. In traversing the ZND reaction zone, one proceeds down the Rayleigh line from the spike point $(P_s,v_s,0)$ to the CJ point $(P_{\mathrm{CJ}},v_{\mathrm{CJ}},1)$—crossing the full set of partial reaction Hugoniots in the process (see Fig. 4). The q in Eq. (9) is the difference in enthalpy between reactants and products at the CJ state and is called the "heat of detonation" (see Sec. 5.2). Note that the chemical heat release in Eq. (9) is assumed to be governed by a single chemical progress variable (λ), and increased reaction always corresponds to increased exothermicity.

The fluid mechanics already discussed is sufficient to describe this process in detail because the flow in the reaction zone is steady. Thus, a space point in the unshocked material and any space point in the steady reaction zone constitute satisfactory stations 1 and 2 of Fig. 3—so the Rankine-Hugoniot conditions obtained in Sec. 2.1 are applicable. The (P,v,λ) state in the reaction zone corresponding to a particular λ is found by solving Eq. (8), but now with C defined as

$$C(\lambda)=\frac{(\gamma-1)}{(\gamma+1)}\left(1+\frac{2q\lambda}{D^2}\right)v_0^2. \qquad (10)$$

The detonation-wave velocity is determined from the tangency of the Rayleigh line and the *fully reacted* Hugoniot, i.e., again $D=\sqrt{2q(\gamma^2-1)}$, as in the CJ theory. The specific volume as a function of λ [$v=v(\lambda)$] can be obtained from Eqs. (8) and (10). The pressure through the reaction zone as a function of λ is obtained by use of $v=v(\lambda)$ in the Rayleigh-line equation [Eq. (4)].

We still do not know the reaction-zone structure in space or time [e.g. $P=P(x)$]. To proceed further one needs to know how the chemical heat is released as a function of the thermodynamic variables, i.e., a chemical rate relation of the form

$$\frac{d\lambda}{dt}=r(P,v,\lambda). \qquad (11)$$

By use of what has been found above, Eq. (11) can be written as $d\lambda=r(P(\lambda),v(\lambda),\lambda)dt$; integrating gives $\lambda=\lambda(t)$. Given $\lambda=\lambda(t)$, $P=P(t)$ and $v=v(t)$ are known, since $P(\lambda)$ and $v(\lambda)$ are known. The dependence of P and v on the spatial coordinate x is determined as follows. The spatial position of a fluid particle relative to the detonation shock is given by

$$\frac{dx}{dt}=D-u_p. \qquad (12)$$

We know from Sec. 2.3 that $u_p=\sqrt{P(v_0-v)}$, and we know $P(t)$ and $v(t)$ from the above work. Therefore Eq. (12) can be integrated to give a function $t=t(x)$, which, in turn, can be used in $P(t)$ and $v(t)$ to yield the functions $P(x)$ and $v(x)$, i.e., the space dependence of P and v through the ZND reaction zone. A typical particle-velocity snapshot of the ZND reaction-zone profile obtained through this process is shown in Fig. 5.

A striking physical result of the ZND theory shown on Fig. 5 is that the pressure *falls* through the ZND reaction zone. This result is implicit in Fig. 4, i.e., as one moves across the partial-reaction Hugoniots from $\lambda=0$ to 1, the pressure falls.

Consider the ZND picture for a Rayleigh line with $D>D_{\mathrm{CJ}}$; the solution with $P>P_{\mathrm{CJ}}$ is again rejected because the flow at the point of complete reaction is subsonic relative to the following flow. The solution with $P<P_{\mathrm{CJ}}$ cannot be reached from the spike point by moving down the Rayleigh line because of the absence of partial-reaction Hugoniots at some

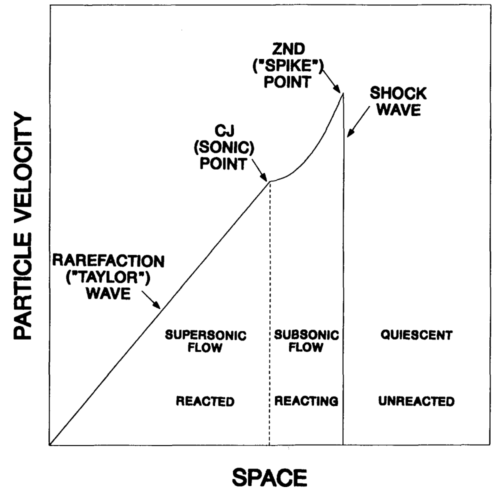


FIG. 5. Schema of the flow in a ZND detonation in the particle-velocity versus space plane; the Taylor wave is also shown (see Sec. 3.5).

points on the path and is rejected for this reason. More general types of the heat-release function (e.g., with reversibility of reaction or reactions with both exothermic and endothermic parts) can make the point with $P < P_{\mathrm{CJ}}$ accessible (see Fickett and Davis, 1979).

The main features of the ZND model are borne out by experiment; e.g., direct measurement of the particle velocity versus time in detonating explosives shows a particle-velocity discontinuity (shock front) followed by a zone of decreasing particle velocity (see Fig. 6). X-radiography of the explosive products have been used to show that the flow behind the shock does become sonic. This latter feature was done by tracking strong rarefaction waves introduced into the reaction products.

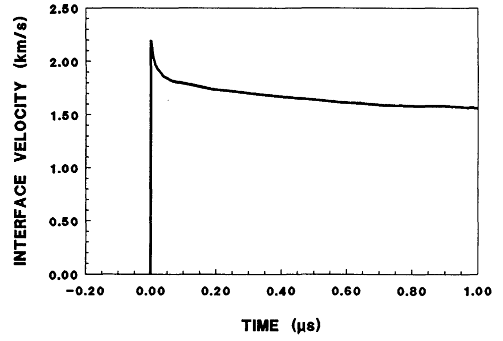

FIG. 6. Experimentally measured interface velocity history showing the ZND reaction-zone structure. See Sec. 5.4 for details of the experiment.

Various other detonation properties can also be measured, e.g., spike pressure, detonation velocity, etc. Methods of making such measurements are discussed in Sec. 5.4.

3. EQUATIONS GOVERNING REACTIVE FLOW

In Sec. 2 a description was given of 1D steady detonation theories where the chemical-heat addition either is unresolved in time or is especially simple in form; i.e., one forward exothermic rate process. The essentially algebraic form of the CJ and ZND theories must be generalized when more complex detonation phenomena are considered. Here, "complexity" can mean, for example, multidimensionality in the flow (e.g., steady two-dimensional detonation—see Sec. 4.2) or flow in which the shock wave moves unsteadily (e.g., the shock initiation of detonation—see Sec. 4.1). These more involved situations are what are met most often in the experimental situation.

The more general situation is governed by the applicable partial differential equations of fluid mechanics (with initial and boundary conditions) and material constitutive relations. The fluid-mechanical equations governing condensed-phase detonation are usually taken to be the Euler equations of inviscid compressible flow with chemical reaction—augmented by the suitably generalized shock-jump conditions if the flow is multidimensional. The Euler equations govern compressible fluid flow in which transport processes are neglected. The equations are statements of the conservation of mass and energy together with a dynamical (momentum) equation that governs the particle velocity ($\mathbf{u}$) field.

In this section, we describe these equations and then apply them to a few situations to illustrate their usefulness.

3.1 Fluid-Mechanical Equations

As a preliminary to consideration of the Euler equations, it is important to note that in a compressible flow, the time derivative of a flow-field variable [say $F \equiv F(x,y,z,t)$] on a fluid particle is given by the total time (or material) derivative of that quantity evaluated on the particle's path, i.e.,

$$\frac{dF}{dt}=\left[\frac{\partial}{\partial t}+(\mathbf{u}\cdot\nabla)\right]F, \tag{13}$$

where **u** is the velocity vector of the particle. Equation (13) is derived by taking the total derivative of *F* (via the chain rule) and then evaluating the result on a particle path. This result will be needed below where we are interested in defining the dynamical behavior of any particular fluid particle.

When the notation of Eq. (13) is used, the three applicable fluid-mechanical conditions, written in the laboratory reference frame, are as follows. The mass conservation condition for a particle of the fluid is

$$\frac{d\rho}{dt}+\rho\nabla\cdot\mathbf{u}=0. \tag{14}$$

In Eq. (14), the second term results from the mass density being dependent on the fluid particle's volume; the $\rho\nabla\cdot\mathbf{u}$ term accounts for dilation of the fluid particle as the flow evolves. The momentum and energy equations, given next, are dependent on the fluid particle mass and, consequently, do not contain dilation terms. The next equation is the expression of Newton's second law for a continuous inviscid compressible fluid; i.e.,

$$\rho\frac{d\mathbf{u}}{dt}=-\nabla P, \tag{15}$$

where *P* is pressure at the particle's location. When $\nabla P=0$, Eq. (15) expresses the conservation of linear momentum. Note that Eq. (15) is a nonlinear partial differential equation, since the operator d/dt depends on **u** [see Eq. (13)].

The energy conservation condition is

$$\frac{dE}{dt}=-P\frac{dv}{dt}, \tag{16}$$

where *E* and *v* are the internal energy per unit mass and the volume per unit mass, respectively. Equation (16) mirrors the adiabatic nature of the flows being treated. It shows that energy transport occurs only via mechanical work done by or on a particle.

The chemical-heat release in a fluid particle is specified in *E* via dependence on chemical "progress" variables.

3.2 Chemical-Heat-Release Relations

The progress-variable (λ) evolution is specified by "rate laws" that govern their time dependence on the state variables of the system. Such a form is

$$\frac{d\overline{\lambda}}{dt}=r(P,v,\overline{\lambda}), \tag{17}$$

where, in general, $\overline{\lambda}$ is an *n*-dimensional vector.

The energy function that drives the fluid mechanics is the global heat released (Q) into the flow. Thus, when a number of chemical processes are occurring simultaneously, the pertinent mechanical energy is the sum of the individual energy releases q_i, i.e.,

$$Q=\sum_{i=1}^{n}\lambda_i q_i. \tag{18}$$

The difficulty in attempting to probe microscopic energetic events in a detonation via mechanical measurements is inherent in the ambiguities associated with Eq. (18). To probe the microscopic processes that produce the global heat-release function *Q*, one needs to examine events at the microscopic level—e.g., with spectroscopic techniques. This type of investigation is a current area of research in detonation physics and chemistry.

3.3 The Material Equation of State

Equations (14)-(17) are $5+n$ differential equations in $6+n$ dependent variables. Thus, this system of equations is underdetermined. One further constraint involving the $6+n$ dependent variables is required.

The constraint that closes the system is the equation of state (EOS) of the reactive fluid, i.e., a relationship of the form

$$E=E(P,v,\overline{\lambda}); \tag{19}$$

see, e.g., Eq. (6).

We note that since one is dealing with mechanical equations, it is not required that the system temperature be a variable in the EOS; i.e., a full $P(v,T,\overline{\lambda})$ EOS is not required. However, if the chemical-heat-release relations of Sec. 3.2 depend on temperature, this variable must also be known in order to define fully the reactive flow problem. Defining the temperature field in detonations is a current area of research. It is implicit in the above discussion that there is local thermodynamic equilibrium in the system, except for the chemical progress variables. The rate laws [Eq. (17)] define their time evolution.

Shock-jump conditions and Eqs. (14)–(19) (with boundary and initial conditions) define the reactive flow problems found in detonating condensed systems, within the stated approximations. These governing equations are a hyperbolic system; hence a salient feature of their solutions is transport of energy by wave motion (Wood and Kirkwood, 1957).

The usefulness of these equations in the study of detonation phenomena will be illustrated in Secs. 3.4 and 3.5.

3.4 Qualitative Features of Flow with Reaction

Some insight into the effect of chemical-heat addition on a compressible flow can be obtained by eliminating dE/dt between the energy conservation condition and the EOS. From the EOS, we know that

$$\dot{E} \equiv \frac{dE}{dt} = \left[\frac{\partial E}{\partial P}\right]_{v,\lambda} \dot{P} + \left[\frac{\partial E}{\partial v}\right]_{P,\lambda} \dot{v} + \left[\frac{\partial E}{\partial \lambda}\right]_{v,P} \dot{\lambda}.$$

Eliminating $\dot{E}$ from this expression via $\dot{E} = -P\dot{v}$ and rearrangement gives

$$\dot{P} = \left[\frac{[\partial E/\partial v]_{P,\lambda} + P}{[\partial E/\partial P]_{v,\lambda}}\right] \frac{\dot{\rho}}{\rho^2} - \frac{[\partial E/\partial \lambda]_{P,v}}{[\partial E/\partial P]_{\lambda,v}} \dot{\lambda}. \qquad (20)$$

By writing the 1D Euler equations in characteristic form, Wood and Kirkwood (1957) showed that the coefficient of $\dot{\rho}$ in Eq. (20) is the local sound speed ($\equiv c$) squared—at fixed chemical composition, i.e., fixed λ. This speed is called the "frozen" (composition) sound speed. The second term in Eq. (20) depends on the chemical-heat-release rate $\dot{\lambda}$ ($\equiv r$). Use of standard partial derivative relations allows it to be rewritten as

$$-\left(\frac{\partial P}{\partial \lambda}\right)_{E,v} \dot{\lambda} \equiv -P_\lambda \dot{\lambda}.$$

With these definitions, Eq. (20) can be written as

$$\dot{P} = c^2 \dot{\rho} + P_\lambda \dot{\lambda}. \qquad (21)$$

The quantity $P_\lambda \dot{\lambda}$ is a measure of the local rate of chemical-heat addition. For example, for the energy relationship defined by Eq. (6), $P_\lambda \dot{\lambda} = [q(\gamma-1)/v]\dot{\lambda}$. When $P_\lambda \dot{\lambda}$ is positive, Eq. (21) shows that (at fixed $c^2\dot{\rho}$) $\dot{P}$ is larger than it would be without chemical heat addition.

One can use Eq. (21) to obtain an important relationship between the heat-addition rate and the sonic character of steady 1D chemically driven flow. In this case, Eq. (21) specializes to $uP_x - c^2 u\rho_x = P_\lambda \dot{\lambda}$. For steady 1D flow, Eqs. (14) and (15) simplify to $u\rho_x = -\rho u_x$ and $\rho u u_x = -P_x$, respectively; these equations imply that $u\rho_x = P_x/u$. Substitution of this result into the specialized form of Eq. (21) gives

$$\dot{P} = P_\lambda \dot{\lambda} / [1 - (c/u)^2], \qquad (22)$$

where the sign of the denominator of Eq. (22) determines the sonic character of the flow.

Interesting insights into the character of the flow behind a steady 1D detonation shock can be obtained from Eq. (22). For subsonic regions (e.g., in the ZND reaction zone) $c^2 > u^2$; and for $P_\lambda \dot{\lambda} > 0$, $\dot{P}$ is negative; that is, the pressure falls through the ZND reaction zone. An important feature of Eq. (22) is that at points where the flow is sonic ($u = c$), either P_λ or $\dot{\lambda}$ must be zero—otherwise $\dot{P}$ is infinite. For the simple EOS defined by Eq. (6), $P_\lambda [= q(\gamma - 1)/v]$ cannot be zero and so the only possible sonic point corresponds to complete reaction (i.e., $\dot{\lambda} = 0$ at $\lambda = 1$). This is the CJ point defined earlier. For more complex rate laws, P_λ can be 0 (e.g., for a rate containing both exothermic and endothermic parts), and sonic points other than the CJ point are possible. Such a situation can give rise to "weak" detonations in which $P < P_{\mathrm{CJ}}$ (see Fickett and Davis, 1979).

3.5 Taylor Wave

In Secs. 2.3 and 2.4, we derived the fluid-mechanical state at the point of complete chemical reaction in the CJ and ZND models—i.e., the "CJ point" values of the flow field. A natural question to ask is, "What fluid flow connects the CJ point to the final low-density and -pressure state of the expanded reacted gases?" Here we answer this question by use of the compressible-flow equations of Sec. 3.1. The fluid flow that connects these two states is called the "Taylor wave" after G. I. Taylor as explained below.

First note that in a fluid describable by the Euler equations (and in which there are no chemical reactions occurring or shock waves present), the thermodynamic states experienced by an initially isentropic fluid must lie on an isentrope (because shock waves or chemical reactions are the only possible sources of entropy production). The fluid that traverses the CJ plane of a detonation is fully reacted, and we assume that the subsequent flow has no discontinuities; therefore the state of this material lies on an isentrope. We assume that the reacted fluid is describable by a γ-law EOS [see Eq. (6)]; then the isentropes are given by $P=C\rho^{\gamma}$, where C is a constant. In this case, the Euler equations governing the density [Eq. (14)] and momentum [Eq. (15)] are

$$\rho_t+u\rho_x+\rho u_x=0 \quad \text{and} \quad u_t+uu_x+\gamma C\rho^{\gamma-2}\rho_x=0,$$

respectively.

Since there are no pertinent space or time scales in the flow following the CJ point, Taylor (1950) assumed that the flow can be described via the self-similarity variable $z\equiv x/t$. When the density and momentum partial differential equations are expressed in terms of z, they become the ordinary differential equations (ode) $(u-z)\rho'=\rho u'$ and $(u-z)\times u'=\gamma C\rho^{\gamma-2}\rho'$, where the prime denotes the ordinary derivative with respect to z. Division of one of these ode's by the other results in the differential relation $u'=(\gamma C\rho^{\gamma-3})^{1/2}\rho'$. This can be integrated to yield

$$u=\frac{D}{\gamma-1}\left[\frac{2\gamma}{\gamma+1}\left(\frac{\rho}{\rho_{\mathrm{CJ}}}\right)^{(\gamma-1)/2}-1\right], \tag{23}$$

where the known values at the CJ point of $u_{\mathrm{CJ}}=D/(\gamma+1)$, $c_{\mathrm{CJ}}=\sqrt{\gamma P_{\mathrm{CJ}}v_{\mathrm{CJ}}}=\gamma D/(\gamma+1)$, and $\rho_{\mathrm{CJ}}=\rho_0(\gamma+1)/\gamma$ have been used to evaluate the integration constant and to simplify the expression. Equation (23) can be used in the equation $(u-z)u'=\gamma C\rho^{(\gamma-2)}\rho'$ to find the dependence of ρ on z. One finds two cases: a trivial solution $\rho'=0$ and

$$\rho(x,t)=\rho_{\mathrm{CJ}}\left[\frac{(\gamma-1)x/t+D}{\gamma D}\right]^{2/(\gamma-1)}. \tag{24}$$

Use of Eq. (24) in Eq. (23) gives the particle velocity flow field

$$u(x,t)=\frac{1}{\gamma+1}(2x/t-D). \tag{25}$$

Figure 5 shows a schema of the $u(x,t)$ Taylor wave solution. Note that if the back boundary is free, Eq. (24) shows that the density and pressure are zero along the $x-t$ line $x/t=-D/(\gamma-1)$. Thus, for a $\gamma=3$ material, the speed of free expansion of the reacted gas is one-half the detonation speed.

We now have obtained a quantitative picture of a 1D steady detonation as a shock wave followed by a steady space-dependent reaction zone that ends at a sonic point. The sonic point is, in turn, followed by a self-similar flow that takes the flow field variables to ambient values (see Fig. 5).

3.6 Solutions of Reactive Flow Equations for Complex Systems

There are a number of difficulties associated with obtaining solutions of Eqs. (14)–(19) for real physical systems. A mathematical obstacle is that the flow equations are nonlinear (in general, partial) differential equations, and so the solution techniques available for linear systems are not available. This difficulty is usually avoided by solving the set of equations numerically (see Mader, 1979).

A more fundamental physical problem involves Eqs. (17) and (19). These equations require specification of constitutive properties of dense systems consisting of mixtures of many molecular species at extreme conditions of pressure, density, and temperature. There have been various attempts at obtaining the EOS of explosive-reaction products by use of statistical-mechanical techniques. Such an approach is to be contrasted with the use of an experimentally calibrated form such as Eq. (6). A recent example of the statistical-mechanical attack on the EOS problem is that given by Ree and van Thiel (1985); also see references therein.

Specification of the chemical-heat–release function(s) [Eq. (17)] in condensed-phase explosives is in a primitive state. Usually a mathematically simple rate form containing adjustable parameters is postulated and its parameters calibrated to the results of experiments on real systems. This calibrated rate can then be used with the other governing equations to make predictions of behavior of systems “closely” related to the calibration. Some experimental spectroscopic work in probing the microscopic chemical events in detonations has been done recently. Such studies are in their embryonic phase.

Much theoretical work has been done on numerical solution of the flow equations for multidimensional systems in an effort to understand the initiation and detonation regimes. The interested reader can find discussions of such work in Mader (1979), Nunziato *et al.* (1982), and the proceedings of the various Detonation Symposia.

4. EXPERIMENTAL ASPECTS OF INITIATION AND STEADY DETONATION

Initiation and detonation of explosives depend on the physical nature of the materials, their density, the dimensions of the explosive, and the surrounding confinement materials. In terms of their physical nature, explosives are generally grouped into homogeneous and heterogeneous materials. Homogeneous materials are typically liquids or single crystals of molecular explosives with no physical imperfections (e.g., bubbles, voids, etc.) that can cause perturbations in the input shock and the flow behind it. Homogeneous materials viewed with the macroscopic probes characteristic of detonation physics experiments appear uniform.

Heterogeneous explosives are generally all other types; these are usually pressed, cast, or extruded into the shapes desired. Here, heterogeneous means a material that contains any kind of imperfections that can cause fluid-mechanical irregularities ("hot spots") when a shock or detonation wave passes over them. Such hot spots cause associated space-time fluctuations in the thermodynamic fields (e.g., the pressure or temperature fields). These thermodynamic variations affect the local chemical heat-release rate. When averaged over a sufficiently large space scale, such variations convoluted with the underlying chemical rate(s) produce an average heat-release rate that is a combination of chemistry and mechanics. Examples of some conditions that cause hot spots are

1. voids collapsing by impact of one side on the other,
2. shock-wave propagation through irregular particles causing complex shock interactions,
3. shock-wave interactions between particles and voids leading to jetting,
4. plastic flow involving crystal breakage and shearing, and
5. shocking impedance mismatch between components of the explosive that cause stagnation points and shock reflections and interactions.

Some of these have been modeled using wave propagation computer codes (e.g., see Mader, 1979, and Nunziato *et al.*, 1982). Because of these hot spots, heterogeneous initiation and detonation phenomena are qualitatively different from that observed in homogeneous materials.

In Sec. 4.1, we discuss 1D shock initiation of detonation in homogeneous and heterogeneous explosives. Growth to detonation is qualitatively different in these two situations. Detonation can also develop from a burning or deflagration process in some explosive materials with quite particular material and confinement conditions; this initiation process will also be addressed. Steady 2D detonations in homogeneous and heterogeneous explosives have qualitatively different detonation velocity versus charge diameter relationships (diameter-effect curves); the reasons for this behavior will be discussed in Sec. 4.2.

4.1 Initiation of Detonation

As was shown in Sec. 2.4, detonation is a self-sustaining, shock-generated chemical reaction, and so any successful initiation process must eventually lead to shock formation. The most direct initiation method is to introduce a shock mechanically, e.g., with a thrown plate. If the resultant pressure input is sufficiently large, the shock will grow to detonation. This process has been labeled a shock-to-detonation transition (SDT). Shock inputs obviously have a particular duration, depending on how they are generated, and the duration may or may not be relevant to the initiation process. If the shock duration is long compared to the initiation time, it has no relevance. Durations of the same order as the initiation time or shorter can become important because pressure relief from the rear may quench the initiation reactions. Qualitative differences occur in SDT of homogeneous and heterogeneous materials, due to the hot-spot phenomena generated in the latter case. Both the homogeneous and heterogeneous SDT processes will be discussed in some detail.

When the pressure input is less than that required for direct SDT, two other notable processes can take place: a burning or deflagration-to-detonation transition (DDT), or what has been called a low-velocity detonation (LVD). DDT will be discussed in some detail but LVD will only be briefly described here.

LVD is a process completely different from steady laminar detonation. LVD is by its nature multidimensional, depending strongly on the material conditions and the surrounding confinement to create a condition conducive to low-level "hot-spot" reaction (e.g., a mechanical wave in a container of a liquid explosive can "precondition" the explosive by cavitating it; the cavitation bubbles can then become hot-spot loci activated by a low-pressure shock in the liquid explosive). LVD waves are in a sense constant velocity, but long propagation distances (several tens of centimeters) are seldom observed because the wave either dies out or makes the transition to ordinary detonation when slightly perturbed. LVD has been observed in liquid, cast, and pressed explosive charges but is usually associated with liquids or dynamite. LVD phenomena are a safety concern because initiation inputs are on the order of 0.1 GPa. Propagation velocities are about 2 km/s (one-third to one-fourth those of high-order detonation) with only a small portion of the available chemical energy consumed. LVD pressures are about 1.5 GPa or lower but can lead to fatal accidents (many accidents with nitroglycerin have been attributed to this phenomenon). See Johansson and Persson (1970) for additional information concerning this interesting phenomenon.

FIG. 7. (a) A time-distance diagram for the homogeneous initiation process as described by Campbell *et al.* (1961a). (b) The *in situ* particle-velocity measurements of the homogeneous initiation process that led to the diagram in (c) are shown. (c) A time-distance diagram for the homogeneous initiation process as described by Sheffield *et al.* (1989).

4.1.1 1D Homogeneous Initiation. Homogeneous SDT has been studied in detail by Campbell *et al.* (1961a), leading to the classical homogeneous initiation model shown in the time-distance diagram of Fig. 7(a). The explosive is shocked and, after an induction period τ (which depends on the initial shock pressure), a thermal explosion (runaway chemical reaction) occurs at the explosive-driver interface. This explosion produces a superdetonation (i.e., detonation in the explosive precompressed by the initial shock; this detonation has a higher pressure and velocity than a detonation in uncompressed material would have), which runs forward and eventually overtakes the initial shock. This produces an overdriven detonation condition which then decays to a steady detonation.

The simplest theory predicts the induction time (time to thermal explosion) using Arrhenius kinetics as

$$\tau = (C_v R T^2 / AQE) e^{E/RT}, \tag{26}$$

where C_v is the constant-volume specific heat, R is the gas constant, A is a collision factor, Q is the heat release, T is the shock temperature, and E is the Arrhenius activation energy. A number of assumptions, including no heat transfer, lead to this simplified form which comes from a more general theory developed by Frank-Kamenetskii (1955). Because of the exponential dependence of the Arrhenius rate on E, Eq. (26) indicates that the induction time is a very sensitive function of the temperature (provided $E \gg RT$); i.e., a small increase in temperature yields a large increase in reactivity.

It seems reasonable to suspect that a superdetonation does not form immediately after the thermal explosion as depicted in Fig. 7(a) but that rather some type of extended reaction-wave buildup process occurs. Recent *in situ* particle-velocity measurements of this growth process in chemically sensitized nitromethane have shown a developing reactive wave over relatively long time and distance scales [see Fig. 7(b)]. When these measurements are transformed into the time-distance plane, the trajectories of the various waves become those shown in Fig. 7(c). This modified homogeneous initiation model consists of the following processes:

1. The explosive is initially shocked, raising the pressure and temperature to the point that a chemical reaction starts;
2. this reaction produces mechanical waves that coalesce and strengthen;
3. a reactive compression or shock wave is formed within the material;
4. this reactive wave builds in strength (possibly to a steady superdetonation); and
5. this reactive shock overtakes the original shock wave, producing an overdriven condition that eventually settles down to a steady detonation (Sheffield *et al.*, 1989).

This picture is qualitatively different from SDT in heterogeneous materials that will be discussed next.

4.1.2 1D Heterogeneous Initiation. Heterogeneous SDT was also studied in detail by Campbell *et al.* (1961b), leading to much of the basic understanding that exists today. They showed that wave growth occurs at the front as well as behind it. This leads to a relatively smooth growth of the initiating shock to a detonation, in contrast to the abrupt changes observed in the homogeneous case. In this case, no overdriven detonation is observed, leading to the idea that the transition to detonation occurs at or near the shock front. Experiments on heterogenized nitromethane in which *in situ* particle-velocity histories were measured are shown in Fig. 8. These profiles agree with the heterogeneous initiation model of Campbell *et al.* (1961b).

The difference in behavior from that observed in homogeneous explosives is attributed to shock-induced hot spots forming at or near the shock front as a result of physical imperfections in the explosive and their consequent effect on the chemical-energy release into the flow (see Sec. 4). These hot spots can result from any phenomena that disrupts the smooth nature of the flow. On this basis, one could expect differences in initiation behavior to occur because of, for example, the particle size of material used to fabricate the explosive, and this is the case.

Little is known about the exact mechanisms that produce the shock-wave growth other than that the hot spots develop at the inhomogeneities, stimulating chemical-energy release locally and making the explosive initiate at much lower pressure inputs than would otherwise be the case. For example, pure liquid nitromethane can be made to initiate with a sustained shock input of about 8 to 9 GPa, while the same material with a large number of carborundum heterogeneities will initiate at 2 to 3 GPa (Campbell *et al.* 1961b). Many experimental studies have looked at hot-spot phenomena, but the size and nature of the inhomogeneities have not been sufficiently experimentally controlled to allow detailed understanding.

Because the hot spots produce reaction locally, heterogeneous explosives have a much less sensitive, state-dependent, average chemical-heat–release rate than homogeneous materials. The dependence on the bulk material pressure and temperature (all-important in the homogeneous case) is secondary.

4.1.3 Deflagration-to-Detonation Transition. Under some circumstances, transition to detonation can take place from much smaller stimuli than those required in a SDT process. When the initiation and confinement conditions are appropriate, relatively low thermal or pressure inputs start the explosive burning and this can eventually lead to detonation. This process is called deflagration-to-detonation transition (DDT). While SDT takes place on a time scale of a few microseconds, DDT takes place on a time scale 10 to 1000 times slower. DDT has been observed in both cast and pressed solid explosives. Experimental and theoretical research relating to DDT phenomena is active because of the safety concerns associated with small stimuli leading to accidental detonations. Heavy confinement is usually required for DDT.

DDT in low-density pressed materials (e.g., HMX) has been experimentally shown to involve the following phenomena (McAfee *et al.*, 1989). After the explosive starts to burn, the heavy confinement causes the pressure to increase with a consequent increase in the burning rate. The hot product gases move out into the pores of the unburned explosive and convective burning develops. This also drives a compaction wave ahead of the burning making it more difficult for the gases to penetrate the porous bed of material. This compaction wave compresses the material to about 90% of theoretical maximum density (TMD). As pressure builds up, stress waves are formed and coalesce, compacting the explosive to nearly 100% TMD, and a plug is formed in the material. As the combustion process gets near the plug, pressures increase and a strong shock forms near the front of the plug. When the shock amplitude increases sufficiently, a SDT process takes place in the 90% TMD material ahead of the plug. DDT in cast materials is thought to involve similar phenomena with the addition that the burning and compaction processes cause crushing of the material creating pores with resultant enhanced convective burning.

Baer and Nunziato (1989) have had considerable success in modeling DDT processes in a number of materials by using a two-phase flow model. Although many of the phenomena they calculate are similar to the experimental work in low-density HMX, careful experiments are needed to validate the physical and chemical assumptions of their model.

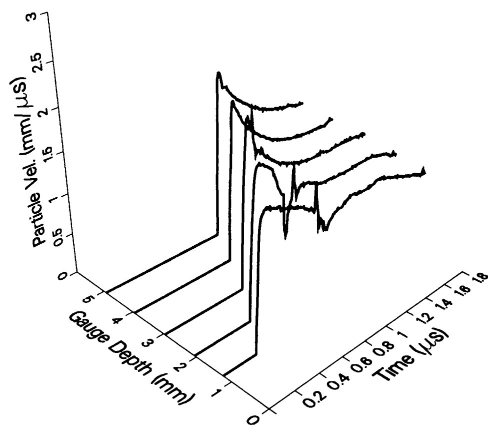

FIG. 8. *In situ* particle-velocity measurements of a heterogeneous initiation process in heterogenized nitromethane described by Sheffield *et al.* (1989).

In addition to heavy confinement, many explosive properties are important (e.g., density, porosity, compressibility, material strength, shock sensitivity, reaction rates, heats of combustion and detonation) in the DDT process. Very little work relating to the detailed chemistry involved in the DDT process has been attempted.

4.2 2D Steady Detonation in Homogeneous and Heterogeneous Materials

An experimental situation with some conceptual simplicity is steady two-dimensional detonation. Such detonations are observed in explosive charges that have an axis of symmetry. The most common experimental configuration is a right circular cylinder of explosive detonated in air (see Fig. 9). A detonation wave propagating in such a charge reaches a steady state after an initiation transient. In high-density explosive charges, experiment shows that a steady two-dimensional shock followed by a steady chemical reaction zone is closely approached after the detonation wave has propagated about six charge diameters. Thereafter, the steady 2D flow in the chemical reaction zone is determined by the interaction of the chemical-energy–release rate and the fluid mechanics of the divergent flow (see Fig. 10). At the steady state, the mode of initiation has been forgotten.

The hydrodynamic equations governing steady axisymmetric 2D flow in a detonation reaction zone are functions of two space

variables and independent of time (in the Galilean frame traveling with the detonation wave).

It is known experimentally that a steadily propagating 2D detonation front, as discussed above, is curved. The shock on the charge symmetry axis leads the remainder of the shock wave; the qualitative form of such a detonation is shown in Fig. 10. A number of features of steady 2D detonation can be obtained from the fact that the detonation shock is curved in this way.

To deduce these features, we need the shock-jump conditions for fluid motion that is oblique (i.e., nonperpendicular) to the shock. Suppose that one rides in the shock reference frame and that the fluid velocity observed from this frame is **u**. As shown in the inset in Fig. 10, the velocity vector **u** can be resolved into components that are perpendicular ($u_\perp$) and parallel ($u_\parallel$) to the local shock surface. The conditions that relate the values of the components of **u** in front of and in back of the shock wave are as follows: The component $u_\parallel$ is continuous across the shock, while $u_\perp$ is governed by Eqs. (1)–(3) with U_s and $U_s - u_p$ replaced by the values of $u_\perp$ and $\tilde{u}_\perp$ in front of and behind the shock wave (see Fig. 10).

One sees from these considerations that more oblique shocks result in lower mass density, pressure, and internal energy jumps across the shock wave than occurs in normal incidence. Further, as can be seen from the inset in Fig. 10, the curvature of the steady 2D detonation shock causes divergence of the flow stream lines away from the central streamline as material crosses the shock. This divergence has a number of effects. First, it introduces mechanically based terms into the 2D Euler equations that have the appearance of an endothermic chemical reaction (see Fickett and Davis, 1979). This "mechanical" endothermicity is due to some of the chemical heat being diverted into producing lateral fluid motion. Because of this, the detonation speed is reduced from that observed in steady 1D detonation. A second more subtle effect is that this "mechanical" endothermicity produces a zero in the total heat-release rate before the full chemical-heat release is completed. As shown in Sec. 3.4, a zero in the heat-release rate is accompanied by a sonic point in the flow [see Eq. (22) and the following discussion]. The chemical heat released behind this sonic point cannot affect the shock and so it is lost in this sense. This effect also contributes to a reduction in the speed of the steady 2D detonation shock wave relative to the planar case.

A question of interest is, "How does the steady 2D detonation speed depend on the lateral charge size?" This is answered experimentally by measuring the detonation speed as a function of the lateral charge dimension. Such measurements produce an explosive's "diameter-effect" curve as shown in Fig. 11.

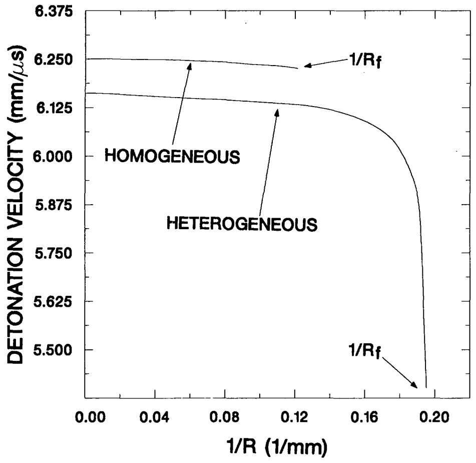

FIG. 11. Typical "diameter-effect" curves for homogeneous and heterogeneous explosives. Steady 2D detonation velocity is plotted versus the reciprocal of charge radius *R*.

Diameter-effect curves are usually plotted in the detonation velocity vs 1/(lateral dimension) plane; this choice allows one to estimate the steady 1D detonation speed by an extrapolation to zero. For cylindrical charges, the pertinent lateral dimension is the charge radius, *R*.

A striking feature of diameter-effect curves (see Fig. 11) is that they end at a finite lateral size. In cylindrical charges, this lateral dimension is called the "failure radius" and denoted by R_f. It is an experimental fact that it is impossible to propagate a steady 2D detonation in a cylindrical charge whose radius is less than R_f. R_f is dependent on the molecular structure of the explosive, its density, the material surrounding the explosive (confinement), the initial temperature, and other variables. Cylindrical charges fired with lateral dimension smaller than R_f result in shock waves that attenuate rapidly and completely. It is thought that the failure phenomenon is a result of detonation waves in charges near failure being catastrophically hydrodynamically unstable to local perturbations.

The 2D steady detonation of homogeneous and heterogeneous materials (see Sec. 4) exhibit strong differences from each other. This parallels the behavior, already discussed, seen in the initiation behavior of such materials and can be traced to the same origin—that is, the absence or presence of hot-spot phenomena (see Sec. 4.1.1 and 4.1.2).

We discuss the homogeneous case first, because it is simpler. The diameter-effect curves of homogeneous explosives are well represented by a line in the D vs $1/R$ plane (see Fig. 11). Second, the detonation-velocity decrease from the steady one-dimensional value $D(\infty)$ to the speed at failure, $D(R_f)$, is small; a value of the velocity deficit $\equiv [D(\infty) - D(R_f)]/D(\infty) \approx +0.01$ is typical.

Heterogeneous explosives have diameter-effect curves that are qualitatively different from those of homogeneous materials; they are strongly downward concave and have a velocity deficit $\approx +0.10$ (see Fig. 11).

It has been experimentally shown in a nitromethane system that the downward concave portion of a diameter-effect curve is caused by flow-field fluctuations (hot spots). Experimental diameter-effect curves for nitromethane exist for the pure liquid and for the liquid heterogenized by the addition of inert silica particles (see Fig. 11). The addition of the heterogeneities produces the expected downward concave region and the roughly ten times larger value of the velocity deficit at failure of detonation relative to that of the homogeneous material. A detailed analysis (Engelke and Bdzil, 1983) shows that the chemical-heat–release rate for the homogeneous material is much more sensitive to the thermodynamic state than is the rate for the heterogenized material.

These results for nitromethane offer a more complete view of the heat-release rates needed to produce the qualitatively different detonation phenomena seen in homogeneous and heterogeneous materials than is allowed by the hot-spot picture alone. A more encompassing view is that homogeneous (heterogeneous) behavior is observed in explosives that have strong (weak) dependence of the heat-release rate on the local average thermodynamic state. Within this picture, e.g., a physically homogeneous material could exhibit heterogeneous detonation behavior provided the thermodynamic-state dependence of the underlying microscopic chemical rates is weak enough. Such behavior is rare enough that the partitioning of explosives as homogeneous and heterogeneous as discussed in Sec. 4 is a useful viewpoint.

5. PROPERTIES OF CHEMICAL EXPLOSIVES

A large number of different materials fall under the category of condensed-phase explosives. These range from rapid-burning compositions to molecular explosives that detonate. Condensed explosives can be categorized into propellants (gun and rocket propellants consisting of mixtures of fuels and oxidizers), pyrotechnics (mixtures of metal fuel and oxidizers), molecular explosives (nitroglycerin, TNT, etc.), and slurry or blasting explosives (mixtures of fuels and oxidizers). Materials in the first two categories are designed to burn rapidly (deflagrate) and serious consequences may develop if they detonate. Materials in the last two categories are designed to detonate, and failure of detonation can lead to difficulties. All except the molecular explosives (which contain in each molecule the fuel and oxidizer necessary to react) are mixtures of fuels and oxidizers. The particular properties desired can be controlled by proper choice of the ingredients. Since there are many choices for fuels and oxidizers, a very large number of combinations are possible. Because of this, developing a particular propellant, pyrotechnic, or blasting material with certain desired properties may involve considerable art as well as science. In order to eliminate the difficulties of describing a large number of mixtures, we have chosen to include only molecular explosives in this discussion. The other three categories of materials will be touched on briefly below to provide only basic information.

Propellants fall into two different classes: gun propellants and rocket propellants. "Single-based" propellants consist of nitrocellulose (NC) only. "Double-based" propellants consists of NC and nitroglycerin (NG) in various compositions (NG is soluble in NC). Gun propellants can be single based, double based, or composite; rocket propellants are either double based or composites. Composite propellants are typically mixtures of NC and/or NG plus other fuel, oxidizer, and binder materials chosen to give the propellant the desired properties. Propellant burn rates are on the order of cm/s with the rate being proportional to the ambient pressure to a power less than unity (typically 0.4 to 0.9). The burning process consists of several steps: heatup, gasification or vaporization, mixing, and the final combustion chemistry. Shapes of propellant grains are designed to control the surface burning area in a rocket so that the ambient pressure and output thrust are controlled. Burning rates can be enhanced by addition of molecular explosives, such as HMX, with some formulations containing up to 50% HMX. Obviously, very careful designs are required to control the burning in these materials since a detonation would be disastrous.

Pyrotechnics are mixtures of metal-based oxidizers (for example, Fe_3O_4) and fuels that are usually metals (for example, Al, Mg, etc.). They are used in ordinary matches, safety flares, gunpowder, fireworks, auto air bags, etc. Pyrotechnic materials can be designed to produce heat, light, noise, or gas depending on the particular formulation. To produce this variety of outputs there are obviously a great many different combinations of fuels and oxidizers. Chemical reactions are generally solid state, and so the reactivity depends strongly on the physical characteristics of the components, how they are mixed, and special preparations of the mixtures. Because these materials are sensitive to very small inputs (so that they will react easily), great care must be exercised in their manufacture to keep from having unwanted ignitions. Manufacturing plants must be carefully designed to eliminate the possibility of introducing small inputs of static discharge, friction, heat, or impact. Even excess amounts of moisture can sometimes cause difficulties. While not detonable, when large quantities of pyrotechnics burn rapidly, considerable damage can result.

Blasting agents or slurry explosives are mixtures of ammonium nitrate and other oxidizers, various fuels including metals (usually aluminum), gelling agents, gassing agents, etc. Since these materials are usually formulated for a particular application, finding a composition with widespread use is difficult. These materials have the advantage that the various components are not explosives, so that an explosive material exists only after mixing. A delivery unit can be loaded with nonexplosive components and driven to the blasting area, and the materials mixed to form a detonable composition just prior to loading it into the blasting configuration, considerably enhancing safety. Blasting agents are thought to have the same fundamental detonation properties as molecular explosives.

The chemical properties of many molecular explosives have been measured; however, only a few materials have been studied to the extent that a complete set of initiation and detonation information is available. Some parameter measurements are intrinsically difficult to make (e.g., reaction-zone length).

On the basis of the ZND detonation theory (Sec. 2), if the unreacted explosive and the reaction-product Hugoniots are known, the von Neumann spike and CJ point can be determined. In practice the unreacted Hugoniot is not well known at higher pressures. Accurate measurements are not possible in this regime, since high-pressure input shocks cause prompt chemical reaction. This makes it necessary to extrapolate to the higher-pressure unreacted Hugoniot values. Similar measurement problems are encountered in determining the reaction-product Hugoniot; estimates are usually developed by using a 2D reactive-wave computer code and varying adjustable parameters to calibrate a particular EOS form to experimental data (for example, a JWL equation of state, see Kury *et al.*, 1965). Because of this and the difficulties in making direct measurements, reaction-zone parameters (e.g., spike and CJ pressures and reaction zone length) are not well defined for any explosive. In contrast, detonation velocity and shock sensitivity are relatively easily measured. Nearly all explosive properties depend on the initial mass density, and so this quality must be accurately known to specify an experiment properly. In addition, some properties, such as shock sensitivity, are dependent on the particle-size distribution of the material used to fabricate the explosive (see Sec. 4.1.2).

In this section we discuss the explosive classifications of primary, secondary, and insensitive materials; these are rather loosely defined groupings according to sensitivity. The chemical and detonation properties for a few representative molecular explosives are given to provide an idea of the magnitude of the various parameters (e.g., detonation velocity). Sensitivity of explosives to shock, impact, thermal, and spark inputs are discussed in order to provide the information necessary to understand the explosive classifications discussed in Sec. 5.1. Finally a brief discussion of some of the experimental methods used in obtaining detonation and initiation information is given and illustrated with figures.

5.1 Explosive Classifications

Explosives are usually classified according to the broad sensitivity classifications: primary, secondary, and insensitive. Primary explosives can be initiated with rather small inputs of mechanical shock, heat, flame, or spark and are used to start an explosive train. Examples of primary explosives are lead azide and mercury fulminate. Small amounts of these materials are located in initiators so that small electrical or mechanical inputs will reliably initiate them. They, in turn, reliably initiate the output charges, e.g., booster pellets and gunpowder. Extreme care is required when handling these materials to prevent accidental initiation.

Secondary explosives are considerably less sensitive to the same inputs and can be handled with less concern about accidental initiation. These materials are reliably initiated by moderate- to high-pressure shock inputs. They are used in some high-input initiating devices (e.g., exploding bridge-wire detonators or exploding-foil–driven flyer-plate detonators), output pellets and boosters, and main charges in explosive assemblies. Examples are 2,4,6-trinitrotoluene (TNT), cyclotetramethylene tetranitramine (HMX), and pentaerythritol tetranitrate (PETN). Hundreds of molecular explosives fit in this category.

Insensitive explosives are difficult to initiate and shock inputs for reliable initiation must be quite large, i.e., careful planning is usually required to eliminate failures, particularly when there can be environmental changes, e.g., low ambient temperature. Examples of materials in this category are 1,3,5-triamino-2,4,6-trinitrobenzene (TATB) and nitroguanidine (NQ).

Some materials are borderline and could be placed in either of two categories, depending on the particular sensitivity property being used as the criterion. For instance, nitroglycerin might be put into the secondary explosive category because it requires a rather high-level shock input to initiate it in the absence of heterogeneities (e.g., bubbles); in this case, it initiates homogeneously as discussed in Sec. 4.1.1. With heterogeneities present, heterogeneous initiation can take place (see Sec. 4.1.2) at much lower input pressures. Under these circumstances it is classified as a primary explosive.

Table 1. Chemical properties of selected molecular explosives.[a] [Data from Dobratz and Crawford (1985) and Meyer (1987).]

Common name	Chemical name[a]	Chemical formula	Molecular weight	Theoretical density (g/cm^3)	Melting point (°C)	ΔH_f Heat of formation (kcal/mol)	$-\Delta H_{det}$ Heat of detonation[b] (kcal/g)
Lead azide	Lead azide	$Pb(N_3)_2$	291.3	4.8	dec.[c]	+112	0.37
NG	Nitroglycerin or glycerol trinitrate	$C_3H_5N_3O_9$	227.1	1.60	13.2	−88.6	1.48

[a] Common chemical names are used rather than the more descriptive names used in the Chemical Abstract Index Guide (see Dobratz and Crawford, 1985).

[b] Heats of detonation are calculated (rather than experimental) and assume that H_2O is a gas.

[c] Decomposes before melting.

[d] Melts with some decomposition.

5.2 Chemical and Detonation Properties for Selected Explosives

Chemical properties of a selected group of molecular explosives (some from each sensitivity class), listed in descending order of sensitivity, are presented in Table 1. Most of these are organic molecules containing nitro groups (NO_2). Detonation-reaction product gases are typically N_2, CO, CO_2, and H_2O, along with small quantities of other chemical species. Very little is known about the chemical reaction mechanisms by which the reactant is transformed into products.

Heats of formation given in Table 1 are the difference in enthalpy between the explosive molecule and its elements (in their reference state). The heat of detonation is the enthalpy difference per gram between the explosive molecule and the product molecules that result from the reaction. Comparison of the heat of detonation values gives a partial measure of the expected output; higher heats of detonation usually correspond to more powerful explosives, as is the case for HMX, RDX, and PETN.

Detonation properties for the explosives of Table 1 are given in Table 2. Densities are given for each entry (except those that are liquids) because the values are density dependent. Detonation velocity is the most accurately measured detonation parameter; consequently, there is a considerable amount of such data available for these and other explosives. In some cases, these data include the dependence of detonation velocity on initial density and temperature. High detonation velocities are associated with high performance; this is apparent in Table 2. The CJ pressure is more difficult to measure and, hence, these values are less reliable. The von Neumann spike and reaction-zone length data are only given for a few materials because of the measurement difficulties. Improved measurements are now being obtained by laser-velocity interferometry and *in situ* gauging

Table 2. Detonation properties of selected molecular explosives. [Densities are given in parentheses after each property value. Data from Dobratz and Crawford (1985) and Gibbs and Popolato (1980). (Most reaction-zone estimates were made by the authors, based on the literature.)]

Material	Theoretical density (g/cm^3)	Detonation velocity (mm/μs)	Estimated CJ pressure (GPa)	Estimated spike pressure (Gpa)	Estimated reaction zone length (mm)	Failure radius (mm)	Plate dent depth (mm)[a]
Lead azide	4.80	5.5(3.80)	23 (4.0)	—	—	—	—
NG	1.60[b]	7.7	25	—	0.2	1.1[c]	—

[f] PBX 9502, which is 95/5 wt. % TATB/Kel-F.

techniques (see Sec. 5.4), so that better estimates are forthcoming. TATB has one of the longer reaction zones at about 2 mm and NM has one of the shorter ones at about 0.1 mm.

Explosives are often mixed with a few percent of polymeric materials (to make them easier to process—press, mold, machine, etc.). Such mixtures are called plastic bonded explosives (PBX).

Many explosive properties depend on initial temperature; e.g., NG has a failure radius of 2 mm at an initial temperature of −20 °C and 0.6 mm at 70 °C. Properties given in Table 2 are at ambient initial temperature.

5.3 Sensitivity Properties

Explosive materials vary widely in their sensitivity to different inputs. Because experience has shown it necessary to understand explosive hazards, a rather large number of sensitivity tests have been developed. Some of these are peculiar to a particular operation or hazard. Methods have been developed to measure response to various inputs, including shock, friction and crushing, heat, and spark or static electricity.

"Gap" tests, of which there are several different types, are widely used in measuring shock sensitivity. In this test, a standard explosive driver system produces an output shock that is attenuated to different pressure levels by varying a thickness of inert attenuator material. The attenuator thickness at which the explosive sample is just initiated is the "gap" thickness reported. Data from two different gap tests are given in Table 3 for some of the materials of Table 1. A large gap indicates a more sensitive material since, with a larger amount of the inert material present, the pressure is attenuated to a lower value before it enters the explosive. These data indicate that the materials are listed in Table 3 in descending order of sensitivity (with minor exceptions).

Another shock sensitivity test is obtained by impacting a flyer plate on the explosive; in this test, a critical energy input for initiation is the recorded index. Flyer material, thickness, and velocity can all be varied to change the characteristics of the input pressure pulse. The required critical energy has been found to be relatively constant over a range of input pressures and pulse widths. Values obtained

Table 3. Sensitivity properties on selected molecular explosives. Densities are given in parentheses after each sensitivity value where appropriate. [Data from Dobratz and Crawford (1985), Gibbs and Popolato (1980), and Smith (1987).]

Material	Theoretical density (g/cm^3)	Gap test[a] (mm)	Gap test[b] (mm)	Drop weight[c] (m)	Spark input[d] (J)	DTA exotherm (°C)	Critical energy (cal/cm^2)

[a] NSWC (Naval Surface Warfare Center) Gap Test.
[b] Los Alamos (LANL) Small-Scale Gap Test.
[c] 5-kg weight using Type 12 tooling (sandpaper surfaces).
[d] Highest electrostatic-discharge energy at 5000 volts without ignition; sample confined.
[e] 2.5-kg weight using Type 12 tooling (sandpaper surfaces), modified tooling for liquids.

from this test are given in the last column of Table 3. These data indicate that the critical energy to initiate an explosive follows the same order as the gap test sensitivity. A notable exception is liquid nitromethane, which initiates homogeneously in contrast to the other materials, which undergo heterogeneous initiation (see Sec. 4.1).

"Impact" sensitivity is important because this type of test mimics inputs in many accident situations. Drop weight setups (there are several with different drop heights, weights, anvils, and anvil surfaces) are used to determine impact sensitivity. Samples are usually in the form of powders or pellets. The samples are placed in an anvil setup and then the drop weight is allowed to undergo free fall onto the sample. The height of free fall that causes reaction is the value reported. Evidence of reaction is determined by both active measurement and postmortem examination of the debris from the test. Data from one type of impact test setup (Type 12 tooling) are given in Table 3. Sensitivity as measured by this test generally agrees with that of the other tests.

A differential thermal analysis (DTA) test is often used to determine sensitivity to thermal input. This test involves a continuous comparison of an explosive sample's temperature with that of an inert standard, when both are heated at a constant rate. Energy excursions are determined in this test, i.e., the temperatures at which endotherms or exotherms occur. The temperature at which large exotherms are observed are given in Table 3. Another thermal input test involves the immersion of an explosive sample in a constant high-temperature metal bath and measuring the time to reaction or explosion. By use of the thermal explosion analysis developed by Frank-Kamenetskii (1955), Arrhenius rate parameters can be determined from this experiment.

Sensitivity to spark input (such as might be produced by the human body) is of interest because of the possibility of discharging through an explosive material when working with it. Critical spark-energy values from this test are test specific (i.e., there are several different test setups). Data given in Table 3 are from one such setup. Note that this test gives the same sensitivity order as the other tests.

Because threshold reaction conditions are being measured, probabilistic data comes from the above tests. Therefore, it is necessary to run several tests at each input condition to establish statistically the lowest input reaction condition.

The data of Table 3 show large differences in sensitivity among the various explosive materials. TATB and NQ are obviously very insensitive explosives. The differences between lead azide (a primary explosive) and PETN (which is considered one of the more sensitive secondary explosives) are considerable. Differences between the secondary and insensitive explosives are less apparent. The order of the materials in Table 3 (from top to bottom) is from more to less sensitive, but there are order reversals for some tests. This indicates that one cannot reliably determine the sensitivity of an explosive by conducting only one type of test.

5.4 Initiation and Detonation Measurement Techniques

Because of the harsh environment produced by the detonation and initiation processes, measurements of certain phenomena are extremely difficult, e.g., measurement of the detailed chemistry occurring in an initiation or detonation. However, considerable progress has been made in measuring the mechanical aspects of initiation and detonation phenomena. A wide variety of experimental techniques are employed to make such measurements including various gauging techniques, laser velocity interferometry, streak cameras, framing cameras, flash x-ray, "time of arrival" ionization and piezoelectric pins, and integrated output tests such as plate dent testing. We will only discuss a few of these. Articles in the various Detonation Symposia contain more detailed discussion of experimental methods.

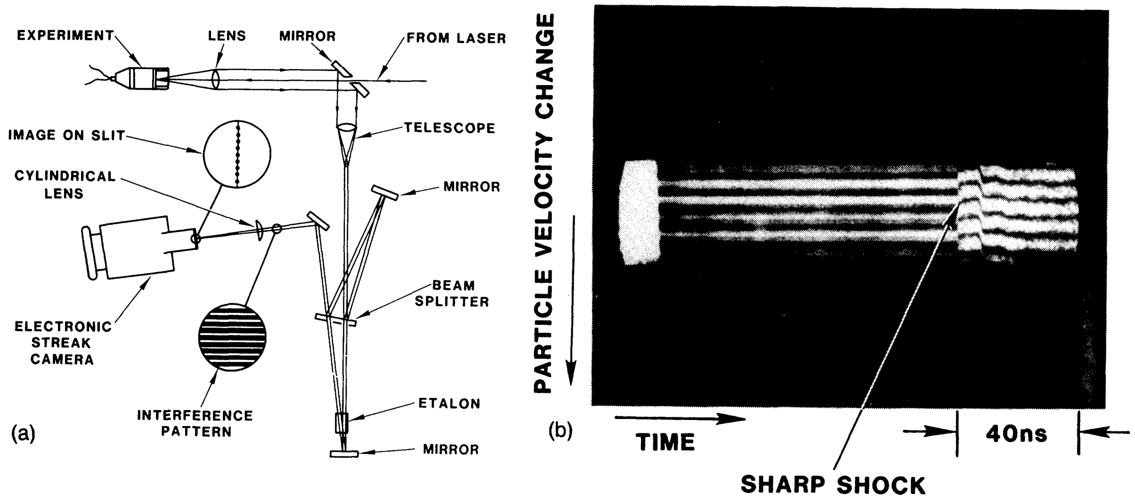
In situ gauging (i.e., low-perturbation gauges located in the flow field) is becoming important. These gauges give direct information on wave profiles in the flow and contain implicit information on how the chemical heat release is occurring. The particle-velocity waveforms shown in Figs. 7(b) and 8 are examples of *in-situ* gauging measurements in which the initiation process has been measured in nitromethane-based materials. These measurements provided the insight necessary to modify the long-held homogeneous-initiation model as discussed in Secs. 4.1.1 and 4.1.2. *In situ* Manganin pressure measurements are also providing important insights into these processes.

Laser-velocity-interferometry measurements also provide wave-profile information as an initiation or detonation wave accelerates an explosive/window-material interface from which a laser beam is reflected. An important advantage (over *in situ* gauging) is that extremely high–time-resolution measurements are possible even at very high pressure. A disadvantage is that the wave profiles are perturbed by the mechanical impedance mismatch at the window through which the observations are made. Figure 12 shows information regarding ORVIS (Optically Recorded Velocity Interferometer System) velocity-interferometer measurements of a detonation wave in a TATB-based explosive interacting with a 12-μm-thick copper foil backed by a water window. Fig. 12(a) shows the experimental setup, Fig. 12(b) the electronic streak-camera record, and Fig. 12(c) the particle-velocity history obtained from reducing the data. Wave reverberations in the foil (with subnanosecond time resolution) are readily apparent in the reduced data. This method provided the reaction-zone-length estimate given in Table 2 for TATB (PBX 9502).

Figures 6 and 13 contain information from a Fabry-Pérot velocity-interferometer measurement of a detonation wave in nitromethane (NM) interacting with a polymethylmethacrylate (PMMA) window. In this case, the reflecting film was a submicron thick layer of aluminum. Figure 13(a) shows the experimental setup, Fig. 13(b) the experimental streak-camera record; and the interface particle-velocity history obtained from reducing the record in Fig. 13(b) is presented in Fig. 6. PMMA is a good mechanical impedance match with NM, and so perturbations of the detonation-wave profile were small. These data provided the reaction-zone-length estimate given in Table 2 for NM.

Detonation velocity is precisely measured in rate-stick experiments as shown in Fig. 9. Ionization switches (in some cases consisting of 50-μm-diam copper wire) are installed between precisely measured pieces of the explosive and provide wave arrival time information from which the detonation velocity is obtained. Diameter-effect curves (see Sec. 4.2 and Fig. 11) are generated when the charge diameter is varied in a set of such rate-stick experiments.

Wedge experiments yield run distance- or time-to-detonation data from sustained shock input experiments. A precisely machined explosive wedge is mounted on a plane-wave explosive driver/attenuator system as shown in Fig. 14(a). The wedge is illuminated by a light source (usually explosively driven) and



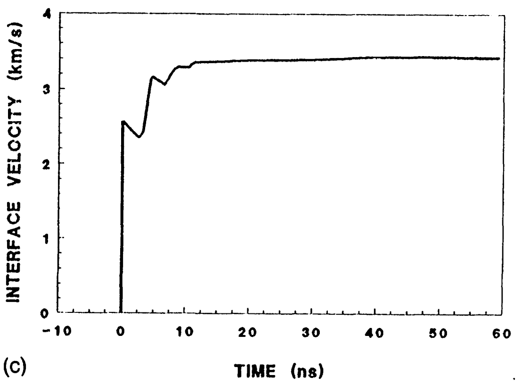


FIG. 12. (a) The experimental setup for an ORVIS. (b) An electronic-streak-camera recording of the fringe changes with time. (c) The interface velocity history obtained by reduction of the record in (b). This experiment consisted of a detonation wave in TATB (PBX 9502) interacting with a 12-μm-thick copper foil backed by a water window.

a streak camera is used to monitor the light changes as a function of time along the wedge surface as the shock interacts with the surface; such a trace is shown in Fig. 14(b). The point at which the distance-time streak record has a large change in slope is the distance or time to detonation for that particular pressure input. This is clearly shown in Fig. 14(c) in which the slope (shock velocity) is plotted versus distance of shock travel into the wedge. By doing several experiments, in which the input shock pressure is varied, a set of pressure versus distance- or time-to-detonation data are compiled. A plot of these data in the log(pressure) vs log(run distance) plane is typically a straight line (Ramsay and Popolato, 1965) as shown in Fig. 15. Note that for the explosives on this plot, PETN is the most-sensitive and TATB and NQ are the least-sensitive materials.

Rotating-mirror framing cameras and electronic image-converter cameras are used to make stop-action pictures of detonation events. Exposure times range from microseconds to nanoseconds, depending on the camera used. For example, Fig. 2 was taken using an electronic image-converter camera that was triply shuttered so that there are three stop-action pictures at different times superimposed in the photograph. This picture shows the progress of the detonation wave up the charge and also the form of the shock waves driven into the liquid surrounding the charge. Estimates of the reaction-product Hugoniot of the explosive can be obtained from this type of data by using it to calibrate computer models of the event. A related test involves the measurement of the wall expansion of a precisely machined and explosively loaded metal cylinder when the explosive is detonated. This experiment is conducted with a streak camera and is called a "cylinder test." Information obtained from this test is also used for calibrating reaction-product Hugoniots (see Sec. 5).

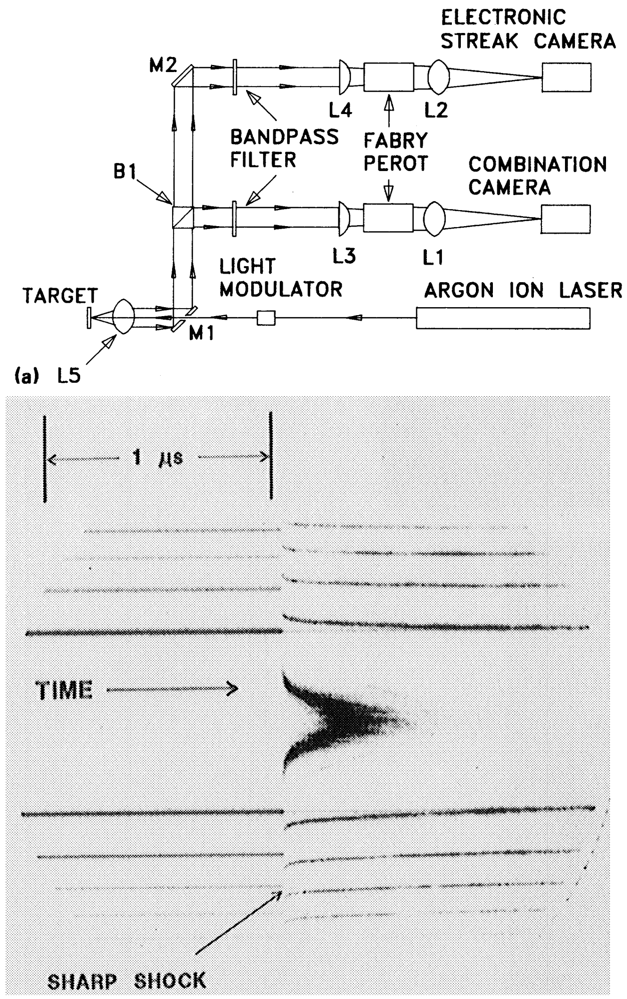

FIG. 13. (a) The experimental setup for a Fabry–Perot velocity interferometer system. (b) An electronic-streak-camera recording of the fringe changes with time. The interface velocity history obtained by reduction of the record in (b) is plotted in Fig. 6. This wave form was obtained from an experiment in which a detonation wave in liquid nitromethane interacted with a polymethylmethacrylate (PMMA) window.

Failure radii for propagation of steady detonation waves are determined by making a series of shots at progressively smaller radii until detonation failure occurs. Failure is determined by the condition of dent blocks or post-shot examination of the debris. Failure radius is reduced by heavier confinement, e.g., NM has a failure diameter of $\approx$16 mm in Pyrex and $\approx$2.5 mm in brass.

Other measurement methods are discussed in several of the references cited in the "Further Reading" list.

6. SUMMARY

Developments in condensed-phase explosive technology in the last 150 years have led to substantial increases in understanding of the initiation and detonation process. A planar steady detonation is a chemical-reaction–supported shock. The shock takes the unreacted material to a high pressure (the von Neumann spike); this is followed by decreasing pressure in the chemical-reaction zone in which the explosive is transformed into gaseous reaction products. The chemical-reaction zone terminates at a sonic point (the CJ state). *In situ* and interface velocity measurements of the reaction zone support the 1D steady detonation theory. Spectroscopic measurements that attempt to interrogate the reaction-zone chemistry are a current area of research.

Explosives are classified according to sensitivity as primary (the most sensitive), secondary (which have intermediate sensitivity), and insensitive explosives (the least sensi-

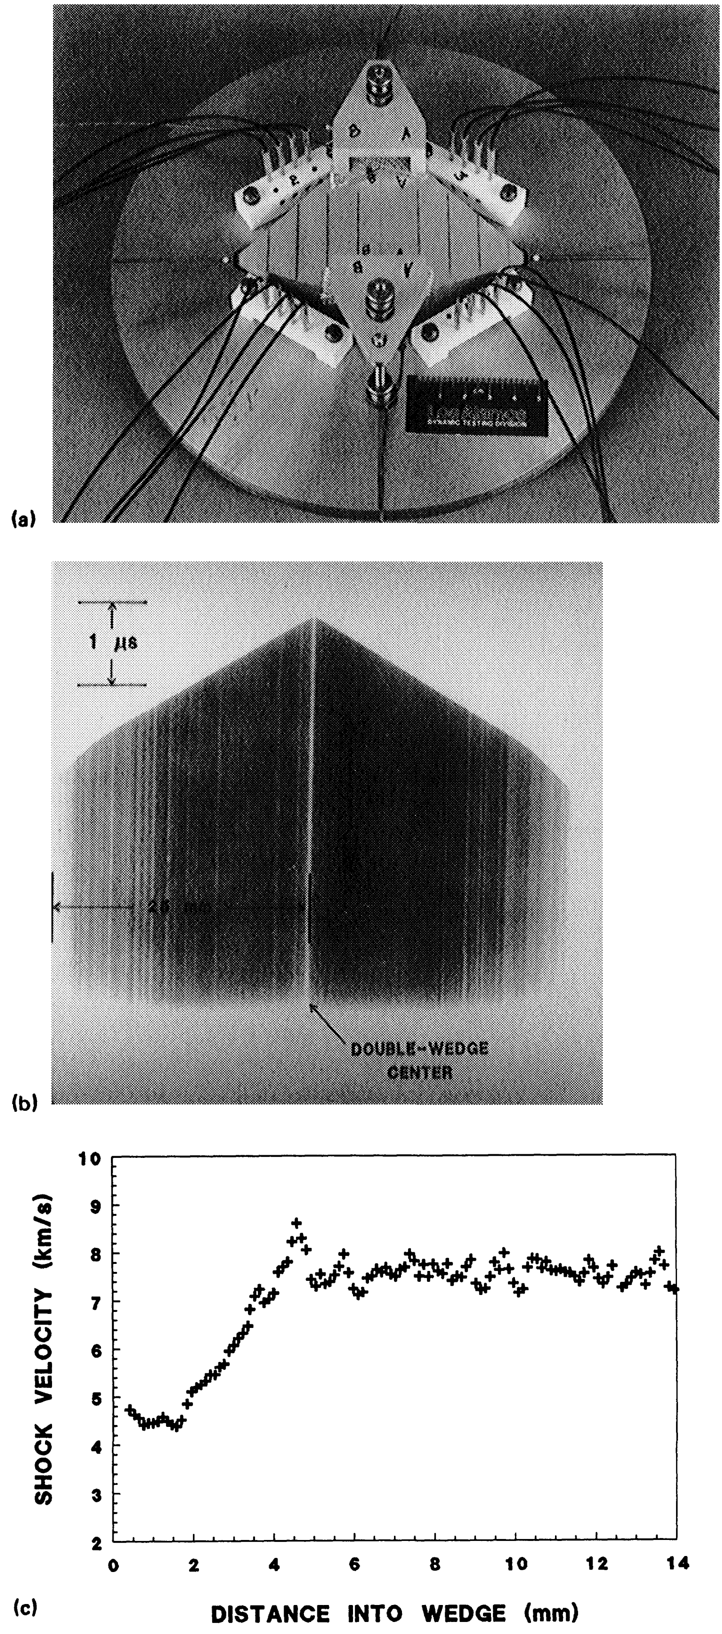

FIG. 14. (a) The experimental setup for an explosively driven wedge experiment. The 16 wires are leads for electrical pins to measure the input conditions into the explosive wedge. (b) A streak-camera record showing shock contact with the wedge surface. Shock contact with the wedge surface reduces the reflectivity and therefore the light intensity. The dark area in the streak record photograph is the region of high reflectivity. (c) The shock velocity plotted versus distance into the wedge obtained from the space-time trajectory of the shock contact with the wedge surface. The distance-to-detonation point is about 4 mm.

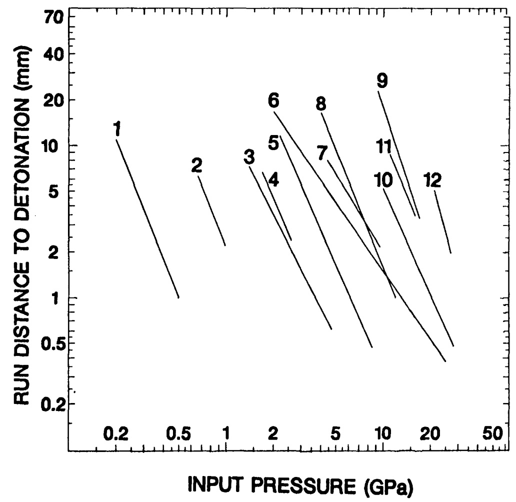

FIG. 15. Plot of sustained input shock pressure vs run distance to detonation (in the log-log plane), as obtained from wedge tests, for a number of explosives. Explosives are as follows (numbers correspond to numbers on graph): (1) PETN ($\rho_0 = 1.0$ g/cm^3); (2) PETN ($\rho_0 = 1.4$ g/cm^3); (3) PBX 9407 (94/6 wt. % RDX/Exon, $\rho_0 = 1.60$ g/cm^3); (4) PETN ($\rho_0 = 1.75$ g/cm^3); (5) Tetryl ($\rho_0 = 1.70$ g/cm^3); (6) PBX 9404 (94/3/3 wt. % HMX/nitrocellulose/chloroethylphosphate, $\rho_0 = 1.84$ g/cm^3); (7) HMX ($\rho_0 = 1.891$ g/cm^3); (8) pressed TNT ($\rho_0 = 1.63$ g/cm^3); (9) cast TNT ($\rho_0 = 1.635$ g/cm^3); (10) superfine particle TATB ($\rho_0 = 1.806$ g/cm^3); (11) TATB ($\rho_0 = 1.876$ g/cm^3); (12) NQ ($\rho_0 = 1.688$ g/cm^3). Data taken from Gibbs and Popolato (1980).

tive). Sensitivity is measured by a number of well-defined test methods in which sensitivity to shock, impact, heat, and electrical inputs are measured.

The initiation and 2D steady detonation processes depend qualitatively on whether the explosive is homogeneous or heterogeneous. Homogeneous explosives are typically liquids or single crystals; their initiation and detonation behavior depend on the bulk temperature and pressure generated by an input shock. Heterogeneous explosives have voids, grain boundaries, etc., which perturb the flow so that spatially localized hot spots are produced; these hot spots are energy concentrations where the chemical reaction rate is greatly increased. These regions control the initiation and detonation behavior of heterogeneous explosives.

Explosives are used in gun propellants, rocket propellants, and pyrotechnics; such materials are designed to burn (deflagrate) rather than detonate. Under some accident conditions, these explosives can burn too rapidly or even detonate, with great consequent damage to the surroundings.

Important areas of explosive research have been neglected in our exposition. Examples of this are

1. the study of the hydrodynamic stability of detonations to perturbations,
2. studies concerning numerical solution of the partial differential equations governing multidimensional time-dependent initiation and detonation, and
3. another type of steady 1D detonation solution possible when more complex chemical-heat–release functions are used ("weak detonations").

Discussion of these and other important topics can be found in the Further Reading list.

We have attempted to show that, in contrast to the intuitive feeling that explosives are disorderly, irreproducible, and chaotic processes, they can be quite orderly and are governed by the conservation equations of compressible fluid mechanics along with material constitutive relations.

Evidence has been discussed showing that there are explosives with widely varying characteristics. These include, e.g., explosives with different sensitivities to accidental insult, levels of power and pressure generation during detonation, and cost. Because of this variation, one can choose an explosive appropriate to the application. Further work is being done to increase this variety of choice. An important example of this is the study of insensitive explosives for use in nuclear weapons, the goal being to produce a situation where it is virtually impossible to produce detonation of the explosive, except by design.

GLOSSARY

CJ (Chapman-Jouguet) Model: The simplest model of planar steady detonation, in which the exothermic chemical reaction is assumed to be instantaneous.

DDT (Deflagration-to-Detonation Transition): The mechanical compaction and reaction buildup processes that an explosive goes through to make the transition from deflagration (burning) to detonation.

Diameter-Effect Curve: The relation between steady 2D detonation velocity and the lateral charge size.

EOS (Equation of State): The functional relationship between internal energy, pressure, and volume for a material in thermodynamic equilibrium.

Failure Radius: The radius of a cylindrical explosive charge below which it is impossible to propagate a steady detonation.

Heterogeneous Explosive: A material in which the release of chemical heat is controlled by local high-temperature and -pressure regions at flow irregularities ("hot spots").

Homogeneous Explosive: A material in which the release of chemical heat is controlled by the bulk temperature and pressure.

Hot Spots: Localized regions in a shocked explosive where energy is concentrated by fluid-flow irregularities in the vicinity of physical imperfections.

Hugoniot: A curve, obtained from the conservation laws, that restricts the locus of end states achievable behind a shock wave or in steady laminar flow.

LVD (Low-Velocity Detonation): A low-level reactive wave in an explosive that is dependent on the existence of nonreactive precursor waves. LVD is not a true detonation.

Rankine-Hugoniot Conditions: The three mathematical conditions that guarantee conservation of mass, momentum, and energy across flow discontinuities (e.g., shocks); they also apply between any two locations in laminar steady flow.

Rayleigh Line: A line in the P,v plane obtained from the conservation laws that restricts the states possible behind a shock wave or in steady laminar flow.

SDT (Shock-to-Detonation Transition): The reaction buildup process that an explosive goes through to make the transition from a shock input to detonation.

Superdetonation: A detonation that occurs in an explosive precompressed by an initial shock.

Taylor Wave: The pressure-relief wave (rarefaction) following a planar steady detonation.

Thermal Explosion: A rapid chemical reaction that occurs when the temperature in an explosive gets above a threshold value.

von Neumann Spike: The leading (high-pressure) point in the ZND model of planar steady detonations (sometimes referred to as the chemical peak).

ZND (Zel'dovich, von Neumann, Doering) Model: The simplest model of planar steady detonation with a resolved chemical-reaction zone.

INTRODUCTION

Ions and electrons may be generated by the application of very high electric fields, of the order of 3–5 GV/m in the case of electrons and 10–50 GV/m in the case of ion generation. Fields of this order are conveniently generated by applying a voltage of several kV to sharp needles with an apex radius of ~ 100 nm. In the case of liquid-metal ion sources, the liquid necks down to form a spatially stable jet of radius ~ 2 nm, which is sufficiently small to generate the required high electric fields in spite of the shielding by the nearby liquid cone from which the jet issues. The basic mechanism in all of the above cases involves tunneling of electrons through a potential energy barrier which has been altered by the high electric field.

The above phenomena have been applied to the creation of three very important instruments: the field-emission microscope which has a resolution of 1 nm, the field-ion microscope, and the scanning tunneling microscope. The latter two instruments have atomic-level resolution.

Several important industrial applications of both field-electron emission and field ionization have been developed. They include flash x-ray emission, electron-beam lithography, and, very recently, flat-panel display technology.

1. PRINCIPLES

1.1 Field Emission

It is well known that thermally excited electrons can escape from a heated conductor by passing *over* the potential-energy barrier that confines electrons to the conductor. This is called thermionic emission. Electrons may also escape from a conductor by the application of a sufficiently high negative electric field. In this case, the electrons escape from the conductor by tunneling *through* the field-deformed potential-energy barrier, thereby generating a current of field-emitted electrons. Tunneling of an electron from a conductor into vacuum was first investigated by Fowler and Nordheim (1928), who employed the new wave mechanics of Schrödinger to calculate the tunneling current. This calculation was based on the fact that small particles, like electrons, could exhibit wavelike proper-

ties under some circumstances. The wavelength λ of the particle, in this case an electron, is given by

$$\lambda = h/p = h/(2mE)^{1/2}, \qquad (1)$$

where h is Planck's constant, p is the electron momentum, m is the electron mass, and E is the electron energy.

The distinction between thermionic emission and field emission may be understood by examining the potential-energy diagrams shown in Figs. 1 and 2 for electrons confined inside a conductor. According to the principles of classical mechanics, a particle confined, as shown in Fig. 1, cannot escape from within the potential-energy well unless it is given enough energy to reach the top of the potential-energy barrier and hence pass *over* it. This is what happens in thermionic emission when the electron acquires enough thermal energy when the emitting conductor is heated. However, the wavelike properties of the electron also allow the electron to pass *through* the barrier, at an appreciable rate, if the barrier is lowered below the level E_F in a distance comparable with λ. Solid-particle tunneling is analogous to the transmission of light through a transparent medium of varying refractive index.

The electron field-emission tunneling current density J is exponentially dependent on the ratio $\phi^{3/2}/F$ and was calculated by Fowler and Nordheim to be

$$J(0) = (CF^2/\phi t^2)\ \exp\{-Bv\phi^{3/2}/F\}, \qquad (2)$$

where F is the electric field strength, ϕ is the conductor work function, and C and B are constants, given by

$$C = e^2/8\pi h\phi t^2, \qquad (3)$$

$$B = 4(2m)^{1/2}/(3eh/2\pi). \qquad (4)$$

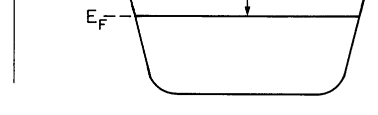

FIG. 1. Plot of potential energy for an electron confined within a structureless metal crystal. In order for the electron to escape it must receive an energy of ϕ, the metal work function, either from a photon or by heating of the metal.

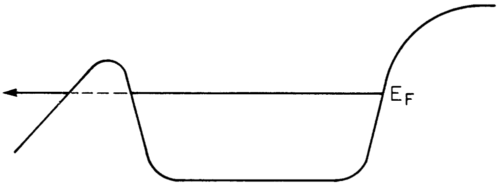

FIG. 2. The electron potential-energy curve of the metal crystal has been bent over by the application of a high electric field, $F = -dV/dx$, so that the slope of the downward sloping line is equal to the magnitude of the field. The deformation of the potential energy by the field now makes it possible for the electron at the Fermi level to "leak" out of the potential-energy well by quantum mechanical tunneling even at 0° K.

If J is expressed in A/m^2, F is expressed in V/m, and ϕ is given in units of eV, then $C = 1.54 \times 10^{-10}$ and $B = 6.83 \times 10^{-9}$. The terms t and v represent slowly varying dimensionless functions of $F^{1/2}/\phi$. Typically, $v \sim 0.5$. Fowler and Nordheim assumed that the electrons in the metal were confined by a box-shaped potential energy distribution, in which details of the electron energy band structure were ignored. The temperature dependence of electron emission, $J(T)$, is given by

$$J(T) = J(0)\ \sin(\pi p/d), \qquad (5)$$

where d and p are given by

$$d = ehFt/4\pi[2m\phi]^{1/2} = 9.75 \times 10^{-11} F/t\phi^{1/2}, \qquad (6)$$

$$p = kT/d, \qquad (7)$$

where k is Boltzmann's constant, d is in eV, and p is dimensionless.

Electric fields of the order of 3–5 GV/m are needed in order to thin the potential energy barrier sufficiently to allow appreciable amounts of tunneling. Fields of this magnitude are conveniently created by applying a negative potential V of a few thousand volts to a needle of small radius r separated from a grounded anode electrode a few cm away; then the electric field at the emitter apex is given by

$$F = V/kr, \qquad (8)$$

where k depends on the needle shape and, to a small extent, on the details of the grounded-electrode geometry. Typically, $4 < k < 8$, vs 1 for the case of a spherical conductor of the same radius.

Converting current density J to current I through $I = JA$ and using $F = V/kr$, the Fowler-Nordheim equation is converted to

$$I/V^2 = (AC/r^2k^2)\ \exp\{-Bkr\phi^{3/2}v/V\}. \qquad (9)$$

Hence a plot of $\ln(I/V^2)$ vs $1/V$ will give a nearly straight line of slope s given by

$$s = -Bkrv\phi^{3/2}. \qquad (10)$$

Here we have assumed $t \sim 1$. If r and k are known, then ϕ may be obtained by an iterative procedure in which it is initially assumed that $v = 1$. From this first approximation to the work function ϕ_1, a better value of v may be obtained by computing $v(F^{1/2}/\phi_1)$. This can be used to obtain a better value of ϕ by substituting the improved value of v in Eq. (10). Alternatively, work functions of individual crystal planes of the needle crystal may be obtained if I/V measurements are made for the planes and the work function of one plane is known. Work functions are then given by

$$\phi^{3/2}/\phi_{\text{ref}}^{3/2} = s/s_{\text{ref}}. \qquad (11)$$

Since I is exponentially dependent on $-\phi^{3/2}$, regions of the emitter needle of high work function will emit considerably fewer electrons than other regions of the needle. For clean field emitters, the close-packed planes—e.g., (110), (100) for tungsten—have higher work functions than the rest of the needle. Hence these planes emit considerably fewer electrons than other regions.

If the needle is brought very close to the counter electrode, the potential-energy barrier is thinned even when the potential difference between the two electrodes is only a few millivolts. This is the mechanism by which electron tunneling is effected in the scanning tunneling microscope (STM), first introduced by Young (1972) and later developed to achieve atomic resolution by IBM workers: Binnig, Rohrer, Gerber, and Weibel (1982). In this technique, a sharply pointed needle of a conductor is scanned across a surface at very close distances from it in order to develop a scanning image of the surface at very high magnifications and at atomic resolution. At close enough separations, a few millivolts difference in potential is sufficient to cause appreciable electron tunneling. Unlike the field emission case, tunneling at close distances can occur in either direction, depending on the relative potentials of the two electrodes. A distinction can be made between field emission, which involves electron tunneling from metal to vacuum (MV), and scanning tunneling microscope (STM) tunneling, which involves tunneling from metal to vacuum to metal (MVM). Semiconductors may, of course, be substituted for conductors.

The energy distribution of field-emitted electrons is of interest from both a theoretical and a practical point of view. The energy distribution is affected by surface conditions and, to a lesser extent, by bulk band-structure properties of the emitting needle.

For many metals, the electronic energy levels in the metals may be regarded as being distributed according to the free-electron theory of metals in which the density of energy levels per unit of energy increases with energy so that more electrons have energies at the Fermi level than at energy levels below it. The thickness of the high-field–reduced potential-energy barrier is smaller at the Fermi level than at energy levels below it. Both the reduced barrier thickness and the higher energy-level density favor electron emission at energies equal to the Fermi level so that more electron emission will occur at this energy level than any other, as shown in Fig. 3.

At low temperatures, few electrons populate energy levels in the metal at energies above the Fermi level. Hence, this is the cutoff level above which few electrons are emitted at low temperatures. As emitter temperatures are increased, more electrons occupy energy levels above the Fermi level and some tunneling begins to occur from these levels. This leads to a rounding off of the peak of the energy distribution, as shown in Fig. 4. Neglecting band-structure effects (see Swanson and Bell, 1973), the energy distribution of field-emitted electrons is given by

$$J(\epsilon) = J(0)\ \exp(\epsilon/d)\{1 + \exp(\epsilon/pd)\}/d. \qquad (12)$$

Plots of $J(\epsilon)$ vs ϵ for various values of T are shown in Fig. 4. At a temperature corresponding to $p = \frac{1}{2}$, a symmetric distribution of the emitted electrons occurs about $\epsilon = 0$, which corresponds to emission from the Fermi level. The half-width $\Delta E_{1/2}$ of the energy distribution at low temperatures is given approximately by

$$\Delta E_{1/2} = d\ \log_e 2. \qquad (13)$$

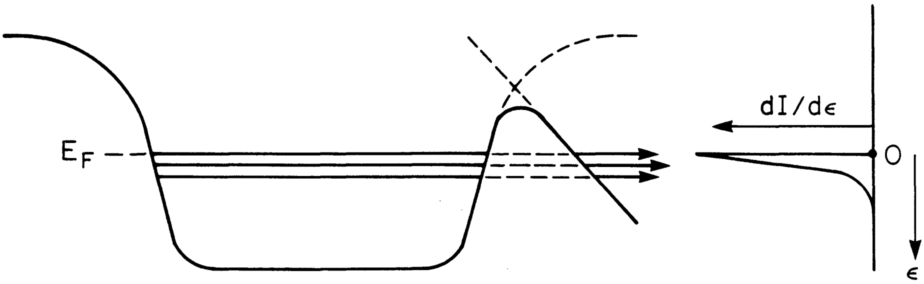

FIG. 3. An explanation of why the energy distribution curve of field-emitted electrons, shown on the right, is peaked at the energy corresponding to the Fermi energy level. There are no electrons above the Fermi level to supply electrons for tunneling, and below the Fermi level the tunneling probability drops off exponentially.

As shown by Gadzuk and Plummer (1971), at high temperatures (>1000 K) the energy distribution widens considerably beyond the amount predicted by Eq. (13).

There is considerable interest in $\Delta E_{1/2}$ because of the role it plays in limiting performance when high-intensity, small-diameter field-emitted electron beams are used in applications such as electron-beam lithography, a crucial technology needed for fabricating integrated circuit lithography masks.

At very high temperatures, a large proportion of the electron emission comes from electrons with enough thermal energy to surmount the potential-energy barrier. In this case there is a considerable further increase in the value of $\Delta E_{1/2}$ as emission comes both from tunneling through and emission over the potential-energy barrier.

Another interesting effect that arises as a property of the energy distribution is the possibility of both positive- and negative-energy exchanges of the field-emitted electrons with the emitter. If the average energy of the emitted electrons is less than that of the electrons arriving at the emitter surface via conductors of the circuit, heating of the emitter will occur. This will occur for values of $p<0.5$. For values of $p>0.5$, cooling of the emitter will occur because electrons will leave the emitter with more energy than provided by replacement electrons which arrive at the emitter at the Fermi energy level. The temperature at which the transition from cooling to heating occurs was investigated by Swanson *et al.* (1966) for tungsten field emitters.

1.2 Field Ionization

As suggested first by Oppenheimer (1928), the application of electric fields of the order of 1–50 GV/m to free molecules or atoms enables bound electrons to escape by tunneling in a process called field ionization (FI) depicted in Fig. 5. On the basis of their theoretical studies, Inghram and Gomer (1954) showed that experiments of Mueller and Bahadur (1956), in which they were able to obtain hydrogen-ion images of a tungsten needle cooled to −195 °C, were the first direct experimental evidence of field ionization.

Field-ion currents at conductor surfaces can be calculated by considering the issues of ion formation and gas supply to the conductor surface and the subsequent generation of ion current separately.

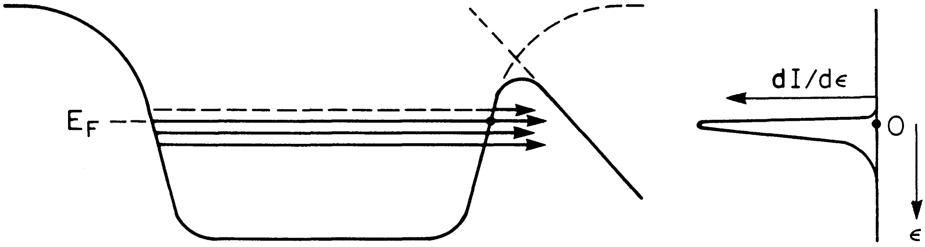

FIG. 4. The combined effect of temperature and electric field is to allow some electrons to tunnel from above the Fermi level, as shown by the dotted line.

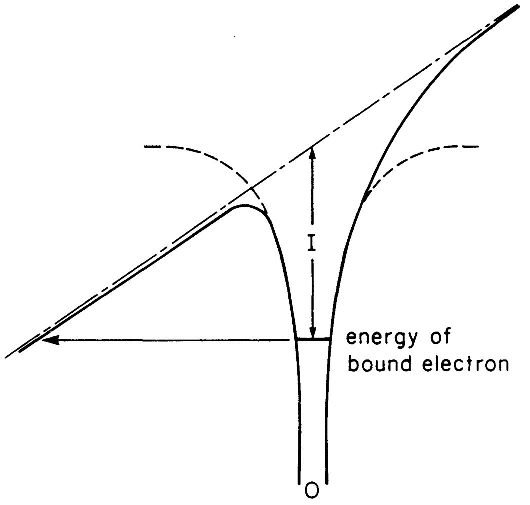

FIG. 5. The effect of the electric field on the potential energy of an electron for a field-free atom (dotted line) and for the potential energy in the presence of an electric field. Tunneling of the bound electron can now occur from the atom.

1.2.1 Ion Formation. The process of field ionization of an atom or molecule is directly comparable to field emission, except that the potential-energy box of the metal is replaced by the narrower, Coulombic well for the single atom or molecule.

The mean lifetime for the ground-state electron in the molecule is given by

$$\tau = 1/\nu D, \tag{14}$$

where ν is the frequency with which the bound valence electron arrives at the barrier and D is the tunneling probability of the electron through the electric-field reduced potential-energy barrier. Typical values of ν range from $4.1 \times 10^{16}\ \mathrm{s}^{-1}$ for H to $2.4 \times 10^{16}\ \mathrm{s}^{-1}$ for Ar. The expression for D, derived by the method of Wentzel, Kramers, and Brillouin, is a useful approximation:

$$D(E, V(x)) = \exp\{-(8m/h^2)^{1/2} \times [V(x) - E]^{1/2}\} dx, \tag{15}$$

where $V(x)$ is the electron potential energy and x_1 and x_2 are, respectively, the positions where the tunneling electron enters and exits from the potential energy barrier at the energy E.

Field emitters are also used to generate the high fields required for FI, except that the tips are sharper for FI, because FI requires higher field strengths than field electron emission from conductors. The higher fields for FI are a consequence of the fact that the ionization potentials of molecules are greater than the work functions of conductors.

Close up to a conductor surface, the required fields for FI are reduced because the tunneling electron energy is reduced by its image charge in the nearby metal. This is shown in the following expression, given by Mueller and Tsong (1969) for the potential energy of the tunneling electron at a distance x from the metal:

$$V(x) = -e^2/|x_i - x| + eFx - e^2/4x + e^2/|x_i + x|. \tag{16}$$

The first term is the Coulomb potential energy of the electron due to the positively charged ion, the second is due to the field, while the last two terms are due to the images in the metal of the electron and the ion.

Tunneling can only occur if there is an empty energy level available in the metal; hence, molecules closer than a critical distance x_c will not field ionize because the energy level of their ground-state electron is below the conductor Fermi energy level. An approximate value for x_c is given by

$$eFx_c = I - \phi. \tag{17}$$

Estimates of τ, based on the Wentzel–Kramers–Brillouin (WKB) model for He near W, range from 10^3 s at an electric field of 10 GV/m to 10^{-13} s at a field of 50 GV/m.

The validity of the above mechanism of ion formation has been confirmed by kinetic energy distribution measurements of field ionization carried out by Tsong and Mueller (1964). One consequence of the mechanism is a very narrow energy spread which is explained as follows. The kinetic energy of an ion will depend on how far away from the metal point field ionization occurs, because the potential energy of an ion will be $\sim eV(x)$ and decreases from a maximum close to the metal surface to a minimum at the collector. The maximum energy occurs for ions at the critical distance from the metal, x_c. The tunneling probability D declines rapidly with distance away from the emitter because it is a highly sensitive function of field and inverse potential-energy barrier width, both of which decrease the further away from the surface an atom is.

Tsong and Mueller (1964) found that the very narrow energy half-widths for the energy distributions obtained for He/W corresponded to an effective ionization zone of only 0.02 nm wide, a value that is about 30% less than the value predicted by the approximate one-dimensional theory discussed above.

Jason (1967) discovered additional weak, periodic peaks in the low-energy tails of the kinetic energy distributions of hydrogen and neon ions. These peaks were shown to correspond to quantized states (resonances) of a tunneling electron in the triangular well between the emitter's surface and the potential-energy line of the electric field.

1.2.2 Ion Current Generation. Ion current generation is a complex function of F, T, and emitter geometry, but may be discussed in terms of two limiting cases: high and low electric fields.

The ion current produced in a small volume near the emitter is given by

$$I=eS[1-\exp(-\Delta t/\tau)], \tag{18}$$

where S, the gas supply, is the number of particles entering the volume in question and Δt is the residence time a nonionized particle spends in the small volume. In the high-field limit τ is very small and $\Delta t>\tau$ so that

$$I\sim eS.$$

The quantity S was found to be considerably greater than the normal gas-phase supply function S_0 at zero field; S_0 is given by

$$S_0=A_0P(2\pi mkT)^{-1/2}. \tag{19}$$

where P is gas pressure, and A_0 is the area enclosing the ionizing volume.

The field enhancement of gas supply results in about an order of magnitude increase in supply and is a result of the reduced potential energy of a particle in the electric field due to polarization and dipole forces:

$$-V(F)=\mu E+\alpha F^2/2, \tag{20}$$

where μ is the permanent dipole of the particle and α is the polarizability of the particle. S is related to S_0 by

$$S=S_0\exp[-\pi V(F)/kT]. \tag{21}$$

At the low electric field limit, τ is long relative to the residence time of a gas particle in the very thin ionization zone above the emitter ($\Delta t<\tau$), and Eq. (18) simplifies to

$$I\sim eS_0\Delta t/\tau=enV_{\mathrm{FI}}/\tau, \tag{22}$$

where V_{FI} is the volume in which ionization occurs and n is the equilibrium gas density in that volume given by

$$n/n_0=(T_G/T_T)^{-1/2}\exp[-V(F)/kT_0], \tag{23}$$

where n_0 is the gas density at zero field, T_G is the temperature in the gas, and T_T is the temperature of the emitter surface, which is usually cooled well below room temperature. Equation (22) predicts a steep rise of current with field and this is observed.

The electric-field enhancement of gas density near the emitter surface for molecules with large dipole moments such as water or acetone can amount to several orders of magnitude. Beckey (1977) found that at fields of the order of 7 GV/m, multilayer adsorption occurred in accord with the theory of Brunauer, Emmett, and Teller (1938) for multilayer adsorption. Ion clusters, such as $[(H_2O)_n{*}H_3O]^+$, consistent with these ideas have been observed in field ionization mass spectrometry.

1.3 Field Evaporation and Field Desorption

As discovered by Mueller (1941), adsorbed atoms or molecules may be removed from a surface by field desorption as ions if the electric field is high enough. Field evaporation, a special case of field desorption, is the thermally activated evaporation of ions over the image-force (Schottky) barrier. This image-force barrier will be described in the following section.

1.3.1 Image-Force Model of Desorption. The potential-energy curves for an atom and for an ion, both in the absence of and in the presence of an electric field, are shown respectively in Figs. 6 and 7. If for an atom the desorption energy is Λ, then by using the Born–Haber thermochemical method, the barrier Q_0 to desorption of an ion of charge ne is given by

$$Q_0=\Lambda+\Sigma I_n-n\phi, \tag{24}$$

where ΣI_n is the sum of the ionization potentials up to the nth ionized state. This equation explains why the potential-energy curve for the ion is above that for the metal since

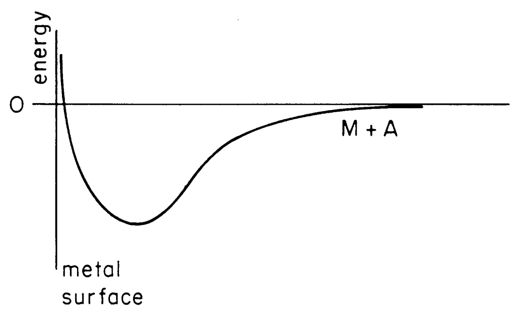

FIG. 6. Plot of the potential energy of an atom interacting with a metal surface.

$\Sigma I_n \gg n\phi$. The electric field reduces the potential energy of an ion at a distance x from the surface by eFx. There is a further lowering because of the interaction between the ion and its negatively charged image in the metal surface, located a distance x behind the metal surface. Hence, the total potential energy of an ion at x, relative to that of a free atom at infinity is

$$Q(F,x) = Q_0 - eFx - (ne)^2/4x. \tag{25}$$

The maximum in the potential-energy curve, obtained by differentiation, is at

$$x_m = (ne/4F)^{1/2} \tag{26}$$

and the energy maximum at this location is

$$Q(F,x_m) = Q = Q_0 - (n^3e^3F)^{1/2}. \tag{27}$$

Thermal evaporation, at the rate κ, can now occur over the energy maximum, known as the Schottky hump, according to

$$\kappa = \nu_p e^{-Q/kT}, \tag{28}$$

where ν_p is the vibration frequency of the bound particle. Substituting Eq. (27) into (28) and rearranging gives

$$F = (ne)^{-3}[\Lambda + I_n - n\phi - kT\ln(\kappa/\nu_p)]^2. \tag{29}$$

If F is minimized with respect to n, $F_{\min}$ will be the predicted evaporation field, and the nearest integral value of n that minimizes F will be the predicted charge state of the evaporating ion. Two polarization terms, $\mu_{\text{eff}}F$ and $\frac{1}{2}(\alpha_a - \alpha_i)F^2$, should also be added to Q_0. The first arises from the effective polarization of the double layer of electric charge that exists at the surface of a metal due to spillover of electrons from the metal, and the second is the interaction energy difference between that of an atom and that of the corresponding ion in an electric field. The α terms are the polarizabilities of an atom and an ion, and μ_{eff} is the effective dipole moment of the double electric charge layer. The image-force model, as embodied in this value of Q, yields quantitative predictions of desorption rate as a function of electric field that are in agreement with experimental results by Brandon (1965), and by Barofski and Mueller (1968).

1.4 Liquid-Metal Ion Sources (LMIS)

If a sufficiently high positive voltage is applied to a needle coated with a thin film of a liquid metal, the liquid at the needle apex will distort into a cone- or cusp-shaped form from the end of which issues a stream of positive ions. The onset of ion emission comes when the surface tension forces of the liquid metal are overcome by the stresses generated by the electric field. The end of the stressed liquid elongates into an extremely thin nipple of about 2–4 nm in diameter and about 10 nm long. This has been predicted by calculation carried out by Kingham and Swanson (1984) and verified by high-voltage electron microscopy work carried out by Ben Assayag and Sudraud (1984). The electric field at the end of the nipple is high enough for field evaporation of the liquid metal to occur at a rate that limits further growth of the nipple.

Such ion sources of liquid metals have been created from a variety of metals such as gallium, indium, aluminum, uranium, gold, and alloys of palladium and boron, palladium and arsenic, gold and silicon, etc. These alloy

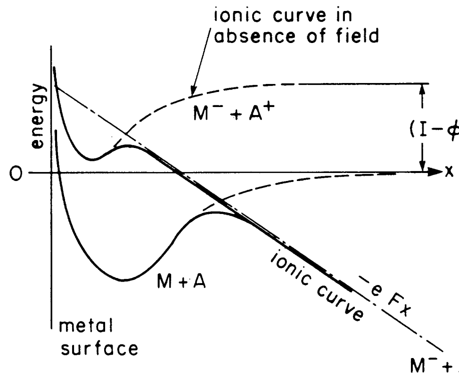

FIG. 7. Effect of an electric field on the potential-energy curve for an ionized atom A^+ and on that of a neutral atom A. At close distances from the metal, the neutral atom is favored, while at larger distances, the ionic species is clearly the lower-energy form.
